Another arrangement of the dissymmetrical network B is obtained grounding O and applying the voltage at the G end. In this case, the fundamental wave predominates throughout the network and furthermore its amplitude is reduced in amount. There are other intermediate combinations of the circuit elements. In general, a departure from symmetry in a network does not modify the fundamental to the same relative extent that it affects the amplitude, period, and distribution of the higher harmonics.

The effect of mutual inductances in an otherwise symmetrical network (figure 14C) is apparent from the equations given above and can readily be demonstrated also from a physical consideration of the space waves in relation to the elements of the network. Referring to the space waves of a symmetrical network (figure 3), it is clear that equal mutual inductances M_{12} and M_{23} do not affect the fundamental, for their effects on the center inductance mutually cancel. The mutual inductance M_{13} naturally influences the fundamental period as it couples the outer inductances—and these are elements which determine the period. The space waves for network *C* are then symmetrically distributed. It will be noted from the space-wave distribution that the mutual inductances affect the second harmonic in particular. In general, mutual inductances assume greater importance in relation to and influence more control on the higher harmonics of the network.

For the sake of brevity, the comparison has been based on three-mesh networks but the same principles would be indicated from comparing more complex networks. It must be recognized that the mathematical solution and numerical evaluation of multimesh dissymmetrical networks becomes prohibitive in practice. These difficulties can be overcome in part through the physical approach and interpretation of the particular complex network under consideration; in general, through this process coupled with a basic understanding of circuits, the fundamental and the harmonic oscillations can be estimated to a degree usually satisfactory for practical purposes. Experience in network analysis and in its application indicates that in a number of the cases encountered, the degree of dissymmetry while theoretically appreciable can, for practical purposes, be disregarded and accordingly, in such cases, the solution is attained by arranging the circuit into the symmetrical form and treating it as such. Occasionally, dissymmetry in networks is more apparent than real and in such cases the network is readily conducive to marked simplification through a consideration of the equivalent symmetrical network. Whether an approximate solution is permissible or a rigorous analysis is required, in all cases, the advantages of the physical approach can hardly be overemphasized.

Generalization of Analysis

UNGROUNDED NETWORKS

The analysis of networks grounded at one end can readily be extended to determine the response of ungrounded networks (figure 16). Consider the grounded end of the networks in figure 1 open and unit voltage applied simultaneously at the two ends *O* and *G*. Then from superposition of the space waves and the distribution curves in figures 2, 3, 4, etc., the response is established. It consists simply of the fundamental, third, and other odd harmonics doubled in amplitude and oscillating about a steady-state axis of unity (1.0). By virtue of symmetry, each network in effect consists of two equal parts from the two ends to the middle; one part is shown in figure 16. Thus the response of the ungrounded network *E* in figure 16 is immediately given from E_{G1}, E_{3G}, and E_{5G} for the grounded six-mesh network (appendix I), where in all cases, the first term of the equations becomes unity, the factor of two is applied to the coefficients for the fundamental, third, and fifth harmonic, and where the even harmonics are not present.

IMPEDANCE Z_S AND Z_G GENERALIZED

In the foregoing, the networks are representative of apparatus windings, segments of line or cable, etc. The analysis however is general and is applicable to other engineering problems. As an example, the inductive elements in figure 1 would be replaced by resistance to study the response of a resistance voltage-divider or for determining the voltage across the capacitor banks of an impulse generator during the charging process. Consider a six-mesh network, the solution is given in appendix IV. The pattern of the solution is the same and the same physical principles developed previously apply equally here. Naturally, the modes of the response become exponential terms.

Figure 15 gives the generalized network and it shows also typical circuit elements for the Z_S and Z_G impedances. These can assume other combinations—for instance, Z_G may consist of separate elements mutually coupled thus physically separating the meshes of the network. The more complex the Z_S and Z_G impedances are, the more complex form the operator takes on and correspondingly more unwieldy and lengthy become the equations of the solution. Simplification of the network proper may be possible. For instance, the dissipative characteristics (resistance elements) in inherently oscillatory networks frequently can, for practical reasons, be disregarded in transient voltage analysis, and where this approach is permissible, the solution is much simplified.

TERMINAL IMPEDANCES

Networks are almost invariably interdependent to a greater or lesser degree, that is, apparatus connects to lines or the neutral may be grounded through an impedance; separate windings of a transformer are mutually coupled in more than one way; lines and cables terminate at stations; an impulse generator is charged from a circuit suitable for the purpose, then is rearranged and discharged through either a simple or a complex network depending on the apparatus tested; etc. Mathematical completeness would suggest extending the foregoing analysis for the condition where one or the other or both ends of the network terminate in a lumped or a generalized impedance. A mathematical analysis along these lines while of interest is beyond the scope of the present paper. It will suffice to note here that in practice terminal impedances often are of secondary importance and in some cases can be disregarded altogether. When of importance, their effect frequently can be taken into account sufficiently well from a consideration of the terminal impedances in relation to the characteristics of the network proper or from a simplified network of the combination. Again, through the physical approach well-nigh insuperable mathematical difficulties can be overcome and thus the task of attaining a solution adequate for engineering purposes simplified.

VOLTAGE APPLIED

The unit function is of basic importance in analysis although in practice voltages of this form seldom occur. The response of networks to other forms is obtained from superposition. As a specific case, voltages on electrical systems originating from lightning disturbances usually are considered for purposes of design and in testing apparatus, as exponential. In appendix V is derived the response of a network to a voltage of exponential wave form.

It is apparent from the principle of superposition that the response of a network depends on the duration and the wave form of the voltage applied relative to the characteristics of the network. For instance, a voltage of steep front and short total duration develops more fully, and even can accentuate, the oscillations of shorter duration; whereas a voltage of relatively long front and sustained tail generates largely the fundamental at the exclusion practically of the higher harmonics. In fact, the analytical work often can be simplified from a consideration of the voltage applied in relation to the time constants of the network.

The treatment has dealt hereto with voltages applied. Transient phenomena in networks are produced also from circuit interruption and from other conditions. On a-c interruption usually takes place at current zero and the circuit voltage is re-established in a relatively short time after. The recovery voltages across *OG* in figure 1 for the networks proper, analytically consist in applying a current equal and opposite to the current interrupted,[8] that is, $i=wI_s t=wI_s/p$. Analysis of the networks based on applied currents likewise would bring forth guiding principles, simplifications, practical methods of approach similar to those which already have been discussed for voltages applied to the networks.

Applications

The analysis and the methods outlined in the paper have been applied to determine transients in windings,[2] to the development of impulse testing and of suitable measurement,[1] and to other problems. These methods and the same simplified approach should be helpful in corresponding applications whether these arise from electrical, acoustical, or heat-flow problems.[8]

An important step in the application work is the calculation of circuit elements from the dimensions of the apparatus or the parts which physically make up the network. Another important step is the building up of the equivalent network. Application problems usually require simplification to adapt the problem in a form conducive to calculation. In both these steps sound judgment, based on experience and on a fundamental grasp of network characteristics, is essential in arriving at practical results. To confirm the degree of approach in the calculated results recourse is had naturally to check tests.

In this connection, the cathode-ray oscillograph has served as an indispensable tool.[15] In addition, present progress hardly would have been possible without the impulse generators and other testing equipment which generate and subject apparatus and circuits to the transient phenomena these may experience in service. In recent years various means have been devised to facilitate establishing rapidly by test the transient characteristics of circuits and apparatus for the particular conditions desired.[16] For the larger electrical systems where the physical outlay is so extensive that full-scale testing is impractical or not economical and also because of the general complexity of the system and the phenomena involved, recourse is had to equivalent miniature networks. In this case the response of the system is determined from test on the equivalent built-up network.[17-19]

Analytical results and simplified methods of attack as the paper presents not only are a useful tool in design but likewise can be applied as an effective guide where the experimental approach is essential. From the satisfactory experience and good results obtained in the fields of application mentioned, it would appear that these methods can be extended to be useful in other connections.

Appendix I

This appendix deals with the networks in figure 1. The solutions are for "unit" voltage impressed. The subscripts are the points of the network between which the voltage or the impedance is taken.

Two-Mesh Network, Figure 1A

$E_{1G}=\frac{Z_{1G}}{Z_{OG}}\mathbf{1}$, where $\mathbf{1}$ is the symbol for "unit" voltage.

(For brevity, the symbol **1**, will be omitted hereafter.)

$$E_{1G}=\frac{1}{\frac{Z_S}{Z_G}+2}=\frac{1}{\alpha+2}$$

where $\alpha=\frac{Z_S}{Z_G}=\frac{p^2C_GL}{p^2C_CL+1}$

The solution for the operator, $\frac{A}{\alpha+B}$, where A and B are constants, is:

$$\frac{A}{\alpha+B}=\frac{A}{B}-\frac{AC_G}{B(C_G+BC_C)}\times \cos t\sqrt{\frac{B}{L(C_G+BC_C)}}$$

for the two-mesh network, the response is:

$$E_{1G}=\frac{1}{2}-\frac{C_G}{2(C_G+2C_C)}\cos wt$$

where $w^2=\frac{2}{L(C_G+2C_C)}$

Three-Mesh Network, Figure 1B

$$E_{1G}=\frac{\alpha+2}{\alpha^2+4\alpha+3}=\frac{1}{2}\left[\frac{1}{\alpha+1}+\frac{1}{\alpha+3}\right]$$

$$=\frac{2}{3}-\frac{C_G}{2(C_G+C_C)}\cos w_1t-\frac{C_G}{6(C_G+3C_C)}\cos w_2t$$

where

$$w_1^2=\frac{1}{L(C_G+C_C)} \text{ and } w_2^2=\frac{3}{L(C_G+3C_C)}$$

$$E_{2G}=\frac{1}{\alpha^2+4\alpha+3}=\frac{1}{2}\left[\frac{1}{\alpha+1}-\frac{1}{\alpha+3}\right]$$

$$=\frac{1}{3}-\frac{C_G}{2(C_G+C_C)}\cos w_1t+\frac{C_G}{6(C_G+3C_C)}\cos w_2t$$

Four-Mesh Network, Figure 1C

$$E_{1G}=\frac{\alpha^2+4\alpha+3}{\alpha^3+6\alpha^2+10\alpha+4}=\frac{1/4}{\alpha+(2-\sqrt{2})}+\frac{1/2}{\alpha+2}+\frac{1/4}{\alpha+(2+\sqrt{2})}$$

$$=\frac{3}{4}-\frac{C_G\cos w_1t}{4(2-\sqrt{2})[C_G+(2-\sqrt{2})C_C]}-\frac{C_G\cos w_2t}{4(C_G+2C_C)}-\frac{C_G\cos w_3t}{4(2+\sqrt{2})[C_G+(2-\sqrt{2})C_C]}$$

where

$$w_1^2=\frac{2-\sqrt{2}}{L[C_G+(2-\sqrt{2})C_C]},\; w_2^2=\frac{2}{L(C_G+2C_C)}$$

$$w_3^2=\frac{2+\sqrt{2}}{L[C_G+(2+\sqrt{2})C_C]}$$

$$E_{2G}=\frac{\alpha+2}{\alpha^3+6\alpha^2+10\alpha+4}=\frac{1}{\alpha^2+4\alpha+2}$$

$$=\frac{\frac{1}{2\sqrt{2}}}{\alpha+(2-\sqrt{2})}-\frac{\frac{1}{2\sqrt{2}}}{\alpha+(2+\sqrt{2})}$$

$$=\frac{2}{4}-\frac{C_G\cos w_1t}{2\sqrt{2}(2-\sqrt{2})[C_G+(2-\sqrt{2})C_C]}+\frac{C_G\cos w_3t}{2\sqrt{2}(2+\sqrt{2})[C_G+(2+\sqrt{2})C_C]}$$

$$E_{3G}=\frac{1}{\alpha^3+6\alpha^2+10\alpha+4}=\frac{1/4}{\alpha+(2-\sqrt{2})}-\frac{1/2}{\alpha+2}+\frac{1/4}{\alpha+(2+\sqrt{2})}$$

$$=\frac{1}{4}-\frac{C_G\cos w_1t}{4(2-\sqrt{2})[C_G+(2-\sqrt{2})C_C]}+\frac{C_G\cos w_2t}{4(C_G+2C_C)}-\frac{C_G\cos w_3t}{4(2+\sqrt{2})[C_G+(2+\sqrt{2})C_C]}$$

PATTERN OF THE α OPERATORS

The operational solutions of the networks thus far considered suggest a definite pattern of polynomials in α. Consider the following:

(1) 1
(2) $\alpha+2$
(3) $\alpha^2+4\alpha+3$
(4) $\alpha^3+6\alpha^2+10\alpha+4$
(5) $\alpha^4+8\alpha^3+21\alpha^2+20\alpha+5$
(6) $\alpha^5+10\alpha^4+36\alpha^3+56\alpha^2+35\alpha+6$
(7) $\alpha^6+12\alpha^5+55\alpha^4+120\alpha^3+126\alpha^2+56\alpha+7$

This pattern can be extended to cover any network containing a definite number of meshes. The pattern of polynomials is extended as follows:

(1) 1
(2) $\alpha+2$
(3) $(\alpha+2)[\alpha+2]-1$
(4) $(\alpha+2)[(\alpha+2)(\alpha+2)-1]-(\alpha+2)$
(5) $(\alpha+2)[(4)]-(3)$
(6) $(\alpha+2)[(5)]-(4)$
(7) $(\alpha+2)[(6)]-(5)$
(8) $(\alpha+2)[(7)]-(6)$

Six-Mesh Network

From the pattern set forth above the operational solutions for the six-mesh network shown in figure 1*E* are:

$$E_{1G}=\frac{\alpha^4+8\alpha^3+21\alpha^2+20\alpha+5}{\alpha^5+10\alpha^4+36\alpha^3+56\alpha^2+35\alpha+6}=\frac{\text{polynomial (5)}}{\text{polynomial (6)}}$$

$$E_{2G}=\frac{\alpha^3+6\alpha^2+10\alpha+4}{\alpha^5+10\alpha^4+36\alpha^3+56\alpha^2+35\alpha+6}=\frac{\text{polynomial (4)}}{\text{polynomial (6)}}$$

$$E_{3G}=\frac{\alpha^2+4\alpha+3}{\alpha^5+10\alpha^4+36\alpha^3+56\alpha^2+35\alpha+6}=\frac{\text{polynomial (3)}}{\text{polynomial (6)}}$$

$$E_{4G}=\frac{\alpha+2}{\alpha^5+10\alpha^4+36\alpha^3+56\alpha^2+35\alpha+6}=\frac{\text{polynomial (2)}}{\text{polynomial (6)}}$$

$$E_{5G}=\frac{1}{\alpha^5+10\alpha^4+36\alpha^3+56\alpha^2+35\alpha+6}=\frac{\text{polynomial (1)}}{\text{polynomial (6)}}$$

The final solutions are:

$$E_{1G}=\frac{5}{6}-\frac{C_G\cos w_1t}{12(2-\sqrt{3})[C_G+(2-\sqrt{3})C_C]}-\frac{C_G\cos w_2t}{4(C_G+C_C)}-\frac{C_G\cos w_3t}{6(C_G+2C_C)}-\frac{C_G\cos w_4t}{12(C_G+3C_C)}-\frac{C_G\cos w_5t}{12(2+\sqrt{3})[C_G+(2+\sqrt{3})C_C]}$$

$$E_{2G}=\frac{4}{6}-\frac{C_G\cos w_1t}{4\sqrt{3}(2-\sqrt{3})[C_G+(2-\sqrt{3})C_C]}-\frac{C_G\cos w_2t}{4(C_G+C_C)}+\frac{C_G\cos w_4t}{12(C_G+3C_C)}-\frac{C_G\cos w_5t}{4\sqrt{3}(2+\sqrt{3})[C_G+(2+\sqrt{3})C_C]}$$

$$E_{3G}=\frac{3}{6}-\frac{C_G\cos w_1t}{6(2-\sqrt{3})[C_G+(2-\sqrt{3})C_C]}+\frac{C_G\cos w_3t}{6(C_G+2C_C)}-\frac{C_G\cos w_5t}{6(2+\sqrt{3})[C_G+(2+\sqrt{3})C_C]}$$

$$E_{4G}=\frac{2}{6}-\frac{C_G\cos w_1t}{4\sqrt{3}(2-\sqrt{3})[C_G+(2-\sqrt{3})C_G]}+\frac{C_G\cos w_2t}{4(C_G+C_C)}-\frac{C_G\cos w_4t}{12[C_G+3C_C]}+\frac{C_G\cos w_5t}{4\sqrt{3}(2+\sqrt{3})[C_G+(2+\sqrt{3})C_C]}$$

$$E_{5G}=\frac{1}{6}-\frac{C_G\cos w_1t}{12(2-\sqrt{3})[C_G+(2-\sqrt{3})C_C]}+\frac{C_G\cos w_2t}{4(C_G+C_C)}-\frac{C_G\cos w_3t}{6(C_G+2C_C)}+\frac{C_G\cos w_4t}{12(C_G+3C_C)}-\frac{C_G\cos w_5t}{12(2+\sqrt{3})[C_G+(2+\sqrt{3})C_C]}$$

where

$$w_1^2=\frac{2-\sqrt{3}}{L[C_G+(2-\sqrt{3})C_C]}\qquad w_2^2=\frac{1}{L(C_G+C_C)}$$

$$w_3^2=\frac{2}{L(C_G+2C_C)}\qquad w_4^2=\frac{3}{L(C_G+3C_C)}$$

$$w_5^2=\frac{2+\sqrt{3}}{L[C_G+(2+\sqrt{3})C_C]}$$

Appendix II

The solution[14] for the uniformly distributed network, figure 13, is:

$$e=\frac{n}{N}+\sum_{k=1}^{k=\infty}\frac{\dfrac{2\sin\dfrac{k\pi n}{N}}{K\pi}}{\cos k\pi\left(1+\dfrac{k^2\pi^2}{N^2}\dfrac{C_2}{C_1}\right)}\times\cos\frac{t}{\sqrt{\dfrac{L_0NC_1}{k^2\pi^2}+LC_2}}$$

where $k=1, 2, 3$, etc.

Appendix III

Dissymmetrical Lumped Networks

(a). DISSYMMETRY—L'S, C_C'S, AND C_G'S ALL DIFFERENT

In the dissymmetrical three-mesh network, figure 14*B*, again let the subscripts denote the points of the network between which the impedances and the voltages are taken.

$$E_{1G}=\frac{Z_{1G}}{Z_{0G}}=\frac{ap^4+bp^2+c}{dp^4+ep^2+f}$$

where a, b, c, d, e and f are:

$a=L_1L_2L_3C_1(C_2+C_3)$
$b=L_2L_3(C_2+C_3)+L_1C_1(L_2+L_3)$
$c=L_2+L_3$
$d=L_1L_2L_3[(C_1+C_4)(C_2+C_3)+C_2C_3]$
$e=L_1(C_1+C_4)(L_2+L_3)+L_2L_3(C_2+C_3)+L_1L_2C_2+L_1L_3C_3$
$f=L_1+L_2+L_3$

$$E_{1G}=\frac{a}{d}+\frac{\left(\dfrac{bd-ae}{d^2}\right)p^2+\left(\dfrac{cd-af}{d^2}\right)}{p^4+\dfrac{e}{d}p^2+\dfrac{f}{d}}$$

and from

$$\frac{1}{p^4+\dfrac{e}{d}p^2+\dfrac{f}{d}}=\frac{\dfrac{d}{\sqrt{e^2-4fd}}}{p^2+\dfrac{e-\sqrt{e^2-4fd}}{2d}}-\frac{\dfrac{d}{\sqrt{e^2-4fd}}}{p^2+\dfrac{e+\sqrt{e^2-4fd}}{2d}}$$

it follows:

$$E_{1G}=\frac{c}{f}+\left[\frac{bd-ae}{d\sqrt{e^2-4fd}}-\frac{cd-af}{w_1^2d\sqrt{e^2-4fd}}\right]\times\cos w_1t-\left[\frac{bd-ae}{d\sqrt{e^2-4fd}}-\frac{cd-af}{w_2^2d\sqrt{e^2-4fd}}\right]\times\cos w_2t$$

where

$$w_1^2=\frac{e-\sqrt{e^2-4fd}}{2d}$$

and

$$w_2^2=\frac{e+\sqrt{e^2-4fd}}{2d}$$

$$E_{2G}=\frac{Z_{2G}}{Z_{2G}+Z_{12}}\times E_{1G}=\frac{a_1p^4+b_1p^2+c_1}{dp^4+ep^2+f}$$

where

$a_1=L_1L_2L_3C_1C_3$
$b_1=L_2L_3C_3+L_3L_1C_1$
$c_1=L_3$

$$E_{2G}=\frac{c_1}{f}+\left[\frac{b_1d-a_1e}{d\sqrt{e^2-4fd}}-\frac{c_1d-a_1f}{w_1^2d\sqrt{e^2-4fd}}\right]\times\cos w_1t-\left[\frac{b_1d-a_1e}{d\sqrt{e^2-4fd}}-\frac{c_1d-a_1f}{w_2^2d\sqrt{e^2-4fd}}\right]\times\cos w_2t$$

(b). DISSYMMETRY DUE TO MUTUAL INDUCTANCES, FIGURE 14C

Let $M_{12}=M_{23}=M_1=$ mutual inductance between adjacent meshes; and let $M_{13}=M_3$ = mutual inductance between first and third mesh.

The following are six independent equations for the network:

$e_{01}=i_1pL+i_2pM_1+i_3pM_3$
$e_{12}=i_1pM_1+i_2pL+i_3pM_1$
$e_{2G}=i_1pM_3+i_2pM_1+i_3pL$
$1=e_{01}+e_{12}+e_{2G}$
$i_2+pC_Ce_{12}=i_3+p(C_C+C_G)e_{2G}$
$i_1+pC_Ce_{01}=pC_G(e_{12}+e_{2G})+i_2+pC_Ce_{12}$

where the currents are those in the inductance elements. From these relationships the solution is obtained, as follows:

$$e_{1G}=\frac{1}{2}+\frac{1}{2}\,\frac{L^2+LM_3+2LM_1+2M_1M_3}{L^2+LM_3-2M_1^2+2(L+M_1+M_3)^2}-\frac{1}{2}\,\frac{C_G}{C_C+C_G}\cos w_1t+\frac{1}{2}\left[\frac{C_C}{C_G+3C_C}-\frac{L_2+LM_3+2LM_1+2M_1M_3}{L^2+LM_3-2M_1^2+2(L+M_3+M_1)^2}\right]\cos w_2t$$

$$e_{2G}=\frac{(L+M_3)(L+M_3+M_1)}{L^2+LM_3-2M_1^2+2(L+M_3+M_1)^2}-\frac{1}{2}\,\frac{C_G}{C_C+C_G}\cos w_1t-\frac{1}{2}\left[\frac{C_C}{C_G+3C_C}-\frac{L_2+LM_3+2LM_1+2M_1M_3}{L^2+LM_3-2M_1^2+2(L+M_3+M_1)^2}\right]\cos w_2t$$

where

$$w_1^2=\frac{1}{(L-M_3)(C_C+C_G)}$$

$$w_2^2=\frac{1}{(L+M_3)(C_G+3C_C)}\times\left[1+\frac{2(L+M_3+M_1)^2}{L^2+LM_3-2M_1^2}\right]$$

Appendix IV

The foregoing analyses are generally applicable for other combinations of impedances (figure 15). As an example, replace the inductances of figure 1*E* by resistance (R). From appendix I, the operational solution is written immediately and expanded into the same partial fractions, where now $\alpha = pC_GR/pC_CR+1$. Thus the solution in final form is:

$$E_{1G}=$$

$$\frac{5}{6}-\frac{1}{12(2-\sqrt{3})}\frac{C_G}{[C_G+C_C(2-\sqrt{3})]}\epsilon^{-b_1t}-\frac{C_G}{4(C_G+C_C)}\epsilon^{-b_2t}-\frac{C_G}{6(C_G+2C_C)}\epsilon^{-b_3t}-\frac{1}{12}\frac{C_G}{C_G+3C_C}\epsilon^{-b_4t}-\frac{1}{12(2+\sqrt{3})}\times\frac{C_G}{[C_G+C_C(2+\sqrt{3})]}\epsilon^{-b_5t}$$

where

$$b_1=\frac{2-\sqrt{3}}{R[C_G+(2-\sqrt{3})C_C]}$$

$$b_2=\frac{1}{R(C_G+C_C)}$$

$$b_3=\frac{2}{R(C_G+2C_C)}$$

$$b_4=\frac{3}{R(C_G+3C_C)}$$

$$b_5=\frac{2+\sqrt{3}}{R[C_G+C_C(2+\sqrt{3})]}$$

$$E_{2G}=$$

$$\frac{4}{6}-\frac{C_G}{4\sqrt{3}(2-\sqrt{3})[C_G+(2-\sqrt{3})C_C]}\epsilon^{-b_1t}-\frac{C_G}{4(C_G+C_C)}\epsilon^{-b_2t}+\frac{C_G}{12(C_G+3C_C)}\epsilon^{-b_4t}+\frac{C_G}{4\sqrt{3}(2+\sqrt{3})[C_G+(2+\sqrt{3})C_C]}\epsilon^{-b_5t}$$

etc.

Appendix V

Let $e(t)=A+B\cos w_1t+C\cos w_2t$, be the response to unit voltage impressed. It is desired to obtain the response to an impressed voltage having a steep-front and an exponential tail. This can be effected by applying Duhamel's integral, that is, by superposition:

$$\frac{d}{dt}\int_0^t e(t-\lambda)\epsilon^{-a\lambda}d\lambda$$

The response to steep-front exponential tail voltage impressed is then:

$$E_{1G}=\left[A+\frac{a^2B}{a^2+w_1^2}+\frac{a^2C}{a^2+w_2^2}\right]\epsilon^{-at}+\frac{w_1B}{\sqrt{a^2+w_1^2}}\cos(w_1t-\theta_1)+\frac{w_2C}{\sqrt{a^2+w_2^2}}\times\cos(w_2t-\theta_2)$$

where $\tan\theta_1=\dfrac{a}{w_1}$ and $\tan\theta_2=\dfrac{a}{w_2}$.

The above example illustrates the general application of superposition.

Engineering Features of the 230-Kv Boulder-Chino Transmission Line of the Southern California Edison Co., Ltd.

ALEX A. KRONEBERG

E. M. HUNTER
MEMBER AIEE

THIS paper deals with the problem of transmitting Boulder Dam power to the Southern California Edison Company's system. Preliminary studies were made of this project on the assumption that it should be a high-capacity peak plant with a high degree of reliability of service.[1] It was soon recognized, however, that this power was to be delivered to a system already well equipped for peak demands. This led to a reconsideration of the problem of disposing of this power and the fitting of it into the existing system of the Southern California Edison Company as a base-load-supply project. To justify this base-load operation, it was necessary to keep as low as possible the annual cost of a kilowatt-hour delivered from Boulder Dam to the company's system. However, since this power, 165,000 kw, was about 25 per cent of the present peak load on the system, service reliability of the transmitting facilities was still a major factor. In addition, it was desired to include those features of the peak-plant design which could not be added economically at a later date should the project be converted to a peak-load plant. High inertia constants and low reactance were retained in the design of terminal equipment for such an eventuality.

Electrical Characteristics of Transmission Line

The economic restrictions imposed by the designated base-load method of operation dictated a single-circuit line from Boulder Dam to Chino, Calif., a substation on the eastern boundaries of the company's subtransmission system, 234 miles from the dam, and a single-circuit line from Chino to the Barre substation, near Stanton, Calif., 26 miles from Chino, as shown schematically on figure 1.

Figure 1. Schematic single-line diagram of the Boulder-Chino-Barre 230-kv transmission line

Two 82,500-kva 13,800-volt waterwheel generators furnish power to this line through two 82,500-kva 13.2/230-kv banks of transformers consisting of six single-phase transformers, each rated 27,500 kva and located in the Arizona wing of the dam. A bank of transformers rated 75,000 kva, 220/72 kv consisting of three single-phase units each rated 25,000 kva is located in each of the receiving-end substations at Chino and Barre.

The 230-kv operating voltage of the line was established from a consideration of steady-state stability limits, line losses, and voltage regulation. The electrical characteristics of the final design of the transmission line are summarized in table I.

Table I. Electrical Design Characteristics of Transmission Line

1.	Steady-state power limit........	180,000 kw
2.	Operating voltage at Boulder....	230 kv
3.	Operating voltage at Chino......	216–220 kv
4.	Total line loss at 165,000 kw.....	19,000 kw
5.	Charging current...............	48,000 kva
6.	Charging current loss...........	600 kw
7.	Corona loss not over............	500 kw
8.	Line efficiency at 165,000 kw (per cent)......................	89
9.	Annaul efficiency at 900,000,000 kw-hr (per cent)...............	92
10.	Corona loss with one wire grounded—not over............	25,000 kw

The size of the line conductor was determined from economic studies of annual cost of load losses, charging current losses, corona losses, and annual fixed charges against cost of conductors and steel towers designed for various sizes and types of conductors. The annual loss was computed by an empirical formula determined from studies of load curves and corresponding losses, this formula showing the following relation between load factor of loss (y) and load factor of load (x):

$$3y = 4x^2 - 2x + 1$$

Charging-current loss and corona loss are constant, and produce an annual loss of 8,760 kilowatt-hours per kilowatt of loss. The value of a kilowatt-hour of loss and the rate of annual fixed charges on investment are of course parameters for each specific problem of transmission-line design. The over-all lowest annual cost for the Boulder-Chino transmission line was given by a 605,000-circular-mil aluminum-conductor steel reinforced conductor. The remarkable result of the study was the fact that this conductor gave the lowest annual cost for the operation of the contemplated installation of 165,000 kw at any desired annual load factor. This is due chiefly to the rapid increase in corona loss on conductors of smaller diameter or the higher cost of supporting structures when reduced carrying capacity is obtained without reducing the diameter of the conductor. A 605,000-circular-mil aluminum conductor, steel reinforced, cable composed of 30 strands of 0.1420 aluminum conductors and 19 strands of 0.0852 steel was selected for the line.

The transmission line has a horizontal configuration with a spacing of 23 feet and an average height of 45 feet. Two one-half-inch seven-strand steel overhead ground wires are located midway between and 20 feet above the line conductor plane as shown on figure 2.

Tests were made at the Chino substation on May 14, 1939, to check the no-load characteristics of the 234 miles of line from Chino to Boulder Dam. During these tests the Boulder Dam transformer banks were disconnected, likewise the Chino-Barre line. The high-side terminal voltages were metered by means of six capacitor-type potential devices connected directly to the terminal of each line conductor. The line currents at Chino were measured by current transformers

Service Protection Features

Reliability of service requirements on this line were met (1) by the installation of two overhead ground wires, (2) by the installation of counterpoises at towers where measurements indicated tower-footing resistances in excess of 100 ohms, and (3) by the installation of ground-fault neutralizers at the terminals of the line.

The installation of two overhead ground wires was based on a study of the performance of the 132-kv transmission line of the Nevada-California Power Corporation from Boulder Dam to Victorville, Calif. From the five-year record of this line, and with the help of the excellent data and literature accumulated by the AIEE committee on power transmission and distribution, it was possible to calculate the lightning performance of the proposed transmission line with varying degrees of lightning protection. It was estimated that less than one flashover a year could be expected with the line equipped with two overhead ground wires. This flashover would be limited to a single line-to-ground type of flashover if tower-footing resistances were reduced to 100 ohms or less.

Measurements of tower-footing resistance were taken at four-mile intervals to determine the general levels of tower-footing resistance along the line, and subsequently tower-footing resistances were measured at all towers in the high-resistance regions. Counterpoises of 200 feet, parallel to the line in both directions, were installed at all towers exceeding 100 ohms in tower-footing resistance. As a result, the maximum tower-footing resistance measured after 54 counterpoises had been installed did not exceed 70 ohms. The average tower-footing resistance is in the order of 18 ohms. It is estimated that the installation of two overhead ground wires and the lower tower-footing resistances will limit lightning flashovers to the single conductor-to-ground type.[2]

Operating experiences on this company's other 230-kv lines indicate that faults from causes other than lightning may also be expected from time to time. The majority of these other troubles will probably involve only one conductor and ground and the remaining problem of design was to provide means to mitigate the disturbances resulting from single conductor-to-ground faults. The ground-fault neutralizer (Petersen coil) was a service protective device which was available for dealing with the single line-to-ground type of fault. The application of ground-fault neutralizers to a 230-kv 260-mile, transmission line designed to carry load near its rated steady-state stability limit and at the lowest annual cost obtainable per kilowatt-hour is a unique feature of this transmission project which will be discussed in detail.

General Application Requirements for Ground-Fault Neutralizers

The Boulder-Chino 230-kv transmission line was not to be metallically interconnected with the other 230-kv lines on this system. The Chino and Barre substations were on the Southern California Edison Company's subtransmission system, so step-down transformers were required at these locations. Thus, the new line was a complete electrical unit unto itself which eliminated the necessity of purchasing additional isolating transformers, a contributing factor to make the application of neutralizers feasible economically.

All new electrical apparatus was to be purchased for the line so it could be specified to have the necessary insulation levels required on a ground-fault-neutralizer-equipped system. A ground fault on such a system causes the two ungrounded phases to shift to approximately the normal system line-to-line voltage above ground and the system neutral to shift to approximately leg voltage above ground. Accordingly, the station-type lightning arresters at Boulder Dam were specified for full line-to-line voltage and have a maximum permissible line-to-ground voltage rating of 242 kv. The power-transformer banks at Boulder, Chino, and Barre were specified to have neutral insulation in the 138,000-volt class for operation with ground-fault neutralizers connected from their neutrals to ground.

Application and Design

The neutralizer current ratings were derived from calculations made of the electrical characteristics of the 230-kv transmission line.[3] A study was made which covered the (1) determination of the charging current in the fault when one conductor is grounded, (2) determination of the need for line transpositions, and (3) determination of the in-phase component of current in the fault.

The ground-fault neutralizers were designed to pass during a line-to-ground fault on the line sufficient lagging current to compensate the leading charging current in the fault. The charging current in a ground fault was estimated using the principles of symmetrical components and Maxwell's potential coefficients modified to include the effects of corona applied to the configuration and profile of the Boulder-Chino line shown on figures 2 and 3. For 234 miles of 230-kv line, the estimated charging current was 301 amperes, 50 cycles. This figure included the effect of the formation of corona on the conduc-

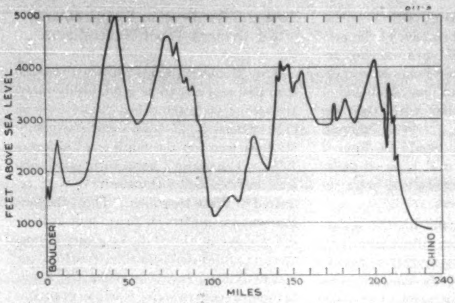

Figure 3. Profile of Boulder - Chino-Barre 230-kv transmission line

tors, which in this case, increased the current by approximately 3.5 per cent. These calculations showed that the charging current in the ground fault would be of the order of 2.17 times the normal three-phase charging current.

It was expected from experiences available on lower-voltage neutralizer circuits that the measured current would be 5 to 10 per cent higher than the current calculated for the transmission line alone. This increase in the current is derived from the capacitance in the towers, line insulators, transformers, and other connected electrical apparatus. Computations made from the results of the tuning tests of May 14, 1939, indicate the current to be 314 amperes, 50 cycles, for 234 miles of line.

The neutralizers in tune with the system would form a series resonant circuit for any normal unbalance in the system neutral-to-ground voltage. In a circuit like this, the normal neutral-to-ground voltage present with the system neutrals ungrounded would be amplified probably at least 15 times, and calculations were made to determine if, with the neutralizers in service, the displacement in the neutral voltage would be greater than could be reasonably tolerated. Due to the dissymmetry of the capacitance of the three-phase conductors to ground, it was found advisable to transpose the line. Transposition of conductors is also required in California to avoid interference with telephone communication circuits, and three transposition barrels were incorporated in the design of the line. The tests showed that the line was well balanced as the neutral-to-ground voltage with the neutralizers in service was less than 1,000 volts.

It was expected that the uncompensated fault current on this system resulting from corona loss would be higher than on any other existing neutralizer-equipped system in this country to date. The corona loss, under conditions of one wire at ground potential and the other two at line potential to ground, was computed to be 15,800 kw by means of Peek's formulas[4] for 234 miles of line of the conductor size selected and the lines transposed. The unsuppressed fault current corresponding to this corona loss was 59.4 amperes, a current which it was believed would not maintain the arc with the arcing distances involved. The arcing tests to be described later justified this contention. The measured fault current on solid ground faults was between 60 and 70 amperes on the 234-mile section of line.

It was planned to construct the Boulder-Chino line first and later extend it to the Barre substation when additional power became available at the dam. Thus, the neutralizers were to be suitable for compensating 234 miles of line when first installed and later 260 miles of line.

Ground-fault neutralizers were planned for the Boulder Dam, Chino, and Barre transformer neutrals. The Chino and Barre neutralizers were designed to compensate, each for one-third of the total length of line. The Boulder neutralizer has a double winding mounted on a single magnetic core, each winding designed for operation either singularly or in multiple with the other and to compensate for a third of the total line length. The double winding feature is to permit retuning by the station operator at Boulder Dam in the event either the Chino or Barre transformer bank is out of service by the simple expedient of switching the second winding into service. Disconnecting switches, mounted on the cover of the Boulder neutralizer are available for this purpose. Installation photographs of the Boulder, Chino, and Barre neutralizers are shown on figures 4, 5, and 6.

These neutralizers were specified to have a current range of 100 to 135 amperes at 50 cycles with 20 per cent additional current capacity at 60 cycles. Tap

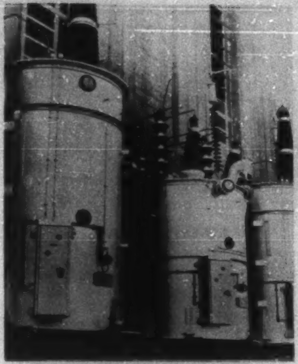

Figure 4. Ground-fault neutralizer, 230 kv, 100/135 or 200/270 amperes, 50 cycles (center) on line of Southern California Edison Company, Ltd., at Boulder Dam

changers were provided for manual operation to adjust the impedance to give approximately ten-per-cent increments from minimum to maximum of current rating. Tap-changer handles were located on the side of the tank convenient for making adjustments with provision for locking. The neutralizers were suitable for carrying rated current on any tap for ten minutes without exceeding the temperature limits established by the AIEE.

Each neutralizer was equipped with a 138-kv bushing on the transformer end of the winding and a 15-kv bushing on the

ground end and given an induced voltage test with the ground end solidly grounded of 277 kv at 420 cycles for 18 cycles.

The Boulder and Chino neutralizers were equipped with Thyrite by-pass resistors to protect them from abnormal voltages which might reach them through the transformers in the neutrals of which they were connected. The Barre neutralizer, furnished at a later date, has a Thyrite station-type lightning arrester mounted on the side of the tank.

The Boulder Dam neutralizer is one of the largest reactors ever built. An interior view of it showing the built-in resistor is shown on figure 7. Some idea of its physical size may be judged from the single-phase 27,500-kva 230-kv transformers adjacent to it on figure 3.

The current and ohmic characteristics of these neutralizers are given in table III.

Auxiliary Equipment

The auxiliary equipment on each of these neutralizers consists of an instantaneous overcurrent relay, a timing relay, and an operation-recording device which at Boulder is an automatic oscillograph. No automatic switch or oil circuit breaker is furnished for short-circuiting the neutralizers and solidly grounding the transformer neutrals in case of permanent ground faults. Since there is a single line from Boulder to Chino, the operating procedure during permanent ground faults will be to keep the line energized up to possibly the full time rating of the neutralizers so that the power which is to be lost upon opening this line can be picked up on the other generating stations on the system. It is expected that this added feature of being able to operate with this line grounded for several minutes will greatly reduce the number of disturbances to the system which would otherwise occur if the line were tripped out immediately upon the occurrence of a ground fault.

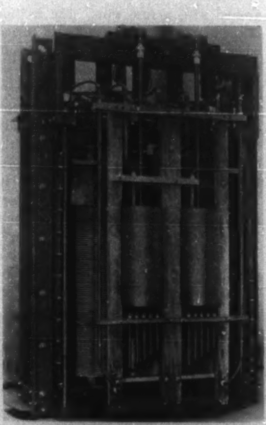

Figure 7. Interior view showing assembled core and coils of ground-fault neutralizer shown in figure 4

Tuning Tests

The Boulder and Chino neutralizers were tuned to the system on May 14, 1939. At the time of these tuning tests, construction work on the 26-mile line from Chino to the Barre substation was not completed so all of the testing was done on the Boulder Dam-Chino 234-mile line. Thus, for these tuning tests, both windings of the Boulder Dam neutralizer were in service.

The transmission line was energized from the Chino end and with this system setup, it was necessary to tune both neutralizers as a unit with the line. The Boulder Dam neutralizer tap positions were predetermined by calculation and tuning curves taken on the Chino neutralizer in two different ways as described in detail in the technical literature.[5]

First, with the system normal: Each winding of the Boulder neutralizer was set on tap number 7 and the amperes through the Chino neutralizer recorded for successive tap positions. The neutralizers and the system are in tune when the current is the maximum. This was tap number 8 on the Chino neutralizer with a current of 0.7 ampere. This current is produced by the slight unbalance in the phase voltages to ground and the relatively low magnitude of the current shows that the transmission line is well transposed.

Second, with one line solidly grounded: The Boulder Dam neutralizer was set on tap number 7 as on the previous test and the current in the ground fault was recorded for different tap positions on the Chino neutralizer. The tuned position was given by minimum fault current, which was tap number 8 on the Chino neutralizer. The minimum current in the fault varied between 60 and 70 amperes rms and results mostly from corona loss, although resistance and leakage loss, and harmonics, also contribute to it.

The Barre neutralizer was tuned to the system on September 19, 1939, by which time the Barre line extension from Chino and the second 82,500-kva generator at Boulder Dam were ready for service. The transmission line was energized from Boulder Dam and carrying the full output of one generator during the tests. For these tests, only one of the Boulder neutralizer windings was in service and with the Boulder neutralizer set on tap number 7 and Chino neutralizer set on tap number 8, tuning curves were made on the Barre unit. The tap position on the Barre unit giving the maximum current for normal tuning conditions was tap number 3 and likewise this same tap position gave the minimum current on fault tuning. The uncompensated fault current during these tests was of the order of 80 amperes.

It is to be noted that the two methods of tuning gave the same tap position. This indicates that corona did not increase the line capacitance sufficiently so that it could be detected within the tuning limits set by the spacing of the taps on the neutralizers.

Arcing Tests

After the tuning tests with system normal were completed, arcing faults were put on the system to check and demonstrate the performance of the neutralizers. For the May 14 tests an automatic magnetic oscillograph was installed at Chino, connected to record the system line-to-ground voltages, neutralizer, and fault currents. Arcing faults to ground were made by short-circuiting a 14-unit insulator string suspended from a spur line in the Chino substation yard. A 0.5-ampere fuse wire and also a cotton string soaked in a salt solution were used to initiate the arc. These were suspended from a weighted cotton cord looped over the transmission line by which means the fuse was drawn into position to span the insulator string.

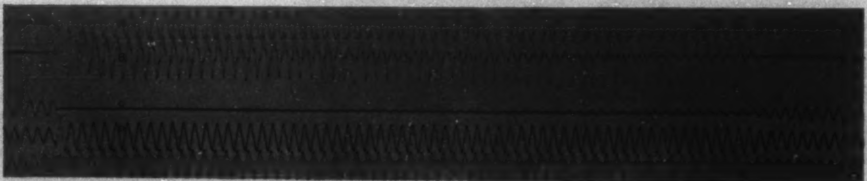

Figure 8. Oscillogram of ground-fault-neutralizer operation during staged arc to ground in Chino substation of Southern California Edison Company, Ltd., on May 14, 1939

A—Ground-fault-neutralizer current, 100 amperes rms

B—Fault current, 60 amperes rms

C—Line-to-ground voltage, phase *A*, 132 kv rms

D—Line-to-ground voltage, phase *B*, 132 kv rms

E—Line-to-ground voltage, phase *C*, 132 kv rms

A series of eight tests were made and in each case, the arc to ground was suppressed without any system disturbance or oil-circuit-breaker operations. The arcing time varied from the minimum of 0.86 second to the maximum of 3.76 seconds. These results are summarized in table IV.

Table IV. Arcing Tests

Arc to Ground Over 14-Disk Insulator String With Ground-Fault Neutralizers in Service

Boulder Neutralizer Tap Position Winding 1	Boulder Neutralizer Tap Position Winding 2	Chino Neutralizer Tap Position	Barre Neutralizer Tap Position	Arcing Time (Seconds)
Chino tests—May 14, 1939; 234 miles of line in service				
7	7	8	Not in service	3.76
7	7	8		1.20
7	7	8		1.78
7	7	8		0.86
7	7	8		1.46
7	7	8		1.36
7	7	8		1.44
7	7	8		1.28
Boulder tests—September 19, 1939; 260 miles of line in service				
7	Not in service	8	3	2.45
7		8	3	1.70

For the September 19 tests, the arcing faults were initiated by closing in with one of the 230-kv oil circuit breakers on a test setup located in the Boulder Dam switch yard consisting of a 14-unit string of insulators which was short-circuited to ground with a fuse wire. The melting of the fuse wire started the arc to ground which was extinguished by the ground-fault neutralizers. The various system electrical quantities during the tests were recorded by the automatic oscillograph which was part of the regular auxiliary equipment of the Boulder neutralizer.

Two arcing faults were put on the system in this manner and were quenched in 2.45 seconds and 1.70 seconds respectively. These data are included in table IV.

At the time of both tests, the weather was fair with little or no wind. Visual observations of the arcs indicated that they were very mild in character, showing little of the fire, noise, and elastic properties of the usual arcing fault on a grounded-neutral system. It is probable that if there had been any appreciable movement of the air in the vicinity of the arc, it would have been quenched in even shorter time than was recorded.

An oscillogram of one of the arcing faults is shown in figure 8. The smooth recovery of the line-to-ground voltage of the faulted phase without oscillations is a very definite indication that the neutralizers and system were in tune.

Inspection of the aluminum line conductor after eight arcing tests disclosed absolutely no burning or pitting of the conductor. Only a few bright spots were visible. It appears reasonable to expect that most of the flashovers to ground on this line in the years to come will leave insufficient evidence for the line patrolmen to discover the fault location.

Summary

The economic restrictions of base-load operation plus the necessity for a high degree of reliable service owing to the relatively large amount of power to be transmitted, has led to the design of a single-circuit transmission line with two overhead ground wires, counterpoises, and ground-fault neutralizers with an expected service continuity record closely approaching that which heretofore was obtainable only by two transmission lines located on separate rights-of-way with crossovers and paralleling switching stations.

With this new design, flashovers caused by lightning are expected to be reduced to single line-to-ground faults by the two overhead ground wires and counterpoises and suppressed by the ground-fault neutralizers. Permanent ground faults are not to be removed immediately, but are to be allowed to remain on the line until the load can be backed off the Boulder Dam generators. This alleviates the shock to the system which might otherwise occur if the load was rejected immediately. Operating in this manner is

Surge Characteristics of a Buried Bare Wire

E. D. SUNDE
ASSOCIATE AIEE

BURIED bare wires are frequently used as grounds or counterpoises for transmission-line towers and also as shield wires for underground rubber-covered telephone wires. Experience has verified the effectiveness of such wires in reducing insulator flashovers for direct strokes to transmission towers and breakdowns of underground rubber-covered wires due to surges. Quantitative relations between surge characteristics of the wires and various fundamental constants are, however, incomplete. Theoretical considerations of surge characteristics appear to have been confined to empirical approximations of test results[1,2,3] and do not reveal the relation to fundamental constants, such as the earth resistivity and dielectric constant of the earth.

In the following theoretical investigation, a previous study of the propagation of alternating currents along conductors with large leakage to ground[4] is extended to include the propagation of transient impulses, and the results are applied to the calculation of certain cases of practical interest. The paper is divided in four parts, the first dealing with propagation of alternating and square-front (unit step) current waves in wires of infinite length, the second with surge impedances under the same conditions. The third part considers current propagation and surge impedances for unit step current and wires of finite length and the fourth part, impedances for surge currents of shape similar to that encountered in case of lightning.

In obtaining working formulas it has been expedient to make certain approximations not impairing the fundamental aspects of the problem. These formulas show that when unit step current enters the mid-point of the wire, the surge impedance rises within a small fraction of a microsecond from zero to a maximum value which depends on the dielectric constant and the resistivity of the earth. From this maximum value the surge impedance decreases nearly inversely with the square root of the time until current reflected at the end of the wire returns to its mid-point. From then on the surge impedance approaches the leakage resistance of a wire in perfect contact with the earth, which is somewhat smaller than the leakage resistance as measured with direct or low-frequency current. For currents produced by lightning the surge impedance is of a similar form and in satisfactory agreement with measured impedances.

I. Current Propagation

Sinusoidal Currents

The wire is assumed to be half buried, that is, with its axis in the plane of the earth's surface, and to be in perfect contact with the earth. It is assumed to have infinite length and negligible internal impedance. For the steep wave fronts usually encountered, the assumption of negligible internal impedance is permissible and simplifies the problem considerably. Displacement currents in the air are neglected in comparison with those in the ground, a simplification which is permissible on account of the comparatively large dielectric constant of the ground.

As shown in the paper referred to above,[4] the propagation of sinusoidal currents and potentials along the conductor when energized at its mid-point is nearly exponential, except for distances from the origin so large that the current is inappreciable. For a conductor of negligible internal impedance in perfect contact with the ground, the current at the distance x from the mid-point of the counterpoise is

$$I(x,i\omega)/I(0,i\omega)=e^{-\Gamma x} \qquad (1)$$

where $2I(0,i\omega)$ is the current entering the counterpoise, and

$$\Gamma=\frac{1}{v}\left[i\omega(1/\rho\kappa+i\omega)\right]^{1/2} \text{ per meter}$$

ν = earth inductivity = $\mu\cdot 1.256\cdot 10^{-6}$ henries per meter
κ = earth capacitivity = $\epsilon\cdot 8.858\cdot 10^{-12}$ farads per meter
ρ = earth resistivity in meter-ohms
v = velocity of propagation = $(2/\nu\kappa)^{1/2}$ meters per second
$\epsilon \gg 1$ = dielectric constant of earth
$\mu = 1$ = permeability of earth

The notation $I(x,i\omega)$ is employed to indicate dependence on frequency, in order later to extend the application to nonsinusoidal conditions.

The above formula applies when the dielectric constant of the earth is much greater than that of the air, as is usually the case. The dielectric constant of the earth varies between wide limits, and is usually about 4 for dry ground, while for wet ground it may vary from 10 to 40.[5] Correspondingly, the velocities of propagation vary between 0.7 and 0.2 times the velocity in free space. Observations on counterpoises have indicated velocities within these limits.

The above expression for the propagation constant is obtained by solving the following equation (reference 4, page 1340, approximate formula)

$$\Gamma=[G(\Gamma)Z(\Gamma)]^{1/2}$$

Paper 40-9, recommended by the AIEE committee on power transmission and distribution, and presented at the AIEE winter convention, New York, N. Y., January 22-26, 1940. possible with ground-fault neutralizers in the power-transformer neutrals.

The installed cost of the ground-fault neutralizers which permits the single-circuit line to approach the double-circuit line in performance, is less than five per cent of the cost of the second line.

The successful suppression of the line-to-ground arcing faults demonstrates conclusively that ground-fault neutralizers will function on 230-kv circuits with in-phase components of current of the order of 80 amperes.

Discussion

For discussion, see page 1176.

where, in case of negligible internal impedance and perfect contact between wire and ground:

$$G(\Gamma)^{-1}=\int_{-\infty}^{\infty} Q(r)e^{i\Gamma v}dv,$$

$$Z(\Gamma)=i\omega\int_{-\infty}^{\infty} P(r)e^{i\Gamma v}dv$$

where $r=(v^2+a^2)^{1/2}$, a being the radius of the conductor. The functions $P(r)$ and $Q(r)$ depend on the earth resistivity, the dielectric constant of the earth and the air, and on the depth of the conductor below the surface of the earth. When the conductor is at the surface of the earth and displacement currents are neglected in the air, corresponding to zero dielectric constant of the air, the following approximate expressions are obtained:*

$$\left.\begin{aligned} G(\Gamma)^{-1}&=\frac{i\omega\nu}{\pi\gamma^2}\log_e\frac{1.12}{a\Gamma} \\ Z(\Gamma)&=\frac{i\omega\nu}{2\pi}\log_e\frac{1.85}{a(\Gamma^2+\gamma^2)^{1/2}} \end{aligned}\right\}\qquad(2)$$

where $\gamma=(i\omega\nu/\rho=\omega^2\nu\kappa)^{1/2}$ is the propagation constant of a plane wave in the earth.

Therefore:

$$\Gamma^2=\frac{1}{2}\gamma^2\frac{\log 1.85/a(\Gamma^2+\gamma^2)^{1/2}}{\log 1.12/a\Gamma}\qquad(3)$$

By inspection it is seen that $\Gamma^2\cong\gamma^2/2$; inserting this value of Γ in the logarithmic terms the expression becomes:

$$\Gamma^2=\frac{1}{2}\gamma^2\frac{\log 1.52/a\gamma}{\log 1.58/a\gamma}\qquad(4)$$

The ratio of the logarithmic terms is practically unity for all frequencies up to several million cycles, so that for all practical purposes $\Gamma=\gamma/\sqrt{2}$. For comparison it may be noted that for a conductor imbedded at infinite depth the propagation of current is strictly exponential and that $\Gamma=\gamma$ (reference 4, page 1343). In the latter case the velocity of propagation is $v=(1/\nu\kappa)^{1/2}$ as compared with $v=(2/\nu\kappa)^{1/2}$ for a conductor at the surface of the earth.

Unit Step Current

The propagation of currents of arbitrary wave shape entering the wire may be formulated in terms of the propagation of a unit step current equal to 0 for $t<0$ and unity for $t>0$. Consideration of a current of this form, which may be regarded as an ideal surge current, also reveals certain fundamental characteristics of wave propagation along buried wires. For a unit step current the operational expression for the current at x is obtained by replacing $i\omega$ by p in (1). The solution of the operational expression thus obtained is:[6]

For $vt<x$: $i(x,t)/i(0,t)=0$

For $vt>x$:

$$\begin{aligned} i(x,t)/i(0,t)&=e^{-\alpha x}+\alpha x\int_x^{vt}\frac{e^{-\alpha u}}{w}I_1(\alpha w)du \\ &=1-\alpha x\int_{vt}^{\infty}\frac{e^{-\alpha u}}{w}I_1(\alpha w)du \qquad(5)\end{aligned}$$

where $\alpha=\rho\kappa v/2=(2\nu/\kappa)^{1/2}/4\rho$, $w=(u^2-x^2)^{1/2}$, t the time in seconds and I_1 the Bessel function of the first kind and order for imaginary arguments. The second expression is obtained from the first by using the condition $i(x,t)/i(0,t)=1$ for $tv=\infty$.

When $\alpha vt-\alpha x<1$ the following formula may be used:

$$i(x,t)/i(0,t)=e^{-\alpha x}+\frac{\alpha x}{2}(e^{-\alpha x}-e^{-\alpha vt})\qquad(6)$$

When $\alpha vt-\alpha x>1$ and $vt\gg x$ the following formula is sufficiently accurate:

$$\begin{aligned} i(x,t)/i(0,t)&=erfc[\alpha x(2\alpha vt)^{-1/2}] \\ &=erfc\ [x(v/8\rho t)^{1/2}] \qquad(7)\end{aligned}$$

where

$$erfc(z)=1-erf(z)=\frac{2}{\sqrt{\pi}}\int_z^{\infty}e^{-s^2}dz$$

is the error function complement.

Expression (6) is obtained by noting that when $\alpha w<1$, $I_1(\alpha w)\sim\alpha w/2$; while (7) is derived as follows:

When $\alpha vt-\alpha x>1$, $I_1(\alpha w)\sim(2\pi\alpha w)^{-1/2}e^{\alpha w}$

and when

$vt\gg x$, $I_1(\alpha w)\sim(2\pi\alpha u)^{-1/2}e^{\alpha u-\alpha x^2/2u}$

Hence:

$$\begin{aligned} i(x,t)/i(0,t)&=1-\alpha x(2\pi\alpha)^{-1/2}\times \\ &\qquad\int_{vt}^{\infty}u^{-3/2}e^{-\alpha x^2/2u}du \\ &=1-\frac{2}{\sqrt{\pi}}\int_0^{Z}e^{-s^2}dz \\ &=erfc[\alpha x(2\alpha vt)^{-1/2}]\end{aligned}$$

where $Z=\alpha x(2\alpha vt)^{-1/2}$.

Curves of the ratio $i(x,t)/i(0,t)$ are shown in figure 1. When $vt>2x$, the current ratio as given by (7) is quite accurate.†

II. Infinite-Length Impedances

Sinusoidal Current

The impedance to ground of the counterpoise, as measured between its mid-point and a remote point, is in the following denoted by $Z(a,i\omega)$. The mutual impedance of counterpoise-to-ground and transmission-line-to-ground circuits is

* In the paper referred to displacement currents were neglected also in the earth, and the formula for $G(\Gamma)$ written in a different form, which is identical with that below when $\gamma=(i\omega\nu/\rho)^{1/2}$.

The present formulas are based on expressions for $P(r)$ and $Q(r)$ with displacement currents neglected in the air, obtained from: "Mutual Impedance of Grounded Wires for Stratified Two-Layer Earth" *Bell System Technical Journal*, volume 12, April 1933, pages 162–7.

† It may be of interest in connection with the propagation of surges along transmission lines to observe that the same formulas and curves apply to the voltage ratio $e(x,t)/e(0,t)$ for an infinitely long line on which a unit step voltage $e(0,t)$ is impressed at some point. In that case $\alpha=(R/2)(C/L)^{1/2}$ and R, L, C the unit length resistance, inductance, and capacity of the line, which is assumed to have negligible leakance.

denoted by $Z(h,i\omega)$ and equals the ratio of transmission line voltage to current entering the counterpoise, the voltage being taken between a point on the transmission line opposite the counterpoise mid-point and a remote point. Assuming exponential current propagation, both impedances are obtained from the following expression by taking y equal to the radius of the counterpoise (a) and the height of the transmission line (h), respectively:

$$Z(y,i\omega)=\frac{i\omega\nu}{4\pi\Gamma}\int_0^\infty\frac{e^{-\Gamma x}dx}{(x^2+y^2)^{1/2}} \qquad (8)$$

$$=\frac{i\omega\nu}{8\Gamma}\left[H_0(\Gamma y)-Y_0(\Gamma y)\right]$$

where the distance y is in meters and

H_0 = Struve's associated Bessel function of first kind, zero order

Y_0 = Bessel function of second kind, zero order

The above integral represents the ratio of earth potential at the perpendicular distance y from the mid-point of the counterpoise to the current entering the latter. This earth potential arises from currents $-I'(x,i\omega)=\Gamma e^{-\Gamma x}$ leaving the counterpoise along its length, the earth potential at y due to unit current leaving the counterpoise at x being $i\omega\nu/2\pi\gamma^2(x^2+y^2)^{1/2}=i\omega\nu/4\pi\Gamma^2(x^2+y^2)^{1/2}$. Since the counterpoise is in intimate contact with the earth, the earth potential at $y=a$ equals the counterpoise potential. In obtaining $Z(a,i\omega)$ from the above expression, the internal impedance of the counterpoise is neglected and in obtaining $Z(h,i\omega)$ a negligible error is committed by assuming the mutual impedance the same for a horizontal separation $y=h$ as for an equal vertical separation. The latter condition is true only when displacement currents are neglected in the air, as assumed here, the equipotential lines in that case being circles about the conductor.

Unit Step Current

For unit step current the operational expression for the self- and mutual impedances defined by (8) is obtained by replacing $i\omega$ by p. For large values of time displacement currents may be neglected and the solution for the surge impedance is:

$$S(y,t)=\frac{1}{4\pi}\left(\frac{\nu\rho}{2\pi t}\right)^{1/2}\exp\,(y^2\nu/16\rho t)\times K_0(y^2\nu/16\rho t) \qquad (9)$$

where K_0 is a Bessel function of the second kind for imaginary arguments, zero order. For $z\cong y^2\nu/16\rho t<0.10$, which is usually the case in applications, $K_0(z)\cong\log_e(1.12/z)$. For larger values of z tables of this function are available.[7]

For small values of time displacement currents must be included and the surge impedance is obtained from the expression:

$$S(y,t)=\frac{(2\nu/\kappa)^{1/2}}{4\pi}e^{-\alpha vt}\left\{\left[1+\left(\frac{\alpha vt}{2}\right)^2+\frac{1}{2}\left(\frac{\alpha y}{2}\right)^2\right]\log_e\frac{tv+(t^2v^2+y^2)^{1/2}}{y}-\frac{1}{2}\left(\frac{\alpha vt}{2}\right)^2(1+y^2/t^2v^2)^{1/2}\right\} \qquad (10)$$

where $\alpha=(2\nu/\kappa)^{1/2}/4\rho$. Expression (9) may be used when $\alpha vt>1$ and (10) when $\alpha vt<1$.

The above results are obtained by observing that:

$$\frac{dZ(y,p)}{dx}=\frac{\nu}{4\pi}(x^2+y^2)^{-1/2}\frac{p}{\Gamma}e^{-\Gamma x} \qquad (11)$$

The solution of this operational expression is:[8]

$$\frac{dS(y,t)}{dx}=0 \text{ when } t<x/v$$

$$\frac{dS(y,t)}{dx}=\frac{(2\nu/\kappa)^{1/2}}{4\pi(x^2+y^2)^{1/2}}e^{-\alpha vt}\times I_0[\alpha v(t^2-x^2/v^2)^{1/2}] \text{ when } t>x/v \qquad (12)$$

where I_0 is the Bessel function of the first kind for imaginary arguments, zero order. Thus:

$$S(y,t)=\frac{1}{4\pi}(2\nu/\kappa)^{1/2}e^{-\alpha vt}\times\int_0^{vt}\frac{I_0[\alpha v(t^2-x^2/v^2)^{1/2}]}{(x^2+y^2)^{1/2}}dx \qquad (13)$$

For $\alpha vt<1$,

$$I_0[\alpha v(t^2-x^2/v^2)^{1/2}]\cong 1+\frac{\alpha^2v^2(t^2-x^2/v^2)}{4}$$

and inserting this value for I_0 expression (10) is obtained by integrating (13).

For $\alpha vt\gg 1$ expression (9) is obtained by observing that

$$I_0[\alpha v(t^2-x^2/v^2)^{1/2}]\rightarrow(2\pi\alpha vt)^{-1/2}\times\exp\alpha vt\,(1-x^2/2vt^2)$$

so that:

$$S(y,t)=\frac{1}{2\pi}(\nu\rho/2\pi t)^{1/2}\int_0^\infty\frac{e^{-x^2\nu/8\rho t}}{(x^2+y^2)^{1/2}}dx \qquad (14)$$

Inserting the value of the integral[9] expression (9) is obtained. The same result is obtained in a simpler way by neglecting displacement currents in operational expression (11), in which case (14) is obtained directly.[10]

As stated before, displacement currents in the air have been neglected throughout. This has a negligible effect for large values of t or for $y=a$ but results in the condition $S(h,t)=0$ for $t=0$, rather than $S(h,t)=0$ for $t<h/c$, c being the velocity of propagation in free space. It would appear that the effect of displacement currents in the air is obtained, in a first approximation, by taking t as the time in excess of h/c. The surge impedance for small values of time is of secondary importance in application to actual surge currents, since these are always small during the interval in which displacement currents have appreciable effect.

In the above formulas the wire is assumed to be half buried in the earth, that is, with its axis in the plane of the earth's surface. For wires at finite depths below the surface, exact formulas would be considerably more complicated. As a first approximation for practical purposes, the surge impedance of a wire at a small depth d is in the following taken as half the sum of $S(a,t)$ and $S(b,t)$, where $b=(a^2+4d^2)^{1/2}$. This is suggested by a corresponding relationship (implicit in equation 16) for the leakage resistance to ground of a buried

Figure 2. Surge impedances for unit step current for buried wires of infinite length

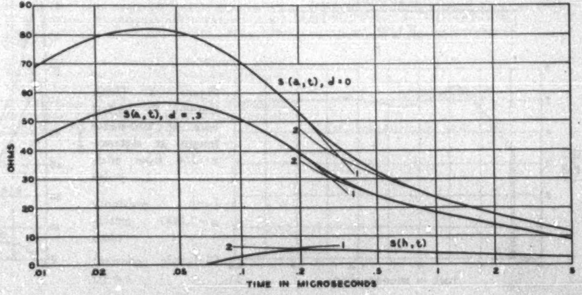
Height $h=20$ meters
Earth resistivity $\rho=1{,}000$ meter-ohms
Dielectric constant $\epsilon=10$



wire of finite length. The surge impedance calculated in this way will be somewhat too small, since the propagation constant increases with depth, but for depths in the order of one foot, as actually encountered, the error is likely to be small.

The variation in $S(y,t)$ with t is shown in figure 2, for a representative case as indicated in the figure. Near the intersection of curves 1 and 2 calculated from (10) and (9), respectively, the actual surge impedance is obtained by drawing a transition curve as shown in the figure.

III. Wires of Finite Length

Propagation of Unit Step Current

For a wire of length l the current at the distance x from the mid-point where energization is effected, is obtained from the following formulas:

$$\left.\begin{array}{ll} \textbf{Condition} & \mathbf{i(x,t)/i(0,t):} \\ x<vt<l-x & \mathit{erfc}\,x\beta \\ l-x<vt<l+x & \mathit{erfc}\,x\beta-\mathit{erfc}(l-x)\beta \\ l+x<vt<2l-x & \mathit{erfc}\,x\beta-\mathit{erfc}(l-x)\beta+ \\ & \quad \mathit{erfc}(l+x)\beta \\ 2l-x<vt<2l+x & \mathit{erfc}\,x\beta-\mathit{erfc}(l-x)\beta+ \\ & \quad \mathit{erfc}(l+x)\beta-\mathit{erfc} \\ & \quad (2l-x)\beta \end{array}\right\} \quad (15)$$

and so on, where $\beta=(\nu/8\rho t)^{1/2}$ and *erfc* is the error function complement, as in expression (7). The first term in each expression is the current for a wire of infinite length, the second term the current reflected at the end of the wire and reaching x at the time $(l-x)/v$, the third term the current reflected again at the mid-point and reaching x at the time $t=(l+x)/v$, etc. The currents are in each case assumed to be given by expression (7), which is sufficiently accurate for practical purposes.

At the mid-point of the counterpoise $i(x,t)/i(0,t)=1$ and at the end point $i(x,t)/i(0,t)=0$. At intermediate points the current varies with time. In figure 3 this variation with time is shown for a point midway between the mid-point and the end point of a counterpoise 100 meters long for an earth resistivity $\rho=1{,}000$ meter-ohms. From this figure it is seen that the condition $i(x,t/i(0,t)={}^1/_2$ for $x=l/4$, corresponding to uniform leakage along the wire, is practically reached within one or two microseconds.

Surge Impedance for Unit Step Current

On account of the many difficulties of a formal solution for the surge impedance of a wire of finite length, this section is confined to a demonstration of a graphical method which appears to be sufficiently accurate for practical purposes.

The surge impedances shown in figure 2 have been plotted in figure 4 along a linear time scale, together with leakage resistances of wires of 100-meter length, buried at depths $d=0$ and $d=0.3$ meter, and being in perfect contact with the ground. For reasons to be explained, the surge impedances are shown dotted for $t>0.74$, and the leakage resistances are the horizontal lines on the right-hand side of the figure. The latter are obtained from the formula:[11]

$$R=\frac{\rho}{2\pi l}[\log_e(4l^2/ab)-2], \qquad (16)$$

where

ρ = earth resistivity in meter-ohms
l = length of counterpoise, meters
$b=[a^2+(2d)^2]^{1/2}$
a = radius of counterpoise, meters
d = depth to center of counterpoise ($d \gg l$)

For a wire 100 meters long the time required for current reflected at the ends to return to the mid-point is $l/v=0.74$ microsecond, when $v=1.35\cdot10^8$ meters per second for $\epsilon=10$, as used in calculation of the surge impedances.

Between this time and the time $t\cong1.5$ microseconds required to obtain uniform leakage along wire, reflected currents increase the surge impedance until it equals the leakage resistance. Since the surge impedance variation in this short time interval is rather small, it is sufficiently accurate to assume a transition as shown in the figure. In the same time interval $0.74<t<1.5$ microseconds, the impedance $S(h,t)$ decreases to zero, as shown in the figure.

The leakage resistance used above is that of a wire in perfect contact with the earth. Usually there is some contact resistance between the wire and the surrounding soil, but the capacity of the wire to the soil is so large, that for surges of short duration this contact resistance may be neglected, and the wire regarded as being in perfect contact with the ground. When d-c or low-frequency measurements are made of the leakage resistance, the latter will include the contact resistance and therefore be somewhat larger than that used above. For wires a few hundred feet long the impulse impedance after a couple of microseconds is therefore somewhat smaller than the leakage resistance as measured with direct current. This condition has been observed in surge impedance measurements on various types of grounds,[12] but has generally been ascribed to the much larger currents used in case of surge-impedance measurements than in case of leakage-resistance measurements.

IV. Surge Impedances for Lightning Currents

Calculation of Surge Impedances

When a surge current $J(t)$ enters the mid-point of the wire the corresponding surge voltage may be obtained from the superposition theorem:[13]

$$V(y,t) = \int_0^t J'(t-\tau)S(y,\tau)d\tau \qquad (17)$$

where $J'(t) = \dfrac{d}{dt}J(t)$ and $S(y,t)$ is the surge impedance for unit step current. It is usually necessary to perform the integration numerically, but the process is not difficult and does not require much time for the accuracy needed here. The surge impedance is defined as the ratio $V(y,t) \div J(t)$.

Lightning current entering counterpoises may usually be approximated by an expression of the form:

$$J(t) = J(e^{-\gamma_1 t} - e^{-\gamma_2 t}) \qquad (18)$$

where γ_1 and γ_2 may be in the order of 0.1 and 1, respectively, when t is taken in microseconds. With these values of γ_1 and γ_2 and with $J = 1.44$, the above expression represents a current rising from zero to a maximum value of 1 ampere within 2.5 microseconds and diminishing to 0.01 ampere within 50 microseconds. Actual lightning current may rise to a maximum value of 100,000 amperes or more.

With a current of the above form and with unit step surge impedances shown in figure 4 for a counterpoise at a depth of 0.3 meter, the surge impedances shown in figure 5 are obtained.

Comparison With Measured Surge Impedances

Although several tests have been made to investigate surge characteristics of counterpoises, it appears that in only a single case were the tests performed in such a way as to obtain reliable results for small values of time.[3] In this case a surge current was impressed at one end of a counterpoise 925 feet long, of 0.25-inch diameter, buried at a depth of 12 inches. Measured leakage resistances of counterpoises of various lengths indicate an earth resistivity at the test location varying between 1,500 and 2,000 meter-ohms. The observed velocity of propagation along the counterpoise indicates a dielectric constant of about 15.

In figure 6 are shown surge impedances calculated for these conditions for unit step current and for a current as shown in figure 5. Since the surge impedance at the end point of a long counterpoise is nearly twice as large as at the mid-point[9] the calculated values are compared with one-half the observed end-point impedance. The shape of the current used in the measurement is not apparent in the publication referred to,[3] but in other tests[1] on the same counterpoise a current with somewhat steeper wave front was used than that upon which curve 2 of figure 6 is based.

Unsolved Problems of Electrical Engineering in the Field of Transportation

J. A. NOERTKER
MEMBER AIEE

THE ability to determine and state what comprises the outstanding problems in any field of activity implies very extensive knowledge of the developments in that field and to state the unsolved problems implies even more than this. When we begin to consider what ought to be done or attempted, the assumption is that there is an accepted standard or goal toward which we are striving. The author knows of no clear and comprehensive statement of the goals or ends of modern transportation. However, competition is making it increasingly clear that if public transportation is to survive, the industry must strive toward higher levels of convenience, speed, comfort, efficiency, and attractiveness. Today, the public assumes that safety has been given adequate consideration. This, then, is taken as the major premise of the paper; that any development that offers hope for improving these factors, through the effort of electrical engineers, is a proper problem for consideration.

Obviously, a paper such as this can only scratch the surface of the potential electrical problems in the transportation field, for, after all, this subject is one that would be more appropriate for a large research or scientific organization. It is suggested later in the paper that there is a great need for such an organization in the field of transportation. Lacking such an organization, we have attempted to state some of the problems facing electrical engineers of the transportation industry, particularly those in the railroad and urban transportation field.

For the purpose of grouping related problems, the paper is divided into five parts:

Power distribution to electric railways
Power utilization by transportation units
Possible electrical solutions of operating problems
Improved research instruments
Conclusion

Power Distribution to Electric Railways

With the development of superpower networks and relay systems furnishing power of utmost reliability, it is taken for granted today that the great power systems which supply our industrial and domestic power needs will likewise furnish power for the electrification of transit systems. Problems involved in the generation and transmission of this power are beyond the scope of this paper. However, vital unsolved problems are involved in the purchase and supply of this power.

The power contract itself, which involves the determination of an equitable method for allocating demand charges is one such problem. A problem of more vital concern is the use of commercial voltages and frequencies for heavy railroad electrifications.

The economic advantage of using central-station power for railroad electrification is due chiefly to two factors:

1. The energy component of the power rate is lower because the central station can operate larger and consequently more efficient generating units.
2. The demand component of the power rate is lower due to the diversification of railway, commercial, and domestic loads with resulting high load factor, and because extensive joint use of generating and transmission facilities is possible.

It is obvious that the maximum economic advantage of using central-station power is obtainable only if the catenary is operated at commercial voltage and frequency. Ten years' experience with an urban-railway power-distribution system wherein all power is furnished to railway substations over regular commercial high-voltage lines, has convinced the author that joint use of transmission lines and distribution facilities is dependable and economical, and that with suitable railway and power-system design, such commercial feeders in no respect jeopardize the transportation service.

A review of the existing power-distribution facilities of various heavy transportation systems (table I) raises the question whether the transportation power system design has been adequately or fully co-ordinated with the power-supply systems.

Although engineers in the United States seem to be satisfied with a variety of d-c and 25-cycle distribution systems, several of the European countries are vigorously experimenting with the use of commercial voltages and frequencies.

Since 1932, Italy has had in service a 10,000-volt three-phase 45-cycle system, which corresponds exactly to the commercial distribution system of that country.

In 1934, the Hungarian State Railways instituted service on the main line section of the intercontinental line, Paris-Istanbul. This electrified line, 120 miles long, is divided into three separate sections. The catenary of each section is fed by means of step-down transformers with 16,000-volt 50-cycle single-phase current, taken from one phase respectively of the 110-kv three-phase public network. The 50-cycle single-phase energy is converted on the locomotive into three-phase current.

An electrification 35 miles long using 20,000-volt 50-cycle current was completed by the German State Railways in 1937 between Frieberg, Baden, and the heights of the Black Forest. This line is divided into two separate sections fed from the 110-kv three-phase industrial network, by means of step-down transformers in Scott connection, statically changing the three-phase into two-phase current. Four different-type locomotives have been provided by four different companies. Two locomotives involve the use of steel-tank mercury-arc rectifiers. One locomotive uses four sets of twin motors capable of three synchronous speeds. The other locomotive uses a tap transformer and four sets of single-phase 50-cycle motors, each set consisting of two 225-volt motors connected permanently in series.

A Swiss locomotive, which has been described by O. K. Marti in a paper before the AIEE, has been designed to operate from a 15,000-volt 50-cycle catenary using commutatorless single-phase motors. The usual commutators, tap switches, starting resistors, and reversing switches have all been replaced by a mercury-arc rectifier with control grids.

It would seem from the above that there are distinct possibilities for the adoption and use of commercial types of power supply for heavy railroad electrifications which should result in reduction of the large investment required for main-line electrification. The solution of the

---

Paper 40-15, recommended by the AIEE committee on transportation, and presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940. Manuscript submitted November 10, 1939; made available for preprinting December 11, 1939; released for final publication March 5, 1940.

J. A. NOERTKER is electrical engineer, Cincinnati Street Railway Company, Cincinnati, Ohio.

problem involved in making such equipment commercially available offers a challenge to the skill and ingenuity of electrical engineers.

Closely related to this problem of power supply is the problem of constructing a catenary and distribution system at a lower cost than those now available. One of the great difficulties in connection with the electrification of main-line railroads is that the catenary and distribution system must be installed complete over fairly large areas in order to secure economies in operation, and it must be installed on the basis of handling the maximum traffic expected within the near future. This requires a heavy investment involving large fixed charges that continue even if the traffic does not come up to expectations. The present trend of main-line motive power to self-contained units is largely due to an effort to avoid these fixed charges. Should a solution be found that would permit a drastic reduction in the cost of catenary and distribution systems, this trend might easily be reversed.

Table I. Power Distribution Characteristics of Principal United States Railroad Electrifications*

	System of Electrical Distribution		
	Current	Voltage	Third Rail or Catenary
Butte, Anaconda & Pacific	D-c	2,400	Cateuary
Chicago, Milwaukee & St. Paul	D-c	3,000	Catenary
Cleveland Union Terminal	D-c	3,000	Catenary
Delaware, Lackawanna & Western	D-c	3,000	Catenary
Fort Dodge, Des Moines & Southern	D-c	1,200	Catenary
Great Northern (Motor generator—d-c)	A-c	11,000	Catenary
Illinois Central	D-c	1,500	Catenary
Illinois Terminal Co.	D-c	650	Trolley
Long Island	D-c	650	Third rail
New York Central	D-c	750	Third rail
New York Connecting Railroad	A-c	11,000	Catenary
New York, New Haven & Hartford	A-c	11,000	Catenary
Norfolk & Western (phase converter)	A-c	11,000	Catenary
Pennsylvania	A-c	11,000	Catenary
Reading	A-c	12,000	Catenary
Southern Pacific Co.	D-c	1,200	Catenary
Virginian (phase converter)	A-c	11,000	Catenary

Note: All a-c electrifications are single-phase 25-cycle.

* Data taken from National Power Survey, 1936.

Considering further the various distribution systems of the electrified rail lines of the United States, it is clear that another major unsolved problem in electrical engineering is involved in the standardization of these systems.

In 1931, Sidney Withington, electrical Engineer of the New York, New Haven and Hartford Railroad, reviewing 25 years of experience with heavy electric traction, at a meeting of the New York Railroad Club, said that the most important problem which now requires solution is, "What electric system is the best for general use for heavy main-line electrification in the United States?"

Inasmuch as this problem is still with us and since his remarks are as pertinent today as they were in 1931 we quote Mr. Withington.

"It is sincerely to be hoped that this important question will be answered before long. With the growth of railroad electrification, the necessity will arise for the interchange of equipment among railroads, and unless a system of power distribution can be agreed to as standard by the railroads of the country, the diversity of electrical characteristics among railroads is going to be a major calamity, comparable, perhaps to the diversity in track gauge which caused so much trouble and loss in the early days of railroading.

"It is perhaps, true that until recently there has not been sufficiently reliable information available to justify standardization of this kind, but this is no longer the case. The dogfights which took place from time to time years ago as to the relative value of the various "systems" were not based on quantitative analysis and led nowhere. If, however, the data now existing can be properly correlated, a conclusion, based on definitely established premises should be reached. It is not pertinent to say that one type of electric power distribution is most satisfactory for terminal or yard switching, another for heavy freight operation on steep grades, or for high-speed passenger service and another for suburban electrification, for such tenets defeat the basic principle of standardization. A single system, one which is by and large most suitable for all electrification requirements should be authoritatively agreed upon. Until this is accomplished, the extension of railroad electrification will be seriously handicapped."

When we consider problems of this kind from the standpoint of national defense, they take on an even greater significance. Transportation units must be capable of mobilization in various parts of the country. England, France, and Germany, realizing this, have adopted national standards.

Standardization of motive-power units is not necessary to obtain the essential requirements for mobility as outlined above, but standardization is desirable in this respect if the railroads are to secure the tremendous economic advantage of mass production.

For the welfare of the electric transportation system as a whole and everyone individually involved in it, standardization is imperative. Major competition today is with transportation units produced by mass-production technic. This is true, not only of private cars, but also of motor and air transportation units. We need not fear that standardization will impair initiative and new development, because the driving force of competition is present today in the transportation field in greater degree than ever before.

Perhaps if some degree of standardization can be attained, the suggestion contained in the National Power Survey of 1936 for an increased electrification mileage of 12,000 miles of track on 20 steam railroads involving an annual energy consumption of 5,000,000,000 kilowatt-hours, can be made a reality or even substantially increased.

Power Utilization by Transportation Units

The elimination or the substantial reduction of the losses involved in starting d-c traction motors is a problem that has long concerned transportation engineers. Early in the history of the industry, these losses were reduced by approximately one-half with the adoption of series-parallel control, which has the further advantage of providing an efficient half-speed running point.

The past few years have seen rapid developments in the control equipment of urban transportation units. Competition with rubber-tired vehicles makes imperative the use of accelerating rates which closely approach the limits determined by rail adhesion. In order to maintain smooth acceleration from the starting point until the full-voltage motor curve is reached, it has been found desirable to eliminate transition points. The reduction in first cost and maintenance occasioned by the simplified control of a single motor, is further reason for modern trolley coaches and street cars to use rheostatic control.

Recent tests show that 40 per cent of the total energy supplied to the modern trolley coach is dissipated in accelerating resistor losses when the coach is operated over a heavy urban route. This is due to the fact that operation is constantly on resistance when the coach is operating in heavy traffic. On lighter urban runs where more free running is possible, this loss probably averages about 30 per cent. Similar conditions prevail on modern PCC cars.

The compound-regenerative motor used

on some recent trolley-coach installations, provides for more efficient medium-speed running, but the major portion of the starting-resistor loss still remains.

It is frequently pointed out that these losses are salvaged during the winter months for heating the coach. This is true, but dynamic braking, now so successfully installed on both trolley coaches and rail equipment, for the primary purpose of reducing brake maintenance, makes the energy available for heating. More energy is being dissipated on modern transportation units of this type than can be comfortably used for heating purposes.

The ideal system of control for transportation equipment would provide for the total elimination of control-resistor losses and make available an infinite number of efficient low-speed running points.

The need for efficient d-c control seems to be appreciated to a greater extent in Europe than in America. This is evident from the fact that development along these lines has progressed farther, and that the foreign technical press carries more articles relating to this problem than the American technical press.

The "metadyne" control, recently furnished on 73 new multiple-unit equipments for the London Passenger Transport Board, is one answer to this problem, although the equipment involved at the present state of development is rather complicated and heavy for general application to small urban transportation units.

The name "metadyne" has been given to a type of d-c machine in which special use is made of armature reaction to control machine characteristics. Metadynes have been built to act as rotary transformers of d-c power and applied to control railway equipments. This control is arranged to convert power from constant voltage to variable voltage so as to give any desired speed-torque characteristics to the traction motors from standstill to full speed and from full speed to stop. For example, for the comfort of passengers when using a high rate of acceleration, it is desirable to start with low acceleration, to rapidly increase the acceleration at a steady rate until a maximum is reached and then to decrease the acceleration steadily so that when the power is cut off, the passengers will not be inconvenienced. Similarly when braking regeneratively, it is desirable to start with a low rate of retardation, increase it to a maximum and finally to ease off the rate, so that just before stopping the rate of retardation is low. These features can be obtained with the metadyne in a very smooth manner by varying the natural characteristics.

The metadyne control thus takes the place of starting resistors, accelerating relays, switches, and cam groups commonly used for traction-motor control, and in addition, provides means for the regenerative control of the machine to standstill. The power wastage ordinarily involved in resistance losses is thereby avoided, while the smooth control has obvious advantage over the use of stepped resistances.

Experiments have been made with inverters and d-c transformers of the commutator type, in which only light rotating parts are used and the actual transformation of power is accomplished by highly efficient static transformers. A device along such lines would seem to offer possibilities for producing smaller and lighter units than the metadyne does at present.

There seems to be no fundamental reason why an efficient d-c control cannot be evolved. Perhaps, the problem needs only to be emphatically brought to the attention of research organizations. Certainly, it should be listed as one of the unsolved problems of electrical engineering in the transportation field in the United States.

Another problem is the definite need for some simple efficient equipment that will convert 600-volts direct current to a low-voltage alternating current. On 600-volt multiple-unit cars, especially those operated from third rail, the only method now commercially available for converting from third-rail voltage to a low-voltage direct current or alternating current for providing low-voltage lighting, is by means of a motor generator set with a 600-volt d-c motor and a low-voltage d-c generator. Such motor generator sets are usually required to have an input of approximately two kilowatts but because they operate over a range of approximately 450 to 750 volts direct current, the motors have to be large in order to maintain the generator output at 450 volts. Also the motor is subjected to terrific abuse whenever a train runs off the end of a stretch of third rail with the traction motors connected to the rail, as then the potential applied to the motor reverses instantaneously from plus 600 to minus 800 or 900 volts due to the inductive kick from opening the traction-motor circuits. The motors of such motor generator sets usually have to be compound wound and the above requirement imposes a very difficult commutation problem because of the tendency of the motor to generate under such a condition and to dissipate its kinetic energy as an electrical short circuit. Motor generator sets of this type have been built but are expensive and require high maintenance on account of commutator troubles.

The ideal solution of this and allied problems would be a device of the nature of a vibrating inverter that would convert from 600-volts direct current to low-voltage alternating current which could be used directly on the lamps, or rectified for battery charging, or both. Such a device should have very lightweight moving parts so that there would be no appreciable kinetic energy to dissipate at times of sudden voltage reversals due to third-rail gaps. Means should be incorporated in the device for maintaining constant a-c output voltage with varying d-c input voltage. Inverter tubes would be excellent for this purpose if they could be developed to withstand the high inverse voltages involved and to deliver the necessary power outputs. The problem of rectifying alternating current from such a source to low-voltage direct current can, of course, be solved in a number of well-known ways.

Still another problem is the need, on certain classes of cars and by certain fixed equipment at remote locations, for a small amount of power for lighting and signal lights without using the conventional systems of generation. The conventional systems of power supply such as straight storage batteries, storage batteries and axle generators, or self-contained gasoline engines all seem to be too expensive in first cost and too high in maintenance for the small amount of power required.

A possible solution is the use of primary batteries with some type of fluorescent lamp requiring very little power, yet giving considerable light. Together with these would be required an efficient inverter for the transformation of power to secure alternating current for the operation of the fluorescent lights. The inverter presents a problem on account of the high efficiency required with a low power input.

Other problems of power utilization on vehicles would be immensely simplified if storage batteries of greatly improved characteristics for transportation purposes could be developed. While great improvements in storage batteries, both of the lead-acid and alkaline types, have been made in the last 20 years, they have been along the lines of refinements rather than fundamental changes. What is needed is a battery of radically new characteristics, such as much lighter weight, higher voltage per cell, greater capacity, and the ability to be charged from commercial a-c sources of supply. While this may sound revolutionary it would be no more remarkable than other developments that have occurred in recent years. The Drumm battery developed in Ireland several years ago is an attempt at a solution of this unsolved problem.

Suitable thermostatic control of heat on transportation units is still an unsolved problem. The use of a single thermostat on a multiple-unit car is far from satisfactory, particularly on runs where doors are opened frequently because of stops being close together on one portion of the run, and closed continuously on other portions where there are no stops. A solution of this problem is desired without resorting to the use of forced ventilation.

There is also a great need for a better d-c lightning arrester. At present, the most effective arrester for d-c traction vehicles is the aluminum-cell arrester. No case is known of damage to equipment where the vehicle has been equipped with one of these devices and it was in working order.

However, these arresters are expensive to maintain, require careful maintenance, and in many parts of the country where they have to be kept operating 12 months of the year they must be protected against freezing in the winter and overheating in summer, the film being very critical at high temperatures. On 3,000-volt d-c cars and locomotives, 12 of these jars have to be used in series and high short-circuit currents can be caused by jar failures.

For a-c circuits, the Thyrite resistance arrester has been developed and has superseded the aluminum cell. For various reasons, this material cannot yet be used on direct current. It would seem as though a similar material could be developed for use on d-c circuits.

Possible Electrical Solutions of Operating Problems

There is no doubt that electrical engineering can play a considerable part in solving some of the more difficult operating problems of transportation. Consider, for instance, the problem of communication between the vehicle and the dispatcher. With the present state of development of ultrashort-wave radio such communication is entirely feasible, yet out of reach economically. It is obvious that such a development would greatly expedite the handling of emergency traffic problems. Another communication problem, which, however, seems about solved is that of communication between the ends of long freight trains.

The electric fare box is a splendid development. But if an electrical device could be developed that would record and collect the amount of the individual fare in proportion to the length of the individual ride, a veritable revolution in urban transportation might result. At present, the major part of short-haul rides are lost because the cost of these rides is, as a rule, out of all proportion to the value to the individual patron.

Notwithstanding the use of many clever mechanical devices, the formation of sleet on trolley wire, and on third rails of the over-running type, is in many parts of the country a serious operating problem. Various schemes have been proposed for preventing sleet from forming or, at least, to keep it from sticking tightly to the wire or rail. However, no satisfactory solution has yet been found.

It might be possible to develop some sort of material that would serve as a coating and would prevent sleet from forming. The problem of preventing the current collectors from removing such material would of course be a considerable difficulty.

On many transportation lines, particularly on subways, the problem of announcing the approaching station is receiving considerable attention. To date, no infallible scheme has been developed that is economically feasible.

Possibly some sort of device, such as motion-picture film projecting the name of the station or announcing the name of the station audibly, could be worked out, which would enable the problem of various routes and changes in destinations to be taken care of without the apparatus becoming too unwieldy.

The same problem is also present to a certain extent on mainline trains, and it is only reasonable to suppose that the train of the future will include some provision to supersede the brakeman's "grunt" which has become over the years synonymous for practically any station on the line.

In connection with signaling and train control, there seems to be a problem of the conduction and detection of very small currents at low voltage through wheels of the free-wheeling type. In general, however, modern systems of train control and cab signaling have been perfected to such an extent that the major problem would seem to be that of financing their installation. Automatic train control is of course a unique advantage from the safety standpoint that rail transportation has over all of its competitors. Unsolved problems in this field certainly merit serious consideration.

Another safety problem that should receive attention is that of providing timely and adequate warning in the event of fractured or broken axles.

The problem of recording headways between rail units or trolley coaches at a central dispatcher's office on urban transportation systems has been solved. Such a system, complete with automatic alarms, operating when pre-established headways are exceeded can be installed today at a reasonable cost. The satisfactory recording of motor-coach headways, however, still remains an unsolved problem. Such a recorder, functioning without street treadles or attention from the coach operator, is urgently needed today.

In general, it seems to the author that the advantages of centralized control and supervision of operation cannot be overemphasized. Such systems can be developed economically and extended over every phase of the power supply and distribution system with great advantage to the transportation service.

Improved Research Instruments

Despite the phenomenal development of scientific instruments, the use made of them by public transportation agencies is not significant. Something is lacking here. No one questions that the essential factors making for convenience and comfort and therefore for public acceptance of transportation units are speed, smoothness of acceleration and retardation, absence of noise and vibration, illumination and ventilation, yet the transportation unit is not periodically checked by suitable instruments with respect to these factors.

The performance of new equipment is not even specified and checked with regard to all of these factors. We still rely on our intuition and feelings after a demonstration ride to determine the most comfortable equipment. All of the factors mentioned are physical and therefore susceptible to quantitative measurement. There is no reason why recording instruments presenting a graphic picture of these factors as the transportation unit proceeds along its route should not be developed and used. The significance of these factors will only be appreciated after they have been recorded in some such manner.

There is seldom much progress made in improving a given situation until objective measures of the results are obtained, for the reason that there is no agreement on the basic facts until we have visual pictures of them.

One of the important physical factors which we have not yet succeeded in measuring is the presence of objectionable odors or fumes. If someone should develop an objective method of determining and graphically measuring these, we would undoubtedly solve the problem of their elimination.

Notwithstanding the need it is unlikely that instrument or meter manufacturers will of their own initiative, develop extraordinary tools for furthering research and development work on transit systems for the reason that the market for such equipment would be so limited that the development would be unprofitable.

Conclusion

The multiplicity of problems facing the industry leads naturally to the vital unsolved problem of stimulating technical developments in the transportation field. Experience has demonstrated the relative ineffectiveness of individual operating companies in the fields of research and progressive achievement. Railway association committees are likewise relatively ineffective. They do excellent work, but the tempo of their achievement due to the very nature of the volunteer type of organization is inadequate to meet present-day competition. Individual manufacturing companies have made noble efforts to keep the public-transportation industry abreast of the times. The money they can afford to spend on new development, however, is strictly limited to potential profits they can make from the sale of new equipment. When the prospects for the sale of new equipment vanish, the development program slackens at the very time when it should be accelerated. Somehow, the problem of maintaining an adequate research and development program must be solved.

Illustrative of what might be accomplished by an adequate approach is the result of several years' activity of the Presidents Conference Committee, the new PCC car—a revolution in urban transportation.

The development of equipment and improved standards for railways, as in practically all of the older industries, has been a sort of evolutionary process, that is, improvements have come through the elimination of the cause of faults and complaints. With the limited funds available for research and development, no other technic was possible. Even with the maximum effort and co-operation only moderate progress is possible by using such a technic. The activity of various technical committees, through interchange of experience and ideas, stimulates and accelerates the evolutionary method, but the results are naturally the refinements of existing equipment instead of the development of revolutionary new methods and equipment.

If the necessary funds, time, and organization were available it would be possible to attack this problem in an entirely different way. The broad general objective could be established a priori or by means of a consumer or patron survey of results that should be accomplished. Research men and scientists could then set about obtaining all factual data relevant to the accomplishment of these results. After the physical factors entering into the solution had been isolated, performance specifications could be set up. Up to this time, no consideration need necessarily be given to past experience or to equipment available at present. The newly evolved specifications would provide the necessary standards by which to judge, not only the performance of existing equipment but also of all proposed equipment.

Probably the best example of the use of this scientific research method in the transportation field is the activity of the Presidents Conference Committee in the development of the PCC car.

The late Doctor C. F. Hirshfeld speaking of this activity said:

> "The important thing to note is that this research enabled us to set fairly exact specifications for those things that would have to be achieved to produce a completely modernized and satisfactory street car. I shall speak of these specifications as performance specifications because that is what they are in essence.
>
> "Frankly, the performances indicated were in many cases so far beyond what the industry had theretofore considered necessary that our demands were at least startling to manufacturers who were asked to produce equipment to give such results. My impression is that they were equally startling to many operating men as well. I confess that in some cases we announced these specifications with some fear of ridicule, because, after all, we were in the position of advocating rather revolutionary changes on the basis of experimental work and without the reassurance that comes from practical use."

It is vital to observe that there is nothing final or absolutely conclusive about performance specifications developed as outlined above. The whole technic and development is based on a premise which is constantly shifting with public sentiment. If noise was disregarded by the public yesterday but considered vital today, our performance specifications must be changed accordingly.

An organization designed to cope with problems in such a manner, must, of course, be permanent and its activity continuous. If its financing were a charge against operating expense as is the case with the development work of the American Telephone and Telegraph Company, development would be greatly stimulated, and furthermore the acceptance and actual use of new developments would be expedited for the following reasons:

1. Operating companies are in direct competition with other forms of transportation and therefore have a keen interest in improving their competitive position. They are able to sense more quickly and accurately public demands in transportation than the more remote manufacturers of equipment. They would therefore initiate more quickly development work actually needed to meet public demands.

2. In an effort to realize on their contributions to the joint development fund operating companies would do everything possible to put new developments into actual service.

3. Due to the fact that new developments would not be loaded with manufacturers development costs, the initial cost of new equipment would be greatly reduced with consequent savings in fixed charges such as interest, depreciation, and taxes.

Such an organization supported by the operating companies and functioning with adequate resources would inevitably present to the manufacturers of this country unsolved and worthwhile problems of the industry which we cannot even comprehend today.

Resistance of the Spot Weld

LADISLÁV CIGÁNEK
NONMEMBER AIEE

Synopsis: This paper covers an investigation of the electrical resistance across a spot weld and offers both calculated and measured data for comparison.

THE OUTPUT of resistance-welding machines is generally determined by Joule's law

$W = RI^2$

where R is the resistance of the heated metal being welded and I is the current flowing during the welding operation. With the majority of machines, welding current is determined by the internal impedance of the machine, the resistance of the weld being but a small part of the impedance of the entire circuit.[1] Therefore the value of R is the only variable which can change the output at the electrodes of a given machine for a given internal impedance. Designers of welding machines are familiar with the value of R for different welding jobs,[2] however, there has been a lack of systematic study of this resistance. This paper indicates one method of evaluating spot weld resistance. Investigations were restricted to the most important case, the welding of the ordinary mild-steel sheets.

Flow of current through the electrodes and sheets is shown in figure 1. The resistance which effects the weld consists of:

1. Two contact resistances between the electrodes and the sheets.
2. One contact resistance between the two sheets.
3. Resistance of the sheets.

Investigations of the contact resistance were based on the studies of R. Holm and his collaborators.[3–7] According to Holm's theory of "sieve-resistance" (*siebwiderstand*), two clean metallic surfaces never touch in a plane, but contact in a larger or smaller number of microscopic projections depending upon surface conditions. The number of these projections in contact increases with the pressure exerted on these surfaces. The resistance of the two surfaces to current flow is in fact but a metallic resistance of the very narrow current fibers, contracting into the contact sieve. The contact area will be best filled with elementary contact areas when the pressure exceeds the compressive strength of the material. With this condition, both surfaces fit into each other nonelastically and the resistance across the contacting surfaces becomes,

$$R_c = \frac{\rho}{d} \tag{1}$$

ρ = resistivity of the metal (with two different metals in contact, the mean value of both should be used)
d = diameter of the contact area

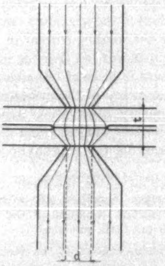

Figure 1. Flow of current through the electrodes and sheets in the average spot weld

Since contact resistance is metallic in nature, its value increases with rising temperature as determined by the thermal coefficient of resistivity.

The current fibers between the electrodes form a space conductor. It can be assumed that the surface contact between the two welding parts is of infinitely large diameter. This assumption is essentially correct since further investigations indicate that most of the current fibers run very close to the axis of the current flow. This is illustrated in figure 3. The potential field of this current can be determined according to Lehman's rules[8,9] by tracing the form of the equipotential and force fields in the axial section of this space. Lines of force and equal potential cross orthogonally and divide this space into ring elements of equal permeance. Referring to figure 2,

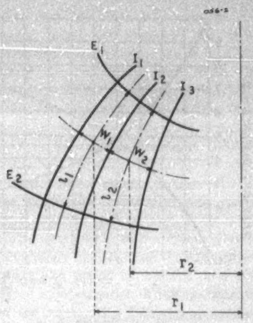

Figure 2. Relation of current fibers with respect to the axis of current flow

$$\mathcal{P} = 2\pi r_1 \frac{w_1}{l_1} = 2\pi r_2 \frac{w_2}{l_2} = \text{etc.}$$

Total permeance of this space is determined by the number of ring elements connected in parallel, divided by the number of elements in series. For the space conductor of figure 3, current path was determined for contact diameter, $d = 0.4$ centimeter (0.164 inch) and for the total sheet thickness $t = 0.8$ centimeter (0.328 inch). Permeance of one ring element becomes 0.95 centimeter, and total permeance of the space occupied by the current 0.534 centimeter. If the current fibers were straight between the circular contacts, permeance of the space conductor would be that of the cylinder 0.4 centimeter in diameter and 0.8 centimeter in height and may be expressed—

$$\mathcal{P}_c = \frac{\pi d^2}{4 \cdot t} = 0.157 \text{ centimeter}$$

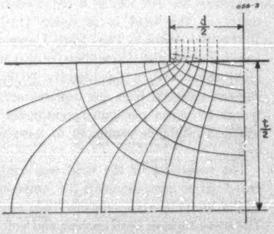

Figure 3. Equipotential and force fields in space conductor

Paper 40-56, recommended by the AIEE committee on electric welding, and presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940. Manuscript submitted June 14, 1938; made available for preprinting January 4, 1940; released for final publication February 23, 1940.

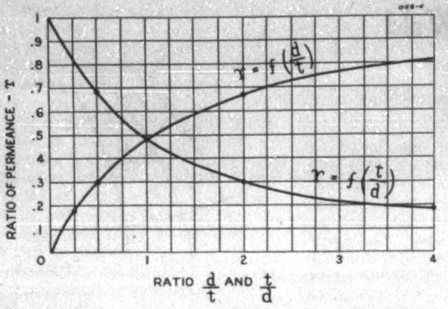

Figure 4. Curves showing ratio of permeances Υ as a function of electrode diameter to sheet thickness and sheet thickness to electrode diameter

Ratio of both permeances

$$\gamma = \frac{\mathcal{P}_c}{\mathcal{P}}$$

will be constant for a given ratio t/d. For the above constants $\Upsilon = 0.295$. Values of Υ were obtained from the field images, traced for $t/d = 4, 2, 1, {}^1/_2$ and plotted against the ratio t/d, d/t respectively as shown in figure 4. Reciprocal curves permit extrapolation by making use of both limits: $\Upsilon = 1$ for $t/d = 0$ and $\Upsilon = 0$ for $d/t = 0$. In the following calculations, resistance of the space conductor between the two circular contacts was computed from the equation

$$R_m = \Upsilon\rho\frac{4 \cdot t}{\pi d^2} \tag{2}$$

The shape and resistance of the space conductor is affected by the strong magnetic field produced by the welding current. Therefore, in obtaining data this effect was minimized by locating the weld near the edge of the sheets, so that only a relatively small flux could affect the space conductor. Eddy currents also affect the resistance value. Current densities in the weld amount to about 10,000 amperes per square centimeter. The resistivity of the hot steel is approximately 10^{-4} ohm per centimeter cube. Therefore the I^2R loss in a cubic centimeter of the weld is of order $(10^4)^2 10^{-4} = 10^4$ watts. The eddy current loss in a very thick (10 millimeter or 0.39 inch) sheet with a flux density 20,000 gausses (129,000 lines per square inch) is but 10 watts per cubic centimeter[10] which is negligible compared to the I^2R loss.

The resistance of the weld was computed from measurements of amperes and of the volts across the electrode tips. The wave form of both current and voltage was found to be practically sinusoidal with sheet thicknesses from 0.5 to 10 millimeter and with currents to 8,000 amperes. A slight deformation of the voltage wave, due probably to the partial discharge in the contact, was found but this deformation never exceeded the degree of accuracy of the method.

Measurements of the resistance were limited to voltmeter readings only, using the volt-ampere characteristic curves of the welding machine.[11] The volt-ampere curve for a given primary tap of the transformer and for given physical dimensions of the secondary circuit gives directly the welding current in terms of voltage. It was felt that the use of one instrument in place of two added greatly to the accuracy of the measurements.

Preliminary observations under various conditions disclosed that the resistance across the weld depends upon:

(*a*). Material being welded.

(*b*). Surface condition of metal being welded (surface condition of the electrode produces but little influence).

(*c*). Pressure exerted by the electrodes.

(*d*). Diameter of the contact.

(*e*). Temperature of the metal.

The relation between pressure, contact area, and temperature is complicated. In general, however, as the heated metal becomes softer, the contact area increases, causing a decrease in resistance. At the same time the rising temperature causes an increase in resistance due to the greater resistivity. Thus the effects tend to balance each other.

In order to analyze the problem it was necessary to eliminate as many variables as possible. With this in view mild-steel sheets, with ground surfaces, were used.

Resistance at Ambient Temperatures

To eliminate the contact resistance between two sheets, measurements were made with only one sheet between the electrodes of the welding machine. The sheet was held at ambient temperature by low-current and high-pressure values. By decreasing the primary voltage of the welding machine, current values from 1,000 to 2,000 amperes were obtained. A fixed pressure of 450 kilograms (990 pounds) was used.

From the experiments of Hertz,[12] it was found that when the compressive strength of the metal is exceeded, the increase in contact area is nearly proportional to the increase in pressure. This is always the case with the ordinary pressure settings of spot welders. Therefore, the contact diameter follows the relationship

$$\frac{\pi d^2}{4} = \frac{P}{p} \tag{3}$$

P = pressure exerted on the contact surfaces
p = compressive strength of the contact metal

For the average hard-drawn copper electrode in contact with a ground mild-steel surface, it was found that $p = 84.5$ kilograms per square millimeter. Pressures from 30 to 700 kg, were used covering all pressures commonly used in spot welding.

Voltages were measured across mild-steel sheets 0.5, 1, 2, and 4 millimeters in thickness with contact diameter of 0.26 centimeter and pressure of 450 kilograms. These readings are plotted against amperes in figure 5. Voltages obtained for each sheet thickness indicate that the resistance is constant. In table I the resistance of a single sheet at ambient temperature as obtained by measurement, is compared with the same values computed from the equations 1 and 2.

The resistance of copper to steel at ambient temperature in equation 1 was taken as $\rho = {}^1/_2(0.13 + 0.0175)10^{-4} = 0.074 \times 10^{-4}$

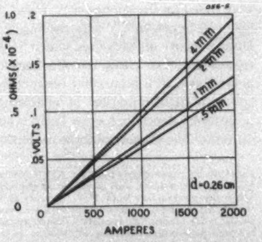

Figure 5. Voltage measurements across single thicknesses of mild-steel sheets for different current values and constant contact diameter of 0.26 centimeter

Table I

Sheet Thickness t (Mm)	0.5	1	2	4
$2R_s$ (equation 1)—10^{-4} ohm	0.57	0.57	0.57	0.57
R_m (equation 2)—10^{-4} ohm	0.1	0.18	0.26	0.34
Total $R_w = 2R_s + R_m$—10^{-4} ohm	0.67	0.75	0.83	0.91

ohm-centimeters. For mild steel in equation $2\rho = 0.13 \times 10^{-4}$ ohm-centimeters.

With the same values of current and pressure, voltages were read across two ground mild-steel sheets of the same thickness. These readings are plotted against amperes in figure 6. A study of the resistance values in figures 5 and 6, corresponding to the same total thickness indicates that the contact between these ground sheets does not affect the resistance value materially. Therefore, in table II values obtained from figure 6 are compared with the values calculated from equations 1 and 2 assuming that the resistance is the same whether one sheet or two sheets of half the thickness, is used.

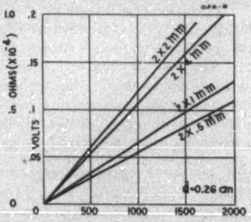

Figure 6. Voltage measurements across two thicknesses of ground mild-steel sheets for the same current values and electrode diameters used in figure 5

The differences between the computed and measured values in table I and table II, are within the accuracy of the method.

With smaller pressure values, the resistance of the surface contact between sheets adds to the total resistance. This higher resistance affects the weld for only a very small part of the welding time and therefore it did not seem necessary to follow the matter further.

Resistance at Elevated Temperatures

During the investigation, the resistivity of the steel was carefully controlled. Figure 7 shows the relation of the resistivity to the temperature. Only two values were carefully measured. These were: $\rho = 0.13 \times 10^{-4}$ ohms per centimeter cube at ambient temperature and ρ max$= 0.96 \times 10^{-4}$ ohms per centimeter cube, the latter being constant above 1,100 degrees centigrade. The curve which was taken from test data falls between the curves found by Stablein[13] for steel containing 0.05 per cent carbon, and by Holm[1] for chemically pure iron. In the measurement of voltages of the "hot" resistance, use was made of the fact that the resistivity of the steel was constant in the temperature range through which the welding operation is performed. By checking the heat color of the metal, the temperature was easily determined for each reading.

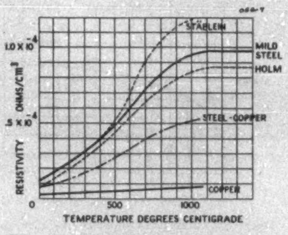

Figure 7. Resistance of copper-steel contacts and of steel and copper at elevated temperatures

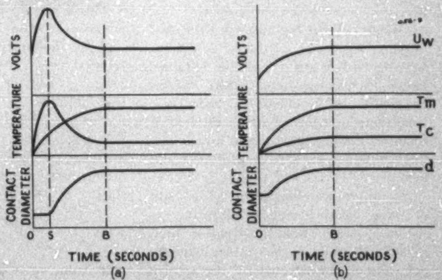
The relationship of the different variables which influence the weld resistance during the period of heating, was obtained by observation of voltage changes on the screen of a cathode-ray oscillograph. In order to observe these effects more closely, the heating period was lengthened by decreasing the output of the welding machine until a heat equilibrium was established. The equilibrium was obtained when the total heat developed was dissipated through the electrodes into the cooling system. The voltage, temperature, and contact diameter during heating was found to be dependent upon the magnitude of the pressure.

Measurements at Low Pressure

Figure 8*a* shows these relationships for a pressure of 30 kilograms exerted on the electrodes. It will be seen that the voltage drop at ambient temperature rises immediately to a high value. This is due to the increasing temperature of the contact while the contact diameter remains unchanged. However, the heated metal softens rapidly and after the inertia of the movable electrode has been overcome at *S*, the contact area increases thus decreasing the resistance. This causes a corresponding decrease in voltage. The voltage, temperatures, and contact diameter become constant at "hot" values which maintain a balance of heat flow at point *B*. The temperatures of both the



(a)

(b)

Figures 8a and 8b. Values of different variables during the weld cycles for low and high pressures respectively contact and of the sheets show that the heating originates in the contact and progresses into the sheets. With lower pressure and improper cooling of the electrodes, the metal melted at the contact surfaces before the welding operation was begun which resulted in unsatisfactory welds. In the balanced final conditions when the heat flow equilibrium is reached, the electrode contacts are much colder than the inside of the weld, forcing the heat to flow through the electrodes into the cooling system.

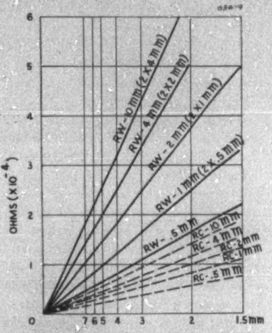


Figure 9. Resistance across one- and two-sheet combinations of mild steel at welding temperatures for electrode diameters of 1.5 to 7 millimeters

Measurements at High Pressure

With pressure at 300 kilograms or greater, the characteristic curves of voltage, temperature, and contact diameter are as shown in figure 8*b*. The voltage across the electrodes rises steadily to a constant value. Curves for temperature and contact diameter also show this same characteristic. The temperature of the weld is always greater than the contacts, due to the greater effect of the resistance of the sheet on the total resistance. With high pressure the heat develops first inside of the weld, and the welding temperature can be obtained before the contact temperature reaches the melting point. However, under these conditions, a short welding interval is required to make a weld and a high current value necessary to develop sufficient heat.

An important observation as a result of these measurements is that the resistance of the weld at welding temperature depends on the contact diameter only and is not affected by the applied pressure. Based on this fact, measurements were made as follows: A steel sheet was placed between the electrodes and heated. When the heat color indicated that a temperature of 1,100 degrees centigrade had been reached the flow of current was interrupted. The voltmeter reading was used to determine the resistance of the hot metal and the contact diameter was obtained from the mean value of the diameters of the electrode impressions on each side of the sheet.

Here again, complete measurements were made with only one sheet between the electrodes to eliminate the effect of the center-contact resistance. Weld resistance, R_w, plotted against the contact diameter, d, reveals a hyperbolic relationship. Where $d=0$, $R_w=\infty$ for any thickness of the sheet, but when $d=\infty$, $R_w=0$. Since reciprocal co-ordinates reduce hyperbolic functions to straight lines a reciprocal scale was used for diameter in figure 9.

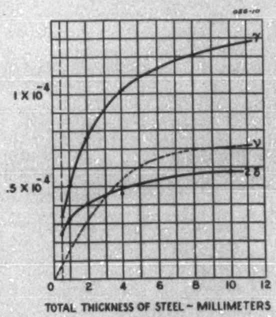

Figure 10. Resistance in weld area of mild-steel sheet

2δ = resistance of both contacts
ν = resistance of metal
γ = total resistance

This diagram illustrates the resistance across a clean, mild-steel sheet 0.5, 1, 2, 4, and 10 millimeters thick at welding temperature. Measurements cover the range of contact diameters commonly used, that is, between 1.5 and 7 millimeters ($^1/_{16}$–$^1/_4$ inch). Extreme extrapolation beyond these limits should be avoided. Straight lines through the measured points indicate the following relationship

$$R_w=\frac{\gamma}{d} \tag{4}$$

The value of γ is determined by the specific resistance and the relationship follows Holm's formula (1). However value of γ changes for various sheet thicknesses even though the temperature of the weld remains constant. Although the data points are scattered, this variation does not exceed the accuracy of the measuring method. The differences are due largely to the difficulties encountered in accurate measurement of the hot contact diameter.

Values of γ plotted against the sheet thickness are shown in figure 10. This curve indicates a probable constant maximum value, similar to the curve $\rho=f(T)$ in figure 7. It seems logical to assume that the resistance of the space conductor in the metal will not vary greatly under different conditions of cooling, since the welding temperatures are in the range of ρ max. Conversely, the temperature of the contacts depends largely upon the method of cooling of the welding tips and the contact resistance varies with the change in temperature. It is advisable to divide the total weld resistance into contact resistance and sheet resistance to permit estimation of the weld resistance under other conditions.

Measurement of Contact Resistance

The voltage drop caused by the contact resistance was measured by use of the special electrode illustrated in figure 11. The hole through the center was made 1 millimeter in diameter and a copper wire 0.5 millimeter was inserted and insulated with asbestos. Voltage between the contact wire and the outer edge of the contact face of the electrode includes all equipotential planes. Before each reading was taken, the contact

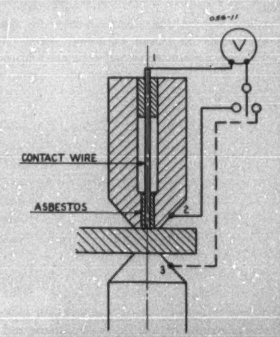

Figure 11. Special electrode and setup used in measuring voltage drop in weld area

face was filed to form a plane surface. The only measurements used were those showing a clear impression of the contact wire in the center of the electrode after contact with the sheet steel. Half of the readings were taken between points 1 and 2, and the remainder between the contact wire and the opposite electrode, that is, points 1 and 3. By subtracting the latter from the reading of the voltage across the weld (points 2–3), the error in measurement of these small voltages was reduced.

In figure 9 the resistance of one contact, computed from the voltage and the current across the contact, is plotted against the contact diameter using reciprocal co-ordinates. This was done for various sheet thickness as noted, the metal being in the range of welding temperatures as in the previous measurements. This relationship may be written as follows

$$R_c = \frac{\delta}{d} \tag{5}$$

This equation is also similar to Holm's formula, equation 1. There is however, a great difference between the meaning of ρ in equation 1 and of δ in equation 5. In equation 1 ρ is a function of the contact temperature, while δ in equation 5 is a function of sheet thickness. Both equations would be comparable, if the contact temperature were equal with all contact diameters for a given sheet thickness and if the contact temperature increased with the sheet thickness. This is impossible of course, since contact of a given diameter reaches equal temperature for all sheet thicknesses because of equal metal temperature and of equal heat conductivity of the electrodes.

Following Holm's theory, a temperature-resistance curve for copper-steel contacts was plotted as in figure 7 based on $\rho = f(T)$ for steel and for copper. In this curve, the following temperatures correspond to the values as shown in figure 9.

Sheet thickness t (millimeters)	0.5	1	2	4	10
Theoretical contact temperature (degrees centigrade)	150	280	390	440	530

The actual contact temperature was checked by the heat flow at equilibrium. This balance was obtained by suitable current adjustment of the welding machine. For the contact diameter of 0.3 centimeter, the heat loss through one electrode was found to be practically constant for all sheet thicknesses. A loss of 735 watts with a given heat conductivity of the electrode gives an actual contact temperature of 550 degrees centigrade. (In this instance the cooling was very inefficient.) With contact diameter of 0.4 centimeter, the loss was 1,000 watts giving an actual temperature of the contact of 650 degrees centigrade.

Thus the theoretical temperature approaches the actual temperature with an increase of the sheet thickness and with a decrease of the contact diameter. The apparent variance also might be a result of the different heating conditions due to two contacts rather than one contact. Holm's theory is based on the assumption, that the heat generated in the contact is equally dissipated in both directions. In the case of the weld, heat is generated in both of the contacts and the metal and flows unidirectionally from the metal toward the contact.

Referring to figure 10, the curve 2δ shows the resistance of both contacts. The curve ν, which is the difference of curve γ and curve 2δ, gives the apparent resistivity of the metal space conductor for the equation

$$R_m = \frac{\nu}{d}$$

The curve ν indicates a maximum value, indicating the limit of the heat absorbed by the metal of the weld. This may explain the difficulties encountered in welding of the heavy sheet gauges.

To check values of ν given by figure 10, the resistance of the space conductor was computed from equation 2 for the various contact diameters and sheet thicknesses, using the maximum resistivity ρ max $= 0.96 \times 10^{-4}$ ohms per centimeter cube. With contact diameters of 0.5 centimeter and larger, close agreement was found between the computed values and the curve ν. With contact diameters of less than 0.5 centimeter the resistance exceeded the values of the curve ν. This is as expected in that as the diameter decreases more of the current fibers pass through the outer, colder zones of the metal and results in a lower value of resistivity of the space conductor.

All of the preceding investigations with steel at welding temperatures were based on only one sheet between the electrodes. However actual welding is never performed under this condition. To simulate actual welding conditions two ground mild-steel sheets of equal thickness were placed between the electrodes of the welding machine and the resistance of the weld at welding temperature was measured by the same methods. The resulting values of R_w for steel sheets 2×0.5, 2×1, 2×2, and 2×4 millimeters were plotted against the contact diameter and are shown in figure 9. These values compare closely with the measurements taken with one sheet of twice the thickness. This proves that the resistance of the contact between the sheets is negligible compared to the total weld resistance. This appears at variance with equation 1 which shows that with the relatively high resistivity of hot steel the contact resistance should attain a considerable value even with large contact diameter. This may be explained as follows: Two plane surfaces of the same metal under pressure and at red heat do not represent the contact sieve of Holm's theory, but fuse together offering resistance to the current flux. This occurs prior to the consummation of the weld, possibly when the creep strength of the heated metal is exceeded.

Summary

This paper presents a study of the resistance of spot welds in ground mild-steel sheets. Surfaces of the sheets must be free from visible oxide coating. The resistance at ambient temperature which determines the power input into the weld at the beginning of the welding cycle consists of two contact resistances and the resistance of the space conductor in the metal. A ratio was found between the resistance of the space conductor and of the cylinder conductor as shown in figure 4. With heavy pressure and ground and polished sheets, the contact resistance between the sheets was found to be insignificant. Contact diameters were determined from equation 3, using the compressive strength of the hard-drawn copper tip against the ground, mild steel as 84.5 kilograms per square millimeter.

Resistance of the weld at the welding temperature, which determines the current required for the greater part of the welding cycle, depends only on the contact diameter and on the total sheet thickness. Values of γ for equation 4 are plotted against the total sheet thickness in figure 10. The same result was obtained with one or two sheets and whether or not a weld was made. Relative importance of both components of the weld resistance is illustrated in figure 10 by the separation of γ into contact resistance 2δ and sheet resistance ν. It was proved that the resistance of the contact at elevated temperatures does not follow Holm's theory with regard to temperature coefficient. This may be explained in that variable heating conditions are found in the contact since the majority of the weld resistance with thin sheets is incorporated in the contacts,

while with thicker gauges a larger proportion of the resistance is through the sheet. The value of ν cannot be affected materially by more efficient cooling of the electrodes as this resistance is determined by the welding temperature. However, the temperature of the contacts depends upon the efficiency of the cooling method, the contact resistance being reduced by greater heat dissipation from the contact. It should be borne in mind that there is no direct relation between the contact temperature and resistance; therefore, for thin gauges only a small difference can be expected from the values given above.

Power-Factor Correction of Resistance-Welding Machines by Series Capacitors

L. G. LEVOY, JR.
ASSOCIATE AIEE

Synopsis: Resistance-welding machines usually are characterized by a large intermittent kilovolt-ampere demand at low power factor which is sometimes difficult to handle on the available power circuits due to regulation problems. Frequently the situation is so acute that power companies are unable to serve large resistance-welding machines, because the cost of reinforcing the system to render the desired service is disproportionate to the revenue received from such an installation.

This paper explains briefly the reasons why the usual method of power-factor correction by means of shunt capacitors is not satisfactory, and presents a system of power-factor correction using series capacitors which avoids the undesirable characteristics of shunt capacitors for this service. Where synchronous control is used, it is shown that by establishing a precharge on the capacitor, the welding transformer can be energized without transients and with complete power-factor correction, thereby greatly reducing the kilovolt-ampere demand. With this system of operation, a given feeder can handle more or larger welders and regulation problems are greatly minimized. Large welders, heretofore considered impractical because of excessive kilovolt-ampere demands, can be served by this means.

The operating characteristics of the power-factor-corrected welding machine, and several methods of current control which may be used with it are described. Oscillograms of an actual welding machine taken under various operating conditions are also included. They show a resistance-welding machine which normally demands 434 kva at 41.5 per cent lagging power factor being served with a line demand of 181 kva at unity power factor. The paper also demonstrates that this system of power factor correction is applicable both to synchronous and nonsynchronous controls and that many benefits accrue for both cases.

THE problem of power-factor correction of resistance-welding machines is of current interest because of their widespread and rapidly growing application. In addition, new and improved methods of capacitor production have diminished the cost of capacitors to a point where it now becomes economically feasible to apply them in many cases where previously the cost was prohibitive.

One of the limitations of resistance-welding machines, both in size and number, is the large intermittent kilovolt-ampere demand at low power factor, which imposes a difficult load on the power system both from the standpoint of feeder regulation and capacity. In many locations, the power company cannot serve large resistance-welding machines because of the small revenue and high installed capacity required to serve them, or because of the "flicker" problem. Under these conditions, the manufacturer either must avoid fabrication of large parts by this admittedly good and usually inexpensive method; or else install large expensive transformers and feeders, or even more expensive rotating machinery to balance the single-phase load on a three-phase system and to smooth out the intermittent load on the system by means of its inertia. Very often the problem of supplying a large number of relatively small welders becomes acute because of the limitations of the power supply, and the interference between welders due to regulation drop.

A large part of the power companies' difficulty in handling the load would be eliminated if it were feasible to correct the power factor to approximately unity so that the power system would have to supply only the energy component of the load.

Regulation problems, interference between given welding machines on the same feeder, flicker, and other problems would all be greatly minimized by such correction. Furthermore, a given feeder could handle many more or larger welders if these machines were power-factor corrected. In many cases, penalties are imposed for peak kilovolt-ampere demand of welding machines. In such cases both the power company and the plant operator will welcome any practical system of power-factor correction, as both parties will benefit thereby.

This paper demonstrates that power-factor correction of resistance-welding machines by means of series capacitors is feasible and that it avoids many of the difficulties encountered with the application of shunt capacitors for this purpose. Since shunt capacitors are so universally used for power-factor correction on other apparatus, it is desirable to discuss the problems arising from their use for correction of the power factor of resistance-welding machines.

Shunt Capacitors

The merits of power-factor correction have been recognized for a long time.

Paper 40-11, recommended by the AIEE committee on electric welding, and presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940. Manuscript submitted November 1, 1939; made available for preprinting December 7, 1939; released for final publication February 24, 1940.

L. G. Levoy, Jr., is in the industrial control engineering department of the General Electric Company, Schenectady, N. Y.

Shunt capacitors have been used very successfully on many more or less constant-load applications for many years. The problem of power-factor correction of resistance-welding machines is unusual as compared with ordinary power-factor correction problems in that the load is of a highly intermittent nature. For instance, a spot welder may operate 100 times per minute, and seam welders may be energized 900 or more times per minute. The amount of inrush to a shunt capacitor each time the welder is energized may be several times the normal welder inrush, depending upon the phase angle of closure of the circuit. Thus, shunt capacitors frequently aggravate rather than help the power-supply problem on a highly intermittent load. It is theoretically possible to eliminate the charging inrush current to the shunt capacitors by precharging them to the correct voltage and connecting them in parallel with the welder primary synchronously and simultaneously with the closure of the primary circuit to the power-supply feeder. This can be accomplished with synchronous control (such as thyratron control). However, such an arrangement requires two sets of power tubes. One pair of tubes permits the precharge of the capacitor by disconnecting it from the welder primary (the precharge would immediately leak off through the welder primary if the capacitor was not disconnected from it) and the other pair of power tubes would act as a synchronous switch on the supply circuit to control the welder in the conventional manner (see figure 1). The controlled power tubes symbolically represented in these circuits may be of any type. Usually they are hot-cathode thyratrons or pool-type ignitrons. All timing and control circuits have been omitted from the diagrams for simplicity.

Series Capacitors

The extra pair of power tubes encountered in the use of shunt capacitors, as mentioned above, may be eliminated by making use of another form of circuit tuning or power-factor correction known as "series resonance". The phenomenon of series resonance is well known and frequently used in radio circuits. There are certain characteristics of the series-resonance circuits which make them ideally suited to highly intermittent low-power-factor loads, many of which exist in industry today. For the sake of brevity this paper is concerned primarily with the application of series capacitors to power-factor correction of resistance-welding machines.

The fundamental circuit is shown in figure 2. It will be noted that in this circuit only one pair of power tubes is required, and that these tubes effectively block the capacitor from discharging during the "off" time, thereby permitting the capacitor to be precharged to the proper value as required for transient-free operation.

The theory of operation of this circuit can best be demonstrated by reference to the vector diagrams shown in figure 3. These vector diagrams represent the conditions in a series circuit (see figure 2) operating on an essentially sine-wave voltage supply, and in a circuit which is linear (no saturation). These conditions are approximated in a properly designed welding-transformer circuit, operating on full wave. (The conditions in a phase-controlled welder cannot be represented by a simple vector diagram but can be readily calculated by mathematical analysis.)

Figure 3*a* shows the conditions existing when the welding-transformer load is corrected to unity power factor. Figure 3*b* represents the same welding transformer partially corrected so that the line is supplying a somewhat lagging load. Figure 3*c* represents the same welding transformer overcorrected so that the line is supplying a leading load.

Figure 8 shows the actual voltage and current relations corresponding essentially to the unity power factor case. It represents part of an interrupted spot weld made on two pieces of iron. Note that the supply-line current (trace *B*) is essentially in phase with the supply-line voltage (trace *A*). Note also that the current (trace *B*) lags the welder voltage (trace *C*). That is, this oscillogram demonstrates the current and voltage relations in both the power-factor-corrected welder (traces *A* and *B*) and the conventional welder (traces *B* and *C*). The calibration of the voltage traces on this oscillogram are all approximately equal so that their magnitudes and the correction ratio may be determined by comparing their relative size.

For purposes of comparison, let the correction ratio be defined as follows:

$$\text{Correction ratio} = \frac{\text{peak kva demand of welder}}{\text{peak kva supplied by line}}$$

The correction ratio, as thus defined, is not a complete measure of the beneficial effects of power-factor correction since, in addition to the lower kilovolt-ampere demand on the line required to make a given weld, the line is supplying this smaller demand at essentially unity power factor so that the voltage drop in the supply system is further reduced.

In the particular case shown in figure 8 the welder was used as an interrupted spot welder welding two pieces of iron each one-quarter inch thick. The welder power factor was 41.5 per cent lagging and the welder demand was 434 kva. The line power factor was essentially unity (99.5 per cent leading) and the line demand 181 kva or a correction ratio of 2.4, with a power factor improvement from 41.5 per cent lagging to essentially unity.

It should be observed that the current of figure 8 contains no transient and the capacitor retains its charge during the off interval. Further, it should be noted that the magnitude and polarity of the residual charge on the capacitor is left exactly correct so that the next spot begins with no transient. This is due to the fact that the control is arranged for unipolar starting, and also for an even number of half cycles or an integral number of

Figure 1. Shunt-capacitor power-factor-correction circuit

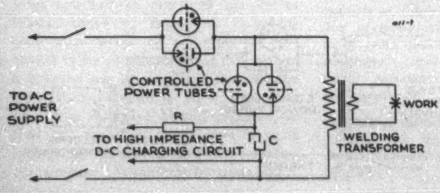

Figure 2. Series-capacitor power-factor-correction circuit

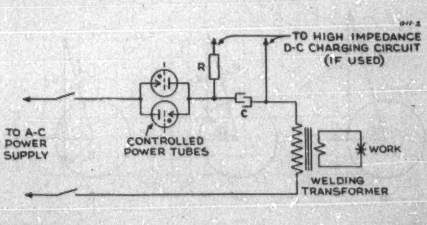


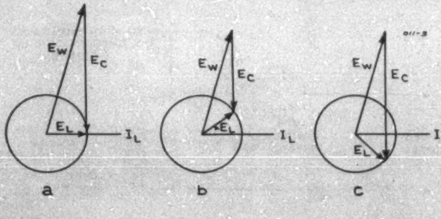
cycles per spot. No precharging circuit was used in this case, the correct capacitor precharge having been established by the preceding spot. Consequently, where a precharging circuit is used, it would have no function after the first spot other than to supply a small leakage current to the capacitor. When it is desired to use an odd number of half cycles per spot, antipolar starting can be used with perfect results, with no precharging circuit.

Figure 9 shows a case of overcorrection where the circuit was corrected to a leading power factor. In this case the welder power factor was 36.6 per cent lagging and the corrected power factor at the supply line was 85.7 per cent leading. It is of particular interest to note that in this case the line voltage shows a slight rise when the welder load comes on. This is due to the fact that when a leading current is drawn from an inductive feeder or supply, there is a rise in terminal voltage. It can be readily seen that if the current is made sufficiently leading to overcome the *IR* drop in an inductive feeder there will be a voltage rise under load. This is a very significant result in that it indicates that the troublesome "flicker" problem and regulation problems caused by resistance-welding machines can be greatly reduced or in some cases eliminated entirely.

Figure 10 shows an interrupted spot weld where no precharge was applied to the capacitor. It will be observed that the initial charging transient current is small, rather than large as would be the case with shunt capacitors. After one cycle the current is substantially up to normal. In a long spot or interrupted spot weld this smaller current during the first cycle makes no significant difference in the total heat delivered to the weld, and consequently for such welds no precharging circuit need be used. The reason for the lack of inrush current on the discharged capacitor is due to the fact that the welder impedance is in series with the capacitor. Furthermore, the driving voltage available on the welding transformer is small until the capacitor charge has built up to its correct value.

Figure 3. Vector voltage relations in series-capacitor power-factor-corrected circuit

I_L—Line current
E_L—Line voltage
E_W—Welder primary voltage
E_C—Capacitor voltage



For short welds, such as from one to ten cycles duration, it is recommended that either a precharging circuit be used or that the first weld be made on scrap stock to obtain the proper charge on the capacitor. Once this charge is established, the welder will immediately give uniform welds, and the charge will automatically be left on the capacitor of the correct polarity and magnitude for the next spot as previously explained.

Figure 10 also demonstrates the use of the phase-control method of reducing current on a power-factor-corrected welding machine, as indicated by the gaps in the current and voltage traces. This method of current control will be discussed under "Methods of Current Control".

Methods of Current Control

There are a variety of methods of current control applicable to power-factor-corrected welding machines. Current control is of utmost importance in resistance welding, since it governs the rate of generation of heat at the weld. The methods may be classified as follows:

1. Phase control
2. Variable-voltage supply
   - (*a*). Tapped autotransformer on supply circuit
   - (*b*). Induction regulator on supply circuit
   - (*c*). Field control on supply generator (if used)
3. Variable reflected resistance at resonance
   - (*a*). Simultaneous switching of taps on welding transformer and capacitor bank
4. Dissonance regulation
   - (*a*). Taps on welding transformer
   - (*b*). Taps on capacitor bank
   - (*c*). Frequency control
5. Variable primary resistor (practical only on small welders)

These methods will be discussed in the order listed above.

1. Phase Control Method of Current Regulation

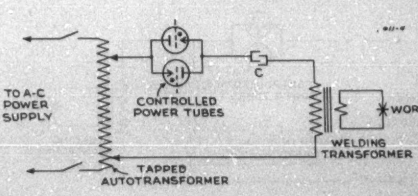
This method is applicable to power-factor-corrected resistance-welding machines in the same manner as it is applied to the uncorrected thyratron-controlled machines. It differs slightly in that for complete control, the phase-shift network must be adjusted to shift over 180 electrical degrees of the supply voltage, whereas in the conventional welder control, complete control is obtained by shifting over a span of 180-β electrical degrees where β is the power-factor angle of the circuit.

It should be pointed out that "power factor" and "kilovolt-amperes" no longer have the same significance for chopped waves that they carry for full waves. To obtain the fullest possible benefit from the capacitors, it is preferable to operate at full wave, although the correction ratio, as previously defined, holds up well for phase-controlled waves. For very low-phase-controlled currents where the correction ratio diminishes, the current is so small that the regulation problem is not important.

Figure 11 shows the results of phase control on a power-factor-corrected welding machine. It should again be observed that the capacitor automatically arrives at the proper precharge for this phase-controlled condition in the same manner as it did for the full-wave case.

In the case of an inductive feeder, the reactance drop, Ldi/dt, is caused by the rate of change of current. In the case of a full-wave welder corrected to unity power factor, the maximum rate of change of current occurs when the supply line voltage is zero, and the rate of change of current is zero when the voltage is at its crest, consequently the feeder regulation drop is small. If, however, in this same circuit, the starting point of each current wave is delayed 90 electrical degrees by means of phase control, the maximum rate of change of current will occur at the crest of the voltage wave and consequently a

Figure 4. Variable-voltage supply circuit for series-capacitor power-factor-corrected resistance-welding-machine circuit



reactance regulation drop will appear. Ordinarily this is not troublesome, however, since the kilovolt-amperes are greatly reduced at the lower currents and further reduced by the correction ratio. Delay of the point of ignition by phase control (reduction of welding current) may be considered as a reduction of power factor, since it introduces higher harmonics in the current wave. For these higher harmonics the circuit is no longer tuned to resonance, as the inductive reactance $(2\pi fL)$ increases while the capacitative reactance $(1/2\pi fC)$ decreases.

When any welder is operating with phase control, the peak current demand on the line is greater than for a full-wave welder making the same weld. However, in the full-wave condition where the demand is maximum, the peak current required is the same, since it is full wave for both cases. Consequently, where it is desired to minimize peak current load on the supply for the maximum current setting of the machine, there is no disadvantage in using phase control. However, in cases where it is desired to minimize the peak current on the supply system at all times, and especially under reduced current conditions, it is necessary to use full wave. Where many welders are operating simultaneously on a high production schedule, at currents considerably reduced from the maximum possible per machine, substantial saving in peak current demand can be effected by using full wave on all machines.

It should be emphasized that the simple vector diagram applicable to the full-wave case is not applicable to the phase-controlled case, except for determining maximum voltages and currents which can exist in the full-wave condition.

2. Variable-Voltage-Supply Method of Current Regulation

The variable-voltage supply in the form of a tapped autotransformer located ahead of the power tubes, as shown in figure 4, makes an ideal method of control for a power-factor-corrected welder. If desired, phase control may be used in addition for finer adjustment between coarse taps. Such an autotransformer is relatively small because it handles only from one-half to one-third the welder kilovolt-amperes, depending upon the correction ratio. In addition, the fact that it is an autotransformer rather than a transformer again diminishes its size by a factor of two or more, depending upon the range of control required, so that the resulting transformer is small indeed as compared with the welding transformer. It would be from one-half to one-third the size of the autotransformer used with a conventional welding transformer where they are furnished. This method is advantageous in that the welding machine may be made to operate at unity power factor (as far as the supply line is concerned) and with full wave at all currents, thereby minimizing regulation and peak currents on the supply line, and making fullest use of the capacitors at all times. The capacitor precharging circuit, not shown in figure 4, may be used if desired.

Other sources of variable-voltage supply mentioned operate in essentially the same manner. Where a rotating machine is used, a much smaller size machine can be used for a given welder; or a given rotating machine will supply a much larger welding machine where power factor correction is applied.

3. Variable Reflected Resistance at Resonance Method of Current Regulation

The resistance of the work, referred to the primary of the welding transformer, is proportional to the square of the turn ratio. For the full-wave resonant condition, the current is limited only by the resistance of the circuit. Assuming a constant line voltage, and that the circuit is tuned to resonance in each case, it is possible to vary the current to the work by changing the turn ratio and switching the capacitor to maintain resonance. Consider the full-wave case (without phase control). If for a given piece of work the turn ratio is doubled, and the capacitor changed by switching to again tune the circuit to resonance, the primary current will be approximately one-fourth of its former value, and the secondary current will be approximately one-half its former value since the turn ratio is doubled. The primary voltage will remain essentially constant since the current has decreased to one-fourth and the impedance has increased by a factor of four.

The effect of variable reflected resistance on the current in a series-capacitor power-factor-corrected resistance-welding machine of any power factor is the same as for the case of $\phi = 1.00$ on figures 6 and 7. The disadvantage of this method of current control is that it requires switching of both the capacitor and welding transformer.

4. Dissonance Regulation of Current

The maximum response of a series tuned circuit occurs at resonance. If the circuit is detuned either by changing the inductance, capacity, or applied frequency, the response can be markedly changed as indicated by the curves shown in figure 5, which illustrate the effect of change of inductance in a simple series circuit operating on full wave. Similar curves may be made for detuning by taps on the capacitor or by frequency control. Analogous conditions exist in an actual welding-transformer circuit with power-factor correction by series capacitors, except that the reflected impedance changes with the tap setting rather than remaining constant, as in the simple *RLC* circuit characteristics shown in figure 5. It should be observed that the resonance peaks become sharper at the lower power factors and the tuning is therefore more critical. For power factors of 20 per cent to 40 per cent, which are typical of welding machines, the resonance peaks are sufficiently broad so that tuning is not difficult.

Figures 6 and 7 show the effect of changing taps (turn ratio) in a welding-transformer circuit in which the capacitor has been adjusted for unity power factor on the highest current tap. The effects of primary resistance, magnetizing reactance, and leakage reactance have been omitted from these curves for simplicity. Their effect will be to modify the curves slightly from the values shown for an ideal transformer. These curves are drawn for

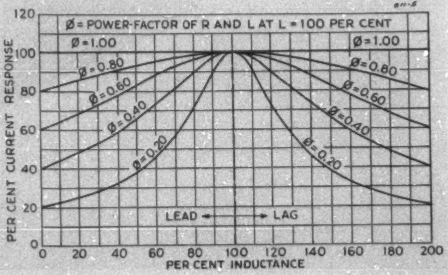


Figure 5. Current response as a function of inductance for a series circuit containing resistance, inductance, and capacitance

Resistance, applied voltage, and frequency maintained constant

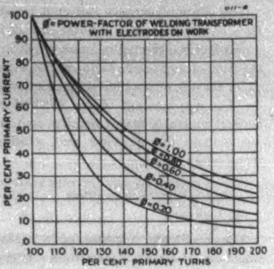

Figure 6. Primary current variation with change of turn ratio

Capacitor adjusted for unity line power factor at 100 per cent turns

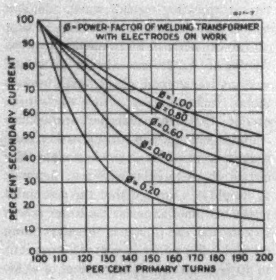

Figure 7. Secondary-current variation with change of turn ratio

Capacitor adjusted for unity power factor with 100 per cent turns

the full-wave condition. It should be noted that the current response variation is greater at lower power factors, as would be expected from the greater sharpness of the resonance curves. It is interesting to note that the curves labeled $\phi = 1.00$ on figures 6 and 7 also represent approximately the current response in an uncorrected welding machine of any power factor, as the primary winding is changed by taps.

In this dissonance method of current control the feeder is not operating at unity power factor, except at one point; consequently the capacitors are not used to best advantage. Furthermore, taps would have to be considerably smaller increments than on the conventional welder to give the same degree of control, particularly on low-power-factor welders—see figures 6 and 7. Where taps on the welding transformer alone are used, the capacitor should be adjusted to give unity power factor, and consequently minimum kilovolt-amperes, on the highest heat tap, where it is most needed.

5. Variable Primary Resistor

The current in a unity-power-factor-corrected welding machine is limited only by the resistance of the circuit, which includes the primary resistance and also the secondary resistance and resistance of the work referred to the primary side. Therefore, by adjusting an auxiliary series variable resistor placed in the primary circuit, control of the current can be readily obtained. This has the further advantage that the additional resistance acts as ballast and consequently the current is less affected by changes in resistance of the work. Because of the additional power loss in the auxiliary resistor, this method of current adjustment is recommended only for small machines or for large welders operating on very low duty cycles.

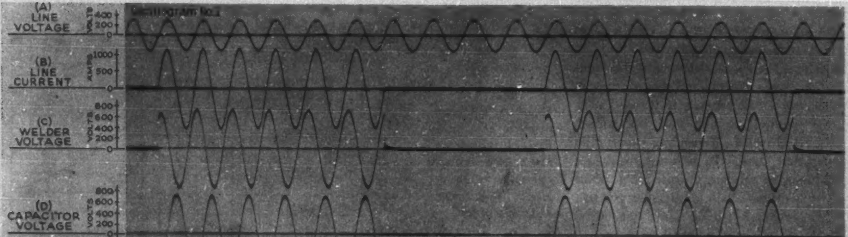
Use With Nonsynchronous Control

Series-capacitor power-factor correction of resistance-welding machines is not limited to use with synchronous control by any means. In fact, this type of power-factor correction has another outstanding advantage when used with nonsynchronous control, such as magnetic contactor control of a resistance-welding machine.

Figure 12 shows portions of an oscillogram taken on a high-speed nonsynchronous contactor making an interrupted spot weld on a conventional resistance-welding machine. Note the excessive primary transients due to unsymmetrical magnetization of the core and cumulative d-c components. It is interesting to note that the high peaks due to magnetizing transient primary current do not appear in the secondary. The line voltage is shown reversed in phase from its normal position on this oscillogram.

Figure 13 presents portions of an oscillogram taken on this same nonsynchronous control and welding transformer, operating at approximately the same welding-transformer voltage, but with series-capacitor power-factor correction. It shows the absence of large transients because of the suppression of any d-c component by means of the capacitor which acts as a blocking capacitor for any d-c component which may be caused by random starting, or inaccurate timing, or both. On this oscillogram, trace *A* is the line voltage, trace *B* the line or welding-transformer current, trace *C* the welding-transformer voltage, and trace *D* the capacitor voltage. Note that the first half cycle of current may be smaller or equal to the steady-state current but is never larger. Thus, the series capacitor not only permits use of a nonsynchronous control without excessive transients when used as an interrupted spot welder, but it also provides power-factor correction, diminishing the feeder kilovolt-ampere requirements, regulation drop, and all of the other attendant advantages of lower kilovolt-ampere demand, high-power-factor operation. It also results in much less severe duty on the welding trans-

Figure 8



former and contactor, thereby augmenting the life of both.

The fact that the current may be smaller than normal for the first cycle may not be a serious disadvantage on relatively long spots on heavy work, because this possibility may be allowed for by increasing the spot length by one cycle longer than that otherwise required. In addition to the excessive primary transients with nonsynchronous control and without power-factor correction, the secondary current may be an offset wave increasing the heat abnormally on the first few cycles, possibly resulting in burned work, splashing, high electrode maintenance, etc.

Series capacitors are applicable, therefore, for power-factor correction and surge suppression on many highly intermittent low-power-factor loads. It is expected that they will find many applications. A few of the possibilities are as follows:

Resistance spot, interrupted spot, seam welders, etc.
Flash, butt, and projection welders
Electric arc furnaces

Characteristics of the Unity-Power-Factor Welder Using Series Capacitors

There are several points of difference in characteristics of a resistance-welding machine operating with a series tuned capacitor for power-factor correction, as compared with a resistance welder operating from a constant-potential bus. Some of these differences are advantageous, others are merely points of difference which may or may not be advantageous, depending upon the type of work involved. It is not claimed that this method is applicable to all resistance-welding jobs, although our experience indicates that it is applicable to many of them.

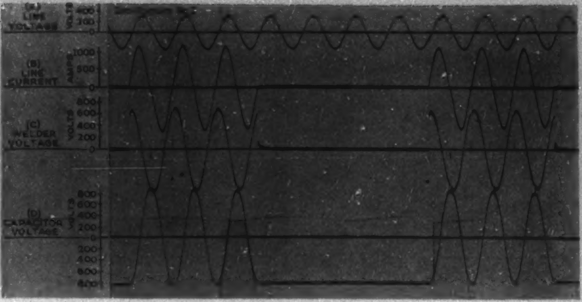


Figure 9

1. Requires less kilovolt-amperes from feeder and at higher power factor, thus improving regulation, diminishing peak demand, and permitting use of more or larger welders from a given supply. The above reasons are the principle justifications for use of this type of power-factor correction. In many instances they are vital factors in determining whether or not resistance welding should be used.

2. Current to welder is essentially resistance limited. Generally speaking, therefore, this type of machine will be subject to greater current variations with changes in resistance of the work than is the conventional low-power-factor machine which is reactance limited. As a consequence of this, low-resistance alloys and materials such as aluminum automatically draw more current than the same thickness of iron for the same voltage. However, more current is required for aluminum, hence a smaller change in circuit adjustment is required to change from welding iron to welding aluminum than would be required for a conventional machine.

3. Small changes of inductance such as might be caused by the presence of iron in the throat of the machine have less effect on the current in a power-factor-corrected welder than a conventional welder. This is because the conventional welder is reactance limited, while the power-factor-corrected welder is resistance limited. This condition exists only as long as the changes of inductance are small enough so that the circuit remains substantially in resonance.

4. Where a precharge circuit is not used and it is desired to make short, accurate spots, one spot on scrap stock should be made to establish the correct capacitor precharge.

5. The open-circuit voltage of the welding transformer cannot be measured by applying power through the series capacitor with the secondary open because the circuit is so far detuned that the current and voltage will be much smaller than exist under load conditions.

6. A phase-controlled power-factor-corrected welder using narrow-peak firing and not equipped with a precharge circuit will not fire the first spot with the capacitors discharged if the phase-control dial is set in the full-wave position. This is because there is no voltage on the starters of the tubes in the full-wave setting, since the peaks occur at the zero point of the voltage wave for full heat at unity power factor.

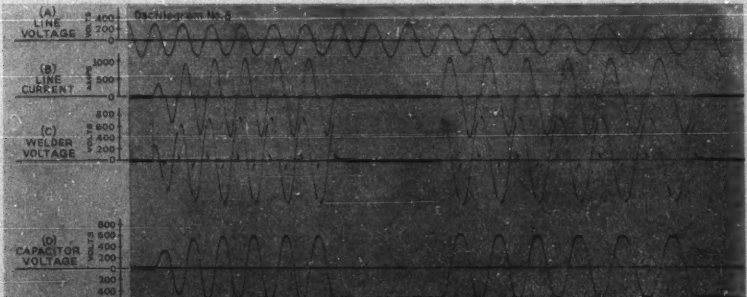

Figure 10

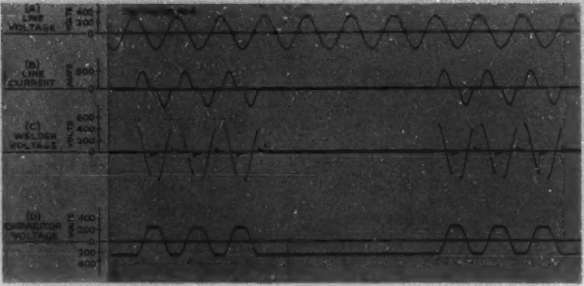

Figure 11

Where a precharging circuit is used, the capacitor voltage is adequate to start the ignitrons. Where such a circuit is not used, an initial charge is readily established by setting the phase control to a lower current and making one spot on scrap stock. The phase control can then be returned to the full-wave position and a second spot made to establish full charge if required. Where sine-wave turn-on voltage is used on the control grids this condition does not arise, since the first tube is maintained open until the voltage reaches the ignition value.

7. The capacitor bank should be equipped with a suitable discharge resistor and contactor which closes on de-energization of the line, discharging the capacitors within a few seconds to a low voltage. This discharge time may be made as short as desired by properly selecting the discharge resistor and contactor. The discharge circuit and interlocking relay, as well as timing circuit details, are not shown on the simplified diagrams.

8. Since the power-factor-corrected welder is essentially a tuned filter when operating on full wave, any distortion in the supply-voltage wave does not result in a corresponding distortion of the current wave. Instead it remains essentially sinusoidal, thereby tending to improve the current wave shape on the system.

9. When used with nonsynchronous control on resistance-welding machines, series-capacitor power-factor correction eliminates destructive high-current transients and makes practical interrupted spot welding with nonsynchronous control.

10. For small or moderate changes in throat of the resistance-welding machine no change in capacitor bank need be made, the change in reactance merely resulting in a change in the line power factor. A compromise capacitor is selected so that the power factor remains near unity. For large changes in throat depth, exceeding $1^1/_2$ to one, the capacitor or welding-transformer primary may be switched as required to maintain good power-factor correction.

11. Machines having extremely deep throats may be built for power-factor correction and such machines will require only slightly more energy from the line than a shallow-throat machine making the same weld. The reactance is entirely cancelled out by the capacitors, hence the increase in power required is due only to the increased resistance of the long throat.

12. The change of power factor occasioned by welding materials of different resistivity and the same permeability does not require any changes in the capacitor tuning, since the inductance is fixed by the geometry of the welder and the permeability of the surrounding media. Changes in resistance of the work result only in changes of current. The line power factor is not appreciably affected. Where the permeability changes, slight changes in tuning will result. Usually the changes are not great enough to require any change in circuit constants.

13. On all machines it is recommended that the transformer and capacitor be designed to withstand the highest voltage which can occur if the operator closes the jaws directly together without having any work inserted between them. In extremely low-power-factor welding machines where this does not result in an economical design, it is recommended that means be provided for limiting the voltage to safe values. The circuit may be detuned leading enough to limit excessive voltages on direct short circuit. However, this limits the maximum response under load. Detuning caused by saturation of the welding transformer may also be made to limit extreme values. Overvoltage or overcurrent trips may in some instances provide ample protection. Where overvoltage trips are provided, they should be located across the welding transformer rather than the capacitor, to avoid leakage of charge from the capacitor. Limitation of voltage on the welding transformer will also limit the voltage on the capacitor.

14. Series-capacitor power-factor correction has the following advantages as compared with rotating machinery:

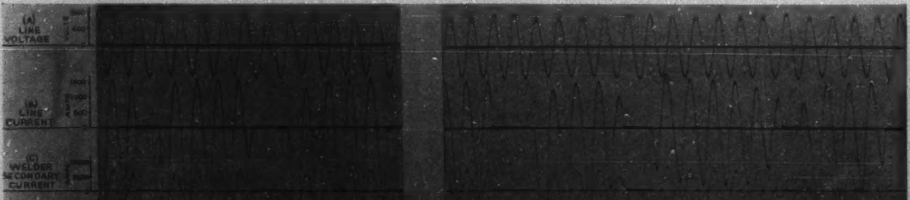
1. Lower initial cost
2. Quietness of operation
3. Low standby loss
4. Less maintenance
5. Less floor space required

15. When phase control is used as a means of current regulation on a series-capacitor power-factor-corrected resistance-welding machine, it is preferable to correct the circuit to unity power factor. Correction to a leading power factor usually results first in a slight increase of rms current as the phase control is retarded from the full-wave position until the zero point of the voltage wave is reached. Beyond this point the rms current decreases in the usual manner as the phase control is further retarded. For this reason there is usually no advantage in correcting beyond unity power factor (to a leading power factor) when phase control is to be used.

Disadvantages of Series-Capacitor Power-Factor Correction as Applied to Resistance-Welding Machines

The advantages and disadvantages of any system depend upon the job it has to do and what it is being compared with. In some cases it will be more economical to install a heavier feeder than to apply power factor correction. In other cases the power factor correction can be justi-

Figure 12



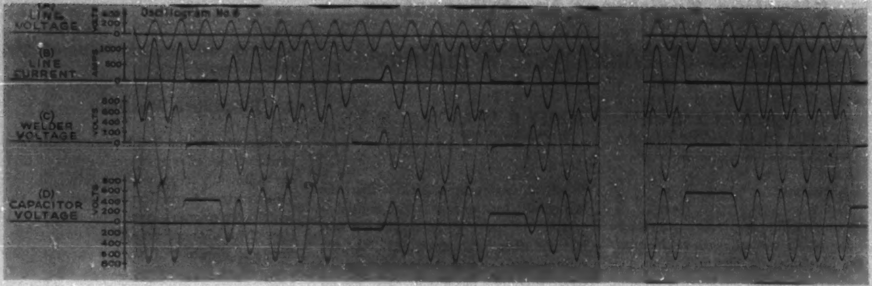


Figure 13

fied economically. The cost trend of capacitors is downward and even at the present level is considerably lower than motor generator sets. The relative sensitivity to resistance changes of this welder as compared with the conventional welder may be disadvantageous on some classes of work.

Installation on Existing Welders and Control

Where it is desired to install series power-factor correction on existing welders and control, it is necessary to lower the feeder voltage or increase the welding-transformer voltage as required by the particular job. Generally speaking, it is preferable to step down the supply voltage since this will require less change in the control, except in cases where the feeder voltage would be reduced below a practical value for synchronous control, in which case it would be preferable to increase the welding-transformer voltage. Where synchronous (electronic) control is used, modification of the phase-shift network, and in some cases modification of the tube bias voltages, may be required.

The greatest correction ratio is obtained on the lowest-power-factor machine. Machines having a power factor of 50 per cent or less, which are in the majority, will show a correction ratio of two or more in kilovolt-ampere demand, and thus will show large demand kilovolt-ampere savings. If the power factor is high to begin with, the savings are less and power factor correction may not be justified.

The application to nonsynchronous control is relatively simple, requiring only the installation of the capacitor together with a contactor and discharge resistor, and a suitable lower-voltage feeder. In any case, however, the capacitor bank and feeder voltages must be properly tailored for the job, otherwise dangerous voltages and damage to the equipment may result.

The floor space occupied by the capacitor is usually less than that required by the welding machine. Frequently floor space is not available, in which case the capacitor may be wall mounted or placed outdoors by using an outdoor type capacitor. It is not essential that it be located adjacent to the control or welder, but the closer it is the less wiring expense will be involved.

Conclusions

This investigation demonstrates the feasibility of series-capacitor power-factor correction of highly intermittent low-power-factor loads, such as resistance-welding machines with either synchronous or nonsynchronous control. By correcting the power factor, the load on the power-supply system is greatly reduced in magnitude as well as being corrected in power factor. This will minimize regulation and "flicker" problems and thereby reduce the opposition of power companies to the installation of such machines.

This method of power factor correction will promote the use of large, deep-throat welding machines previously considered impractical because of the excessive kilovolt-ampere demand. With power-factor correction, deep-throat machines will require only slightly more demand from the system than shallow-throat machines making the same weld.

The method is applicable to many resistance-welding jobs. It will benefit the user by lowering his peak kilovolt-ampere demand in cases where he is paying a penalty for high peak demand, and will benefit the power companies by minimizing disturbances on their lines caused by resistance-welding-machine loads. It will therefore broaden the field of resistance welding with both synchronous and nonsynchronous control.

Discussion

For discussion, see page 1102.

Effective Resistance to Alternating Currents of Multilayer Windings

EDWARD BENNETT
FELLOW AIEE

SIDNEY C. LARSON
ASSOCIATE AIEE

1. Purpose

In any multilayer winding carrying an alternating current, such as the windings illustrated in figures 1, 2, and 3, each layer of copper lies in the alternating magnetic field set up by the current in all the other layers. Eddy currents are set up in each layer in a direction to partly neutralize the magnetic intensities in the interior of the copper wire in each layer. As a result of the eddy-current losses in the copper, the *effective* resistance of the winding to the alternating current it carries may be many times its resistance to continuous currents.

In a general consideration of these eddy-current losses, it is enlightening to think of the losses in any layer as the result of the superposition of two distributions of current densities. The first distribution of current densities in any layer, n, is that which is to be attributed to the magnetic flux set up within the copper of layer n by the current in layer n itself. It is the only distribution in single-layer windings, except as noted in the footnote,* and may be called the *skin effect* distribution.

The second superposed distribution in layer n is that distribution of eddy currents which is to be attributed to the magnetic flux set up within the copper of layer n by the alternating current in all the other layers of the winding. It may be called the *multilayer effect* distribution. In windings having many layers, the loss caused by this second distribution is many times greater than the loss caused by the first. The contribution of this paper is the derivation and interpretation of expressions for the current densities and the losses in multilayer windings in which this second effect occurs.

Since the submission of the manuscript, the attention of the authors has been called to the papers[1–4] dealing with losses in multilayer a-c slot-wound armature coils by A. B. Field, Waldo V. Lyon, A. E. Gilman, and H. W. Taylor. The arrangement treated in these papers is illustrated in figure 10, which shows the cross section of the multilayered copper winding in an armature slot. If by suitable connection the layers each carry the same current, the distribution of the magnetic intensities in the space occupied by the coil will be illustrated by the heights from the zero line MM to the broken line marked H. The lines of magnetic intensity extending from face to face of the slot are substantially straight, and the effective permeability of the space occupied by the coil is substantially equal to $\mu w/s$. The differential equations taken to apply to the system illustrated in figure 10 are identical with the equations used by the authors as applicable to figures 1, 2, and 3.

The end formulas of this paper and of the papers (by the first three writers) dealing with the slot-wound conductors, that is, the formulas for computing the loss in the nth layer, can be transformed into identical forms.

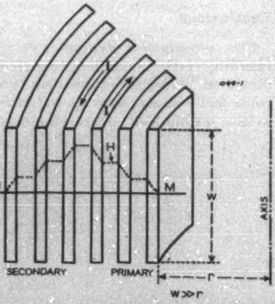

Figure 1. The distribution of the magnetic intensities in the multilayer primary and secondary of a transformer

2. Illustrative Windings

Figures 1, 2, and 3 illustrate windings in which these effects occur and to which the following treatment applies. Figure 1 illustrates an axial cross section of the multilayer primary and secondary windings of an air-core or an iron-core transformer. Figure 2 illustrates the outgoing and return conductors of bus bars each built up of transposed copper laminae (the transpositions of the laminae are now shown). It may also be taken to represent a multilayer solenoid. Figure 3 represents an outgoing bus bar built up of transposed laminations, which bus bar is remote from the return bus bar. (Neither the transpositions of the laminae nor the return bus bar are shown.)

On each of these figures the heights of the ordinates from the zero line MM to the broken line marked H_0 indicate the relative values of the magnetic intensities which would exist at and normal to the central plane MM if the current density, C, in the conductors were uniform over their entire cross section.

3. Notation

In the appendix will be found the derivation of the expressions for the current densities and the power losses in windings or structures which may be represented by figure 2. This figure may be thought of as illustrating the outgoing conductor A and the return conductor B of a bus bar, each conductor consisting of three thin wide copper *laminae* (one end of the structure and the transpositions of the laminae relative to each other are not shown). Or the figure may be thought of as representing two sides of a three-layer solenoid.

In the following discussion, the terms *winding*, *layer*, and *lamina* have the following meanings. The term *winding* designates the entire electrically conducting path between two specified terminals. The *winding* is in the form of *layers* of round, rectangular, strap, or sheet conductors. The *layers* are designated 1, 2, 3, 4, etc. The numbering starts with the layer in the region of lowest magnetic flux density and ends with the layer in the region of highest flux density.

A multilayered winding is regarded as made up of two or more *laminae* which in some cases are connected in series and

Paper 40-99, recommended by the AIEE committee on electrical machinery, and presented at the AIEE summer convention, Swampscott, Mass., June 24–28, 1940. Manuscript submitted October 16, 1939; made available for preprinting April 23, 1940.

Edward Bennett is professor and chairman of the department of electrical engineering, University of Wisconsin, Madison; Sidney C. Larson is engineer, General Electric X-Ray Corporation, Chicago, Ill.

[1] For all numbered references, see list at end of paper.

*Superposed upon the two eddy-current distributions described above, there is a third distribution to be attributed to the nonaxial component of the flux density in the copper near the edges of the layers. This causes the loss at and near the edges of the layers to exceed the loss over their mid portions. It may be called the *end effect* distribution. This effect is not treated in this paper. The equations herein derived do not apply close to the ends of the layers.

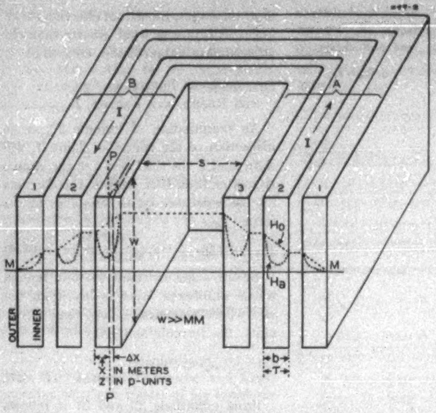

Figure 2. The distribution of the magnetic intensities in two adjacent multilayer bus bars, or in a solenoid

in other cases in parallel between the two terminals. If the *laminae* are to be connected only in series, then *lamina a* may be taken as occupying *layer* 1, *lamina b* as occupying *layer* 2, etc. But if the *laminae* of the winding are to be connected in parallel between the terminals, and if the total alternating current through the winding is to divide equally among the laminae, then the laminae must be so transposed relative to each other that each of the k laminae occupies $1/k$th of the length of each and every layer of the winding.

The equations are derived for the idealized case in which the width w of the layers or laminae is so large in comparison with the distance (MM) that the magnetic intensity normal to the mid plane MM may be taken to be zero on the outer face of layer 1, and nI/w on the inner face of layer n. Under these conditions, the distribution of the magnetic intensities normal to the plane MM will be shown by the line H_0 (figure 2) if the winding carries a continuous current, and will be typified by the line H_a if the winding carries an alternating current.

All symbols represent the values of the symbolized quantities when expressed in units of the meter–kilogram–second system, except where otherwise noted. Capital letters in bold-face type are complex quantities representing the rms value and the phase position of the sinusoidal variable symbolized.

Definitions of Symbols

IMPRESSED QUANTITIES

$\mathbf{E}_1$—rms value (in volts) of the electromotive force impressed upon the loop containing a given lamina
I—rms value of the current (in amperes) in each lamina
f—frequency of the sinusoidally varying quantities in cycles per second

INDEPENDENT VARIABLES

x—distance (in meters) from the outer face (that is, the face at the lower flux density) of any lamina to the plane PP, which is any plane in the same lamina lying parallel to its outer face
z—same distance as above but expressed in p-units (see below)

DEPENDENT VARIABLES

$\mathbf{B}$—rms value of the flux density (webers per square meter) at the plane PP
$\mathbf{C}$—rms value of the current density (amperes per square meter) at the plane PP
$\mathbf{E}$—rms value of the electromotive force of inductance in the loop containing the filaments of the plane PP
$\mathbf{H}$—rms value of the magnetic intensity (in ampere turns per meter) at the plane PP

CONSTANTS OF THE LAMINAE

γ—conductivity of the conducting lamina (in mho-meters)
μ—magnetic permeability of the lamina, $\mu = 4\pi\ 10^{-7}$ for nonferromagnetic materials
w—width of a lamina (in meters)
l—length of a lamina (in meters)
b—thickness of a lamina (in meters)
τ—thickness of a lamina when expressed in p-units. $\tau = b/p$
n—number of the layer and the lamina occupying it. Number 1 is in the region of lowest flux density
R_{nf}—effective resistance of lamina n to the frequency f
P_n—power loss in lamina n
$F_{n\tau}$—*resistance factor*, that is, ratio of the effective a-c resistance of lamina n with a thickness of τ p-units to the d-c resistance of a sheet of the same length, width, and conductivity but having a thickness of 1 p-unit
p—$1/\sqrt{\pi f \gamma \mu}$ meters (see below)

THE PENETRATION UNIT (OR p-UNIT) OF LENGTH

It is shown in section 8 of the appendix that the expressions for the distribution of current density and for the effective resistance of the laminae may be thrown into more elegant and significant forms if *the distance from the face of the lamina to any plane in its interior* is expressed, not in meters, but in terms of a unit of length which may be called the "*penetration unit* (or p-unit) of length of the material at the frequency f." The length of this unit in meters is the value of a constant $p = 1/\sqrt{\pi f \gamma \mu}$ which appears in the differential equations. The values of the p-unit for copper of conductivity $\gamma = 5.8 \times 10^7$ mho-meters for a few frequencies are:

Cycles Per Second	p-Unit (Cm)
60	0.86
1,000	0.200
5,000	0.004
1,000,000	0.0066

4. Effective Resistance of the Lamina

In section 10 of the appendix it is shown that the effective resistance to an alternating current of lamina n of the multilayer structure or winding of figure 2 may be obtained most conveniently from the formula,

$$R_{nf}(\text{ohms}) = F_{n\tau} \frac{l}{wp\gamma} \tag{28}$$

The effective resistance of all the lamina connected in series or in parallel may be

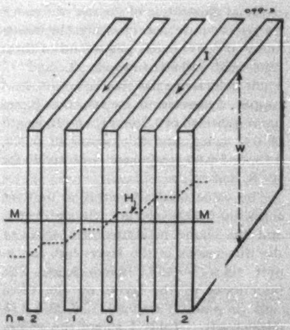

Figure 3. The distribution of the magnetic intensities in a single multilayer bus bar

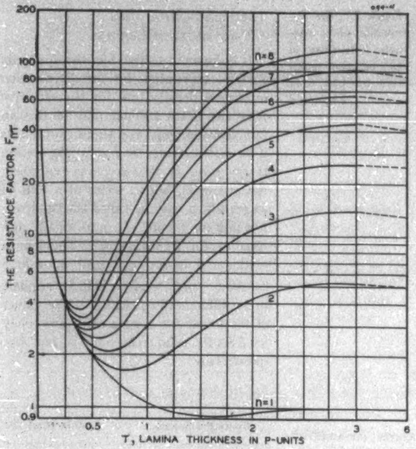

Figure 4. Resistance factor, $F_{n\tau}$ versus lamina thickness, τ in $R_{nl}=F_{n\tau}\frac{l}{wp\gamma}$

obtained by the summations (30) or (31) of the appendix.

In formula 28, the factor $l/(wp\gamma)$ is the readily computed ohmic resistance of a sheet of the lamina material having the same length and width as the lamina but a thickness equal to the penetration unit p of the material. The $F_{n\tau}$ *resistance factor* in (28) is a function of two variables, namely, the numbered position, n, and the thickness, τ, of the lamina. The value of the $F_{n\tau}$ factor may be computed from formula 29 or it may be read off from the curves of figure 4.

$$F_{n\tau}=\left[(2n^2-2n+1)\frac{\sinh 2\tau+\sin 2\tau}{\cosh 2\tau-\cos 2\tau}-(4n^2-4n)\frac{\cos\tau\sinh\tau+\sin\tau\cosh\tau}{\cosh 2\tau-\cos 2\tau}\right] \quad (29)$$

As an illustration of the use of figure 4 let us compute and compare the resistances at 5,000 cycles per second of three solenoidal inductances, A, B, and C. Each inductance has five layers of sheet copper connected in series, the layers having a width of 0.8 meter, a mean length of 0.6 meter, and thicknesses of 0.065, 0.13, and 0.26 centimeter respectively for A, B, and C.

The value of the penetration unit for copper at 5,000 cycles is 0.094 centimeter, and the ohmic resistance of a sheet of the dimensions of the layers but one p-unit thick is 13.75 micro-ohms. The thicknesses of the layers on the three coils (in p-units) are 0.69, 1.38, and 2.76 respectively. Table I shows the values of the $F_{n\tau}$ factors read from the curves of figure 4 for these three values of τ.

Table I. Values of $F_{n\tau}$ for Three Windings

Layer	Winding A $\tau=0.69$	B 1.38	C 2.76
1	1.5	0.92	1
2	1.7	2.5	5.2
3	2.1	5.6	15
4	2.7	10	26
5	3.7	16	44
$\Sigma F_{n\tau}=$	11.7	35.0	91.2
Resistances (micro-ohms)			
A-c	160	475	1,250
D-c	100	50	25
Ratio a-c to d-c	1.6	9.5	50

The high losses in the layers of the heavier copper lying in the strong magnetic field are strikingly shown in the last column of this table and by the curves of figure 4.

If the above coils, instead of being wound with sheet copper giving one wide turn per layer, had been wound with rectangular strap copper of the same thicknesses as above but yielding N turns in a layer of the same width, all the resistances for the strap-wound coils would be N^2 times the resistances in table I. (This makes no allowance for the space required for insulation between turns.)

THE EDGE EFFECT

As explained in the footnote to section 1, the current densities are higher near the edges of the layers than over the wide mid portion. Since the formulas and curves for the $F_{n\tau}$ resistance factor assume no increase in current density near the edges, the actual effective resistances will be somewhat greater than the approximate values herein computed.

APPROXIMATE FORMULAS FOR THE RESISTANCE FACTOR, $F_{n\tau}$

An examination of formula 29, or an inspection of the curves of figure 4, will show that if the thickness τ of the lamina is greater than four p-units, the formula for the resistance factor simplifies to the form,

$$F_{n\tau}=n^2+(n-1)^2 \text{ (approximate for } \tau>4) \quad (36)$$

At the other extreme, for any lamina whose numbered layer is less than ten and whose thickness is less than 0.2 p-units, the formula simplifies to,

$$F_{n\tau}=1/\tau \text{ (approximate) for } n<10 \text{ and } \tau<0.2 \quad (37)$$

From equations 33 and 37 it follows that for $n<10$ and $\tau<0.2$, the a-c resistance of the lamina is equal to its d-c resistance.

OPTIMUM THICKNESSES OF THE LAMINA

An inspection of the curves for the resistance factors figure 4 shows that the effective resistances of the laminae reach minimum values for specific lamina thicknesses. The thicknesses required to obtain minimum loss become smaller as the numbered position of the lamina becomes larger, that is, as the lamina is taken in stronger and stronger magnetic fields.

Let the thickness for which the effective resistance of lamina n is a minimum be called its *optimum thickness*, and let it be represented by τ_{no}. The formula for computing the value of τ_{no} may be

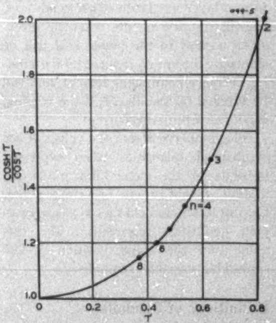

Figure 5. Curve for optimum lamina thickness

$$\frac{\cosh\tau_{no}}{\cos\tau_{no}}=\frac{n}{n-1}$$

found by taking the derivative with respect to τ of the expression for $F_{n\tau}$, (equation 29), equating this derivative to zero and solving for τ. This yields the following expression for optimum thickness,

$$\frac{\cosh \tau_{no}}{\cos \tau_{no}} = \frac{n}{n-1} \tag{38}$$

This may be solved graphically for the values of τ_{no} corresponding to different values of n by plotting in rectangular coordinates the curve of cosh τ/cos τ against τ, as in figure 5. Table II gives the optimum thicknesses for laminae in layers from 1 to 10 and the corresponding minimum values of the resistance factors, as read from figures 4 and 5.

Table II. Optimum Thicknesses and Corresponding Minimum Values of the Resistance Factors

Position of Layer (n)	$\frac{\cosh \tau}{\cos \tau}$ [n/(n−1)]	Optimum Thickness in p-Units (τno)	Minimum Resistance Factor [$F_{n\tau}$ (Min)]
1	1/0	π/2	0.918
2	2/1	0.823	1.62
3	3/2	0.634	2.1
4	4/3	0.536	2.5
5	5/4	0.473	2.85
6	6/5	0.43	3.2
7	7/6	0.393	3.45
8	8/7	0.368	3.7

5. Distribution of the Current Densities and the Magnetic Flux Densities

A clear insight into the cause of the large losses in thick lamina in the strong magnetic fields of other lamina is obtained from curves showing the distribution of current density and of magnetic flux density over the cross section of the laminae. The equations for these curves, as derived in sections 8 and 9 of the appendix, are:

C (amperes per square meter in lamina n) =

$$\frac{(1+j)I}{pw} \times \left[\frac{n-(n-1)(\exp \tau)\underline{/\tau}}{(\exp \tau)\underline{/\tau}-(\exp -\tau)\underline{/-\tau}}(\exp -z)\underline{/-z}+\frac{n-(n-1)(\exp -\tau)\underline{/-\tau}}{(\exp \tau)\underline{/\tau}-(\exp -\tau)\underline{/-\tau}}(\exp z)\underline{/z}\right] \tag{23}$$

B (webers per square meter in lamina n) =

$$-\frac{\mu I}{w} \times \left[\frac{n-(n-1)(\exp \tau)\underline{/\tau}}{(\exp \tau)\underline{/\tau}-(\exp -\tau)\underline{/-\tau}}(\exp -z)\underline{/-z}-\frac{n-(n-1)(\exp -\tau)\underline{/-\tau}}{(\exp \tau)\underline{/\tau}-(\exp -\tau)\underline{/-\tau}}(\exp z)\underline{/z}\right] \tag{19}$$

Sets of curves for ***C*** and ***B*** have been plotted for laminae of two different thicknesses, namely, $\tau=\pi/2$ p-units (the optimum thickness for lamina 1) and $\tau=2\pi$ p-units. Each curve sheet contains four curves applying to lamina 1, 2, 3, and 4 respectively. In these curves, current densities (or flux densities) in the plane PP have been plotted as ordinates against the distance z from the outer face to the plane PP as abscissas. z is expressed in p-units.

In the scale for current density (which is plotted in rms amperes per square meter) appears the factor $I/(w\tau p)$. This factor is the value of the uniform current density which would exist if the current I were a continuous current. In the scale for flux density (which is plotted in rms webers per square meter) appears the factor $\mu I/w$. This factor is the increase which occurs in the magnetic flux density from the outer to the inner face of each lamina. The phase-angles shown are the angles of lead (+) or lag (−) relative to the phase of the current I through each lamina.

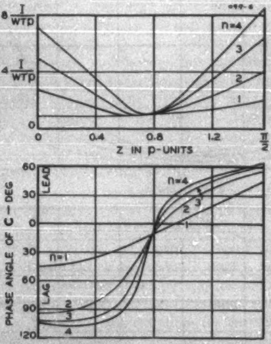

Figure 6. Distribution of current densities

Lamina thickness, $\tau=\pi/2$ p-units; $I/(w\tau p)$ is the density at zero frequency

Refer now to figures 6 and 7 showing the current density and flux density respectively for laminae of thickness $\tau=\pi/2$ p-units. The current density on the inside faces is seen to rise from 2.04 times the d-c density for lamina 1 to 8.57 for lamina 4. In lamina 1, the current density changes from an angle of lag of 45 degrees in the outside face to an angle of lead of 45 degrees in the inside face. In lamina 4, the current density changes from an angle of lag of 105 degrees in the outside face to an angle of lead of 63 degrees in the inside face. By reference to figure 4, it will be seen that the eddy currents disclosed by figure 6 cause the $F_{n\tau}$ resistance factors of these lamina to increase from 0.913 for lamina 1 to 2.9, 7.9, and 15, for laminae 2 to 4.

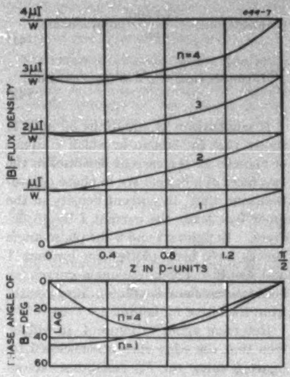

Figure 7. Distribution of flux densities

Lamina thickness, $\tau=\pi/2$ p-units; $\mu I/w$ is the increment in flux density across each lamina

By reference to the flux-density curves of figure 7, it will be seen that the eddy currents disclosed by figure 6, while sufficient to cause large losses, are not sufficient to screen very effectively the central portions of the inner lamina from the magnetic intensities of the outer lamina. This is shown by the fact that the departure from a straight line of the curves showing the increase of the flux density from face to face, while appreciable, is not striking. At the face of each lamina the flux density is necessarily in phase with the current I save in the outer face of lamina 1. As this face is approached, the flux density approaches zero with an angle of lag of 45 degrees. At the mid planes of the lamina the flux densities lag the current I by approximately 34 degrees.

The above relations are to be contrasted with those disclosed in figures 8 and 9 for laminae having a thickness $\tau=2\pi$ p-units. For laminae whose thickness equals or exceeds 2π p-units, equation 23 yields the following simple expressions for the current densities at the faces of the laminae, and for the ratio of the facial current density to the density under an equal direct current.

$$\boldsymbol{C} \text{ (outside face)} = -\frac{(1+j)(n-1)I}{pw} \quad \text{(approximate)} \tag{39}$$

$$\frac{|C_{ac}|}{|C_{dc}|} \text{ (outside face)} = \sqrt{2}\,(n-1)\tau \quad \text{(approximate)} \tag{40}$$

$$C\text{ (inside face)} = \frac{(1+j)nI}{pw}\text{(approximate)} \qquad (41)$$

$$\frac{|C_{ac}|}{|C_{dc}|}\text{ (inside face)} = \sqrt{2}\,n\tau\text{ (approximate)} \qquad (42)$$

A comparison of equations 39 and 41 shows that for lamina in which τ equals or exceeds 2π the current densities in the two faces of a lamina are in phase opposition, and that the current density in the inner face leads the current I by 45 degrees. In figures 8 and 9 the phase-angle curves have been plotted for laminae 1 and 4 only. The phase-angle curves for laminations 2 and 3 will not differ greatly from the curve for lamina 4.

Referring again to figure 4, it will be seen that the eddy currents disclosed by figure 8 cause the F_{nr} resistance factors of these laminae to increase from 1 for laminae 1 to 5.2, 14, and 27 for laminae 2 to 4. The curves of figure 4 show that no matter how much the thickness of the lamina may be increased beyond 2π p-units, there will be no further increase in the F_{nr} resistance factors. This is in agreement with the previous conclusion, namely, that increase in thickness beyond 2π will not cause the surface current densities to increase beyond the values indicated in equations 39 to 42.

This upper limit for the eddy-current densities and for the resistance factors may be accounted for by either of the following statements. It may be said that although doubling the thickness of any lamina doubles the electromotive forces induced in the lamina by the magnetic field of the outer laminae, it also doubles the reactance of the lamina to this system of electromotive forces, and so the current densities are substantially unaffected. (Note: This doubling of the reactance does not occur unless the original thickness is three p-units or greater.) An alternative statement is to say that the system of eddy-current densities which is set up in a lamina 2π p-units thick is adequate to screen the central portion of this lamina from the magnetic intensities of the outer lamina. Therefore the copper added to this screened region by doubling or tripling the thickness of the lamina cannot lead to increased current densities in the system of eddy currents.

The flux density curves of figure 9 show that for all laminae save number 1, the flux densities in the inner and outer faces of the lamina are in phase with the current I. At the two planes each located one p-unit below a surface, the flux density is only $1/\epsilon$th (36.8 per cent) of its value at the nearest surface and lags the current I by one radian. At the two planes each located $\pi/2$ p-units below the surface, the flux density lags the current by 90 degrees. Between these two 90-degree planes and the mid plane of the lamina, the flux density has a component in phase opposition to the current I, and at the mid plane itself the angle of lag reaches 180 degrees.

6. Conclusions

Multilayer windings fall into one of two types:

(*a*). The transformer type (figure 1)

(*b*). The reactor (or field winding) type (figure 2)

In the transformer type of multilayer winding, if the odd-numbered layers constitute the primary winding and the even-numbered layers constitute the secondary (or vice versa), and if the magnetizing current is negligibly small in comparison with the full-load current of the transformer, then the multilayer type of loss associated with the magnetizing current may be neglected in comparison with the loss associated with the full-load current. Under these conditions, the optimum thickness for all the interleaved laminae (except the first and the last) is π p-units. For the first and last lamina it is $\pi/2$ p-units, provided both these laminae belong to the same winding.

The other extreme in the transformer

Figure 8. Distribution of current densities

Lamina thickness, $\tau = 2\pi$ p-units; $I/(w\tau p)$ is the density at zero frequency

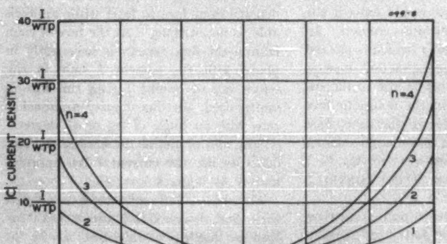

Figure 9. Distribution of flux densities

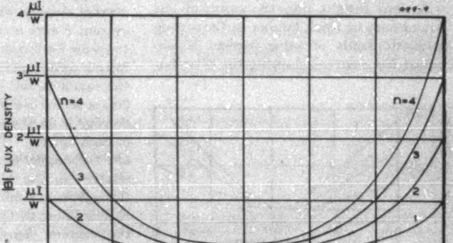
Lamina thickness, $\tau = 2\pi$ p-units; $\mu I/w$ is the increment in flux density across each lamina



type of multilayer winding would be the case in which the magnetomotive force of the magnetizing current in the primary is quite large in comparison with the magnetomotive force of any load current in the secondary. Under these conditions, little is to be gained by interleaving primary and secondary; the optimum thickness for the primary layers are those of the reactor type.

In the reactor type of winding, if the minimum effective resistance is to be obtained with k layers of a specified width and peripheral length, the thicknesses of the lamina should be proportioned as tabulated in table II. In general, it will not be practicable to vary the thickness from layer to layer, but all layers will be made of the same thickness. The optimum thickness for the laminae of a k-layered winding having all layers of the same thickness can readily be determined by the aid of figure 4.

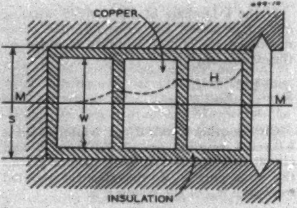


Figure 10. The distribution of magnetic intensities in a multilayer copper coil in an armature slot

If it is feasible to use layers or lamina whose thicknesses do not exceed 0.2 p-units, the *multilayer effect* will not make the effective resistance appreciably exceed the d-c resistance for any number of layers up to 10.

The single multilayered bus bar illustrated in figure 3 (far removed from the return bus bar) falls under the reactor type of figure 2. If the number of layers or laminae is even, all of the equations derived for figure 2 may be applied to the multilayered bus bar.

If, however, the number of laminae in the bus bar is odd, as illustrated in figure 3 then the laminae should be numbered $N=0$, 1, 2, etc., as shown in figure 3. Then the halves of lamina 0, which lie on opposite sides of the plane of zero flux density are each to be viewed as layer $n=1$ of figure 2. The equations for current density, flux density, loss, and resistance factor for layers $N=1$, 2, etc., are to be obtained from the equations derived for figure 2 by substituting $(N+0.5)$ for n, wherever n appears in equations 8, 9, 12, 13, 17, 19, 23, 27, 28, 29, and 34. For example, making this substitution in equation 29 for the resistance factor, it becomes,

$$F_{N\tau}=\left[(2N^2+0.5)\frac{\sinh 2\tau+\sin 2\tau}{\cosh 2\tau-\cos 2\tau}-(4N^2-1)\frac{\cos\tau\sinh\tau+\sin\tau\cosh\tau}{\cosh 2\tau-\cos 2\tau}\right] \qquad (29a)$$

Appendix. The Derivation of Expressions for the Distribution of the Current Densities and for the I²R Losses in Multilayer Windings

7. The Differential Equations of the Winding

For a winding of the type illustrated in figure 2, which is proportioned and idealized as stated in section 3, the differential equations are obtained by writing the following fundamental relations. These relations apply to all loops each of which comprises two corresponding elementary sheets of thickness Δx, width w, and total length l. One of the elementary sheets will be in an outgoing lamina and the other in the corresponding position in the corresponding return lamina.

(*a*). Relation of the Current Density to the Electromotive Force of Inductance

By equating to zero the sum of all the electromotive forces in the loop; namely, the impressed electromotive force, E, (which has the same value for all loops) the electromotive force of inductance, and the electromotive force of resistance, there results,

$$\boldsymbol{E}_1+\boldsymbol{E}+\left(-\frac{\boldsymbol{C}l}{\gamma}\right)=0 \qquad (1)$$

(*b*). Relation of the Rate of Change (With x) of the Electromotive Force of Inductance to the Magnetic Flux Density

The magnetic flux linked with the loop comprised by the inner faces of the elementary sheets of thickness Δx is less than the flux linked with the loop comprised by the outer faces PP by the magnetic flux in the sheet of thickness Δx, namely, $\boldsymbol{B}l\Delta x$. Therefore the electromotive force, $(\boldsymbol{E}+\Delta\boldsymbol{E})$, induced in the inner loop is to be found by subtracting from the electromotive force, $\boldsymbol{E}$, in the outer loop, the electromotive force induced by the flux $\boldsymbol{B}l\Delta x$, namely,

$(-j2\pi fl\boldsymbol{B}\Delta x)$.

Whence,

$$(\boldsymbol{E}+\Delta\boldsymbol{E})=\boldsymbol{E}-(-j2\pi fl\boldsymbol{B}\Delta x)$$

or

$$\frac{d\boldsymbol{E}}{dx}=j2\pi fl\boldsymbol{B} \qquad (2)$$

(*c*). Relation of the Rate of Change (With x) of the Magnetic Flux Density to the Current Density

The magnetic intensity at the inner face $(\boldsymbol{H}+\Delta\boldsymbol{H})$ is greater than the magnetic intensity $\boldsymbol{H}$ at the outer face PP by the magnetic intensity of the current in the sheet of thickness Δx, namely, $\boldsymbol{C}\Delta x$. Therefore,

$$\boldsymbol{H}+\Delta\boldsymbol{H}=\boldsymbol{H}+\boldsymbol{C}\Delta x$$

Whence,

$$\frac{d\boldsymbol{B}}{dx}=\mu\boldsymbol{C} \qquad (3)$$

By eliminating $\boldsymbol{E}$ and $\boldsymbol{C}$ between the three equations 1, 2, and 3, the following second-order linear differential equation in flux density is obtained:

$$\frac{d^2\boldsymbol{B}}{dx^2}=j2\pi f\gamma\mu B \qquad (4)$$

Using p to symbolize $1/\sqrt{\pi f\gamma\mu}$ (5)

equation 4 takes the form,

$$\frac{d^2\boldsymbol{B}}{dx^2}=\frac{j2\boldsymbol{B}}{p^2} \qquad (6)$$

8. Solution for the Magnetic Flux Density

By substituting (7) in (6) it may be verified that the general solution for the flux density may be written in the exponential form:

$$\boldsymbol{B}=\boldsymbol{B}_1\exp\{-(1+j)x/p\}+\boldsymbol{B}_2\exp\{(1+j)x/p\} \qquad (7)$$

The undetermined integration constants, $\boldsymbol{B}_1$ and $\boldsymbol{B}_2$, are evaluated from the following considerations. If equation 7 is to portray the flux densities in lamina n, and if x is measured from the outer face of this lamina, then from physical considerations it follows that:

At $x=0$, $\boldsymbol{B}_{(x=0)}=(n-1)\mu\boldsymbol{I}/w$ (8)

and at $x=b$, $\boldsymbol{B}_{(x=b)}=n\mu\boldsymbol{I}/w$ (9)

in which $\boldsymbol{I}$ represents the current carried by each lamina, and b represents the thickness of lamina n.

But for $x=0$ and $x=b$, equation 7 yields,

$$\boldsymbol{B}_{(x=0)}=\boldsymbol{B}_1+\boldsymbol{B}_2 \qquad (10)$$

$$\boldsymbol{B}_{(x=b)}=\boldsymbol{B}_1\exp\{-(1+j)b/p\}+\boldsymbol{B}_2\exp\{(1+j)b/p\} \qquad (11)$$

By equating the right members of (10) and (8) and also of (11) and (9) and then solving the resulting equations for the integration constants $\boldsymbol{B}_1$ and $\boldsymbol{B}_2$, their values for lamina n are found to be:

$$\boldsymbol{B}_1=-\frac{\mu\boldsymbol{I}}{w}\,\frac{n-(n-1)\exp\{(1+j)b/p\}}{\exp(1+j)b/p-\exp-(1+j)b/p} \qquad (12)$$

$$\boldsymbol{B}_2=+\frac{\mu\boldsymbol{I}}{w}\,\frac{n-(n-1)\exp\{-(1+j)b/p\}}{\exp\{(1+j)b/p\}-\exp\{-(1+j)b/p\}} \qquad (13)$$

The dimensions of the system constant p (defined in equation 5) which first appears in the differential equation of the system (6) are those of a length. Let us name this quantity p (which is expressed in meters) the "*penetration unit* (p-unit) of length of the material for the frequency f." The appropriateness of the name *penetration unit* will become apparent in the application of the solutions.

$$p\text{-unit (meters)}=p=1/\sqrt{\pi f\gamma\mu} \qquad (14)$$

Now an inspection of the solution 7 and of the expressions 12 and 13 for the values of the integrations constants will show that these expressions can all be written in more elegant and significant forms if the distance from the outer face of any lamina to the plane PP is expressed, not in meters, but in p-units. For if, s symbolizes the distance from the outer face to the plane PP expressed in p-units, and τ symbolizes the thickness of lamina n in p-units, then we may write:

$$\left.\begin{aligned}s&=x/p\\ \tau&=b/p\end{aligned}\right\} \qquad (15)$$

Upon substituting these values in (7), (12), and (13) they assume the forms,

$$\boldsymbol{B}\text{ (webers per square meter in lamina } n)=\boldsymbol{B}_1\exp\{-(1+j)s\}+\boldsymbol{B}_2\exp\{(1+j)s\} \qquad (16)$$

$$\boldsymbol{B}_1=-\frac{\mu I}{w}\,\frac{n-(n-1)\exp\{(1+j)\tau\}}{\exp\{(1+j)\tau\}-\exp\{-(1+j)\tau\}} \qquad (17)$$

$$\boldsymbol{B}_2=+\frac{\mu I}{w}\,\frac{n-(n-1)\exp\{-(1+j)\tau\}}{\exp\{(1+j)\tau\}-\exp\{-(1+j)\tau\}} \qquad (18)$$

Solutions written as above in terms of exponential functions are in the form most convenient for the derivation of further equations such as those for the distribution of the current densities and for the effective resistances of the lamina. But for the purpose of plotting curves and of obtaining the most effective physical insight into the relations, the above solution should be thrown into the following trigonometric forms:

$$\boldsymbol{B}\text{ (webers per square meter in lamina } n)=-\frac{\mu I}{w}\times\left[\frac{n-(n-1)(\exp\tau)\underline{/\tau}}{(\exp\tau)\underline{/\tau}-(\exp-\tau)\underline{/-\tau}}(\exp-s)\underline{/-s}-\frac{n-(n-1)(\exp-\tau)\underline{/-\tau}}{(\exp\tau)\underline{/\tau}-(\exp-\tau)\underline{/-\tau}}(\exp s)\underline{/s}\right] \qquad (19)$$

in which

$\underline{/s}$ symbolizes $(\cos s+j\sin s)$ (20)

w is expressed in meters
s and τ are expressed in p-units

9. Solution for the Current Density

Upon substituting the value of $\boldsymbol{B}$ from solution 7 in the fundamental relation 3, the following expression is obtained for the value of the current density at the plane x in lamina n:

$$\boldsymbol{C}=\frac{1+j}{p\mu}\left[-\boldsymbol{B}_1\exp\{-(1+j)x/p\}+\boldsymbol{B}_2\exp\{(1+j)x/p\}\right] \qquad (21)$$

Again expressing distances within the lamina in p-units, this takes the form:

$$\boldsymbol{C}=\frac{1+j}{p\mu}\left[-\boldsymbol{B}_1\exp\{-(1+j)s\}+\boldsymbol{B}_2\exp\{(1+j)s\}\right] \qquad (22)$$

Upon using the values of $\boldsymbol{B}_1$ and $\boldsymbol{B}_2$ and throwing the exponential form into the trigonometric form, the solution for the distribution of the current densities assumes the form:

$$\boldsymbol{C}\text{ (amperes per square meter in lamina } n)=\frac{(1+j)I}{pw}\times\left[\frac{n-(n-1)(\exp\tau)\underline{/\tau}}{(\exp\tau)\underline{/\tau}-(\exp-\tau)\underline{/-\tau}}(\exp-s)\underline{/-s}+\frac{n-(n-1)(\exp-\tau)\underline{/-\tau}}{(\exp\tau)\underline{/\tau}-(\exp-\tau)\underline{/-\tau}}(\exp s)\underline{/s}\right] \qquad (23)$$

10. Equations for the Effective Resistance of the Lamina

Let the effective resistance of lamina n of the multilayer winding to an alternating current $|I|$ of frequency f be defined as the factor, R_{nf} by which the square of the current must be multiplied to obtain the power P_n expended as heat in the lamina. That is,

$$R_{nf}=P_n/I^2 \qquad (24)$$

An expression for R_{nf} may be obtained by deriving an expression for the power loss, P_n, caused by the current I, and substituting this in the defining equation 24. P_n will be the integral of the elementary power losses caused by the known current density distribution in all the elementary sheets of thickness dx which make up the lamina.

In figure 2, the ohmic resistance of the elementary sheet of thickness dx is $R_s=l/(\gamma w dx)$ ohms. The current in the sheet is $I_s=(|C|w dx)$. The power expenditure dP in the sheet is,

$$dP=I_s^2R_s=\frac{|C|^2wl}{\gamma}dx \qquad (25)$$

The power expenditure in the lamina n will be

$$P_n=\int_0^b\frac{wl|C|^2}{\gamma}dx \qquad (26)$$

Upon substituting in (26) the value of $|C|$ as derived from equation 21, carrying out the integration for P_n, and then substituting this value of P_n in equation 24, the following expression is derived for the effective resistance, R_{nf}, of lamina n.

$$R_{nf}=\frac{l}{wp\gamma}\left[(2n^2-2n+1)\frac{\sinh 2\tau+\sin 2\tau}{\cosh 2\tau-\cos 2\tau}-(4n^2-4n)\frac{\cos\tau\sinh\tau+\sin\tau\cosh\tau}{\cosh 2\tau-\cos 2\tau}\right] \qquad (27)$$

Equation 27 expresses the effective resistance of the nth layer as the product of two factors. The factor $l/(wp\gamma)$ is the ohmic resistance of a sheet of the lamina material having a length l, a width w, and a thickness equal to the p-unit for the material. The factor within the brackets is a function of the number n of the lamina and of the thickness τ of the lamina. We may represent this function by the symbol $F_{n\tau}$, call it the *$F_{n\tau}$ resistance factor*, and for each value of n from 1 to 10 or more draw a curve with the values of $F_{n\tau}$ as ordinates and the values of τ as abscissas. See figure 4.

In this symbolism the expression for the effective resistance of lamina n may be written:

$$R_{nf}\text{ (ohms)}=F_{n\tau}\frac{l}{wp\gamma} \qquad (28)$$

in which

$$F_{n\tau}=\left[(2n^2-2n+1)\frac{\sinh 2\tau+\sin 2\tau}{\cosh 2\tau-\cos 2\tau}-(4n^2-4n)\frac{\cos\tau\sinh\tau+\sin\tau\cosh\tau}{\cosh 2\tau-\cos 2\tau}\right] \qquad (29)$$

If the k laminae of a k-layered winding are all in series, the total effective series resistance R_{sf} of the winding is given by the expression,

$$R_{sf}=\sum_{n=1}^{n=k}F_{n\tau}\frac{l_n}{wp\gamma} \qquad (30)$$

On the other hand, if the k laminae of a k-layered winding are all in parallel and are so transposed that each lamina carries the same current I, the effective parallel resistance R_{pf} of the winding is:

$$R_{pf}=\frac{1}{k^2}\sum_{n=1}^{n=k}F_{n\tau}\frac{l_n}{wp\gamma} \qquad (31)$$

11. Ratio of the Effective A-C to the D-C Resistance

If the thickness of a lamina is τ penetration units, its thickness in meters is τp. Therefore its ohmic resistance (or its resistance to direct current) R_{dc} is,

$$R_{dc}\text{ (ohms)}=\frac{1}{\tau}\frac{l}{pw\gamma} \qquad (32)$$

Upon comparing this formula with formula 28 for the effective resistance of the lamina to alternating current, it may be seen that the ratio of the effective to the ohmic resistance of a lamina may be written:

$$\frac{R_{nf}}{R_{dc}}=\tau F_{n\tau} \qquad (33)$$

$$=\tau\left[(2n^2-2n+1)\frac{\sinh 2\tau+\sin 2\tau}{\cosh 2\tau-\cos 2\tau}-(4n^2-4n)\frac{\cos\tau\sinh\tau+\sin\tau\cosh\tau}{\cosh 2\tau-\cos 2\tau}\right] \qquad (34)$$

12. Exponential Versus Bessel Solutions

The linear differential equations with constant coefficients and their exponential solutions as used in this treatment have been derived for multilayer structures in the form of plane sheets. If the plane sheets are bent to form a cylindrical multilayer winding of circular cross-sectional area, as in figure 1, the differential equations take the form of Fourier's equation and the solution is in the form of Bessel functions. However, the exponential or trigonometric solutions apply with great exactness to a

The Output and Optimum Design of Permanent Magnets Subjected to Demagnetizing Forces

R. F. EDGAR
ASSOCIATE AIEE

THE recent development of new permanent-magnet alloys having a high available energy has extended considerably the field of permanent-magnet applications. Prominent among these new materials is the group of aluminum-nickel-iron alloys which has been given the name "Alnico". These alloys are characterized by coercive forces of 400 to 700 oersteds, residual inductions of 6,500 to 7,800 gausses, and available energy values ranging from $1.3 \times 10^6/8\pi$ to $1.7 \times 10^6/8\pi$ ergs. Corresponding values of these quantities for three other well-known magnet materials are given in table I, and characteristic curves for these materials are shown in figure 1.

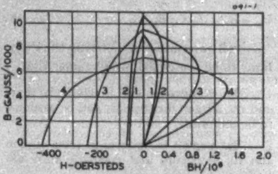

Figure 1. Demagnetization curves and available energy curves for four permanent-magnet materials

1—Chrome magnet steel
2—Tungsten magnet steel
3—Cobalt magnet steel
4—Alnico

Table I. Comparison of Permanent-Magnet Materials

Material	Coercive Force, Oersteds (H_c)	Residual Induction, Gausses (B_r)	Available Energy Ergs × 8π $(BH)_{max}$
Alnico	400–700	6,500–7,800	$1.3–1.7 \times 10^6$
Cobalt magnet steel	240	9,800	0.95×10^6
Tungsten magnet steel	70	10,600	0.32×10^6
Chrome magnet steel	60	9,200	0.23×10^6

In the past, because of the great bulk that would be required if the cheaper chromium or tungsten alloys were used, or because of the prohibitive expense of cobalt steels, the use of permanent magnets was limited to a few special applications where it was inconvenient or impossible to use electromagnets. Instruments, meters, and magnetos represent three of the chief former commercial applications. Today, Alnico is finding its way into an increasing number and variety of electrical and magnetic devices. Relays, contactors, motors and generators, magnetic clutches and chucks, and radio loudspeakers are a few of the many. This permanent-magnet material may be considered as having a possible application wherever a unidirectional magnetic field is required.

Probably because of the rapid advance in the development of these new alloys and their application to new fields of use, the development of design methods has lagged behind the application. The permanent magnet does not always lend itself readily to exact calculation, and each new design involves new problems in determining leakage constants and stabilization factors. Evershed,[1] in a valuable paper, made the first extensive attempt to establish permanent-magnet design as an engineering problem which could be solved by engineering methods. The extension of the use of permanent magnets into some of the applications just mentioned, which involve conditions of varying applied magnetomotive force or varying external reluctance, has raised problems of design not fully treated by Evershed. The object of this paper is to outline graphical and mathematical methods which will be of assistance to the designer in applying permanent magnets to new fields of use. The methods outlined are based on major and minor hysteresis loop data, and are essentially extensions of Evershed's[1] and Watson's[2,3] methods.

Elementary Considerations and Assumptions

Magnetically, a permanent-magnet material is fundamentally the same as any other ferromagnetic material in that all such materials exhibit, to some degree, the property of magnetic hysteresis. The difference between a permanent-magnet material and a soft steel lies in the relative magnitude of the magnetic properties, hysteresis, permeability (μ), coercive force (H_c), and residual induction (B_r). Hysteresis and coercive force, reduced to a minimum in magnetic sheet steels, are developed to a maximum in permanent-magnet materials. The residual induction of magnet materials is usually somewhat less than that of sheet steels, and the permeability, developed to a maximum in sheet steels, may be relatively low. The hysteresis of Alnico is about 400 times as great as that of silicon sheet steel, and its coercive force is about 700 times as great as that of silicon sheet steel.

Paper 40-91, recommended by the AIEE committee on instruments and measurements, and presented at the AIEE summer convention, Swampscott, Mass., June 24–28, 1940. Manuscript submitted March 9, 1940; made available for preprinting May 20, 1940.

circular cylinder in which the thickness of the cylindrical lamina is not greater than 5 per cent of its radius of curvature. This is the case in most of the applications encountered in practice. The solution in exponential and trigonometric functions lends itself to a simpler and more significant physical interpretation than does the solution in Bessel functions.

Discussion

For discussion, see page 1262.

The elementary theory of permanent-magnet design has been adequately presented by Evershed,[1] Sanford,[4] and others. Briefly reviewing, let figure 2 represent the closed-circuit hysteresis loop of a magnet material. The point B_r, corresponding to an applied magnetizing force of zero, represents the induction remaining in the circuit after magnetization and is spoken of as the residual induction. The point H_c represents the applied negative magnetizing force necessary to reduce the induction to zero, and is called the coercive force. The portion of the loop between B_r and H_c is referred to as the demagnetization curve. It may be shown that if a magnet has initially been magnetized to a point represented by the tip of the hysteresis loop and then subjected to the insertion of an air gap in the magnetic circuit, some point on the demagnetization curve will represent the magnetizing force which the magnet is applying to the air gap and the induction existing in the magnet. To illustrate, if the point X of figure 2 represents the conditions existing for some particular magnet and air gap, the induction existing in the magnet is given by B_m and the magnetizing force being applied by the magnet to the air gap is H_m. The line from the origin through X is termed the air-gap line.

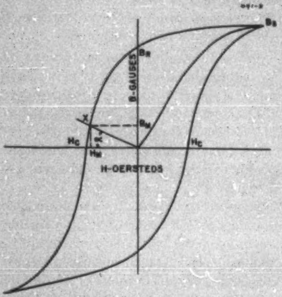

Figure 2. Symmetrical hysteresis loop for a permanent-magnet material

The location of the point X depends upon the relative dimensions of the magnet and air gap, and may be determined as follows. Let A_m represent the area of magnet cross section, A_g the area of air-gap cross section, L_m the length of magnet parallel to the direction of flux lines, L_g the length of the air gap parallel to the direction of the flux lines, and B_g the induction existing in the air gap. Then, since the magnetomotive force applied to the circuit is zero,

$$H_mL_m-B_gL_g=0$$

and

$$H_m=B_gL_g/L_m \qquad (1)$$

If leakage flux is assumed to be negligible the flux in the magnet material is equal to the flux in the air gap.

$$B_mA_m=B_gA_g$$

$$B_m=B_gA_g/A_m \qquad (2)$$

The slope of the air-gap line is defined as B_m/H_m, (tan α in figure 2), and designated by the letter S

$$S=\tan\alpha=L_mA_g/L_gA_m \qquad (3)$$

This is the reciprocal of the so-called demagnetization factor defined by various writers. The volume of magnet material, $V_m=L_mA_m$, required to maintain a magnetic field of density B_g in a gap of length L_g and area A_g is, from equations 1 and 2

$$V_m=B_g^2L_gA_g/B_mH_m \qquad (4)$$

It may be seen that the point X may be located at any desired point over quite a range of the demagnetization curve by properly proportioning the dimensions of the magnet and the air gap. The last equation above indicates that the volume of magnet material required for a given air gap is inversely proportional to the product of B_m and H_m. Hence, the point X should be located where this product is a maximum.

The equations quoted above assume that flux leakage may be neglected so that all the flux is confined definitely to the limits of the magnetic circuit, and that the induction is uniform throughout the magnet. In any magnetic circuit containing an air gap a magnetic leakage flux exists in the space about the working air gap between the ends of the magnet. This leakage flux may be a large part of the total flux, and in some cases can be included in the magnet calculations by a step-by-step method such as described by Evershed, particularly if the magnet is relatively long and of small cross section as is common with magnets of low-coercive-force materials. Fortunately, magnets of Alnico usually are relatively short and of large cross section so that all leakage flux can be treated as coming from the pole pieces or ends of the magnet.

Assuming that leakage flux is a terminal factor makes it a simple matter to modify the elementary equations 1 to 4 to include the effect of leakage flux. Let the quantity which will be called the leakage factor and designated by the symbol K_1 be defined by the following equation.

$$K_1=(P_g+P_1)/P_g$$

where

P_g = permeance of the working air gap
P_1 = permeance of all the leakage flux paths in parallel with the working air gap

The equations 1 to 4 may be modified by this factor as follows:

$$H_mL_m-B_gL_g=0$$

and

$$H_m=B_gL_g/L_m \text{ as before} \qquad (5)$$

$$B_mA_m=B_gA_gK_1$$

and

$$B_m=B_gA_gK_1/A_m \qquad (6)$$

$$S=\tan\alpha=L_mA_gK_1/L_gA_m \qquad (7)$$

$$V_m=B_g^2A_gL_gK_1/B_mH_m \qquad (8)$$

It will be assumed in deriving the equations to be presented in this paper that

1. The working air gap is relatively short and the air-gap flux density can be assumed to be uniform.
2. The magnet is uniform in cross section and its properties and magnetic state are uniform.
3. The magnet has initially been magnetized to saturation so that the discussion applies entirely to the major loop having a tip induction equal to the saturation induction and to minor loops having their origin on this major loop.
4. The quantities involved in the equations are restricted to lie within the limits of the experimental curves.

Empirical Equations and Graphic Construction of Demagnetization Curve

The problem of determining the output of a magnet which is initially magnetized to saturation and not subjected to greater demagnetizing forces than the working air gap is only a special case of the general problem in which variable conditions are involved. However, since this problem can be analyzed more simply as a specified problem, it deserves preliminary consideration.

The demagnetization curve for a permanent-magnet material can be approximated quite closely by Lamont's equation as modified for a material of high coercive force.[3] In terms of the constants of the material this equation results in the following expression:

$$B=\frac{H+H_c}{\frac{H_c}{B_r}+\frac{H}{B_s}} \qquad (9)$$

The quantity B_s is not the true saturation induction, since the curve does not retain its hyperbolic form for positive values of H. For Alnico, B_s is considerably lower than the saturation induction, and for other materials it is closer to it as B_r is larger.

The following equation is approximately true for a sample of Alnico in which $H_c = 430$ oersteds, $B_r = 7{,}400$ gausses, and $B_s = 10{,}000$ gausses.

$$B = (H+430)/(0.0580+0.00010H) \text{ gausses } (H = \text{oersteds})$$

The hyperbolic equation suggests a simple graphic construction for the demagnetization curve based on three constants for the material. This construction was first proposed by Watson[2] as a means of determining whether or not the material had had the proper heat treatments. It has been described also by others.[4]

The hyperbolic equation and the graphic construction have been applied to various compositions of Alnico, as well as to the other magnet materials listed in table I. The constructed curves based on three constants, B_r, H_c, and B_s were found to follow closely the experimental curves. No complete theoretical justification is available for equation 9 at the present time. It is simply an empirical relation which fits the demagnetization curve and may be useful in deriving design equations and in correlating permanent magnet data. It may be shown mathematically and checked experimentally, in so far as the above agreement exists, that if the air-gap line has a slope equal to B_r/H_c it will intersect the demagnetization curve at the point where the product B_mH_m is a maximum. The optimum design of magnet, then, may be determined from the following equations:

$$L_mA_gK_1/L_gA_m = B_r/H_c \text{ (see equation 7)} \quad (10)$$

$$A_m = B_gA_gK_1\sqrt{\frac{H_c}{B_r(BH)_{max}}} \text{ (see equations 5, 6, 8 putting } V_m = L_mA_m) \quad (11)$$

$$L_m = B_gL_g\sqrt{\frac{B_r}{H_c(BH)_{max}}} \quad (12)$$

in which $(BH)_{max}$ = maximum value of the product B_mH_m.

The values $(BH)_{max}$, B_r, and H_c are constants of the material and can be obtained from the demagnetization curve or from test data.

For a sample of Alnico, in which

$$(BH)_{max} = 1.4\times10^6/8\pi \text{ ergs}$$
$$H_c = 430 \text{ oersteds}$$
$$B_r = 7{,}400 \text{ gausses}$$

equations 11 and 12 become

$$A_m = 0.000204B_gA_gK_1 \text{ square centimeters}$$
$$L_m = 0.00351B_gL_g \text{ centimeters}$$

and

$$V_m = 7.14\times10^{-7}\ B_g^2A_gL_gK_1 \text{ cubic centimeters}$$

Equations 10, 11, and 12 apply only to designs involving constant external conditions of air gap and applied magnetomotive force, and, of course, the equations containing the numerical constants apply only to material having the characteristics designated for this sample of Alnico.

The Minor Hysteresis Loop

Many permanent-magnet applications now being made involve either a varying external reluctance or varying applied magnetizing forces, and for such applications the equations so far given are not directly applicable for complete solution of the design problems. Instrument and meter magnets which are stabilized by partial demagnetization, and holding or lifting magnets, are examples. Extension of the above design methods to cover these applications involves consideration of the minor hysteresis loop, as has been pointed out by Evershed[1] and Picou.[5,6]

The relation of the minor hysteresis loop to a condition of varying external reluctance is illustrated in figure 3. The left side of the diagram is an enlarged section of figure 2, showing the demagnetization curve. Suppose that after initial magnetization the maximum reluctance into which the magnet must operate is represented by the air-gap line OX, so that the magnet material is brought to a state represented by X. Suppose, however, that the reluctance into which the magnet operates part of the time is smaller and is represented by the air-gap line OY. The induction and magnetizing force associated with the smaller reluctance will not be represented by the point Y, but by Y', the intersection of OY with the minor hysteresis loop which originates on the demagnetization curve at the point X. If the reluctance be again increased to that represented by the line OX, the induction and magnetizing force will return to the values at X along the upper branch of the minor hysteresis loop which lies slightly above the lower branch and is concave downward as shown. Figure 4 shows a series of minor hysteresis loops in a major hysteresis loop for a sample of Alnico. Obviously if a magnet is expected to operate with a reluctance as represented by OY, figure 3, but must at some part of the operating cycle or preliminary to beginning of operation, be subjected to the reluctance represented by OX, it is a mistake to base the magnet design on the co-ordinates of Y. The co-ordinates of Y' must be used.

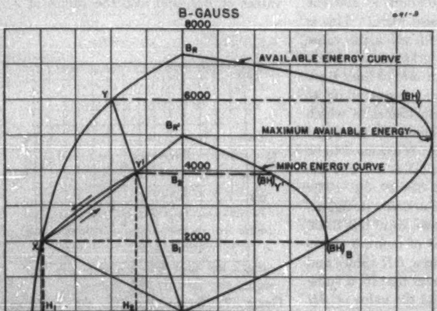

Figure 3. Demagnetization curve and available energy curve for a sample of Alnico showing one minor hysteresis loop and the associated minor energy curve

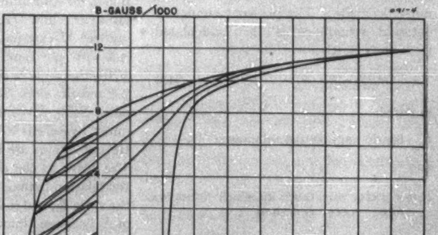
Figure 4. Major and minor hysteresis loops for a sample of Alnico



The best design of a magnet which must be subjected to changes in external reluctance as illustrated in figure 3 will give the magnet dimensions which make the product of B and H at the point of Y', the intersection of the air-gap line with the appropriate minor loop, a maximum. The significance of the BH product for points on the demagnetization curve of the major hysteresis loop has been discussed by Evershed, Watson, Sanford, and others, but little mention has been made of this quantity as associated with minor hysteresis loops. The outer curve to the right in figure 3 represents values of the BH product for points on the major hysteresis loop, and the curve inside this is a similar curve derived from the lower branch of the minor hysteresis loop.

Magnets operating with constant external reluctance and no applied demagnetizing force, as previously described, operate along the major hysteresis loop, and the values of B and H which give the largest BH product can easily be determined and thus the best point for operation. Magnets operating with varying external reluctance, however, may be designed to operate on any one of an infinite number of minor hysteresis loops, and the particular one giving the best economy of material is not readily apparent. It will be shown, however, that for any specified cycle of varying external reluctance there is a minor hysteresis loop which gives the best economy of magnet material.

The limits of the cycle of varying external reluctance must be determined from the dimensions of the external magnetic circuit. These limits are the maximum external reluctance and the normal working reluctance, including both the working air gap and the leakage paths, and they may be approximated by using the methods described by Evershed.[1] It will probably be found in most cases that they are somewhat dependent on the shape and size of the magnet, and for the first approximation a preliminary assumption of the general shape and size must be made. The per cent change in external reluctance is then calculated from the equation

$$\Delta R = 100(R_1 - R_2)/R_2 \qquad (13)$$

in which

R_1 = maximum external reluctance

and

R_2 = working reluctance at which optimum minor energy is desired

Having determined approximately the external reluctances, the best proportions of the magnet are determined in terms of the slopes of the air-gap lines. They are related as follows (see equation 3):

$$S_1 = L_m/A_mR_1 \qquad (14)$$

$$S_2 = L_m/A_mR_2 \qquad (15)$$

$$S_2 = S_1R_1/R_2 = S_1(\Delta R + 100)/100 \qquad (16)$$

in which

S_1 = slope of air-gap line corresponding to the external reluctance R_1

and

S_2 = slope of air-gap line corresponding to the external reluctance R_2

Referring again to figure 3, the line OX has a slope S_1 corresponding to external reluctance R_1 and the line OY has a slope S_2, corresponding to external reluctance R_2. The point Y' represents the point of operation with the working reluctance R_2, and the product $(BH)_{Y'}$ the energy available for the external circuit. The points X and Y can be raised or lowered along the demagnetization curve by varying the proportions of the magnet, while still maintaining the same values of R_1 and R_2 and ΔR. The point Y' and the value of $(BH)_{Y'}$ will also vary. This is illustrated in figure 5 in which the value of $(BH)_{Y'}$ has been graphically determined for four different sets of lines similar to OX and OY, all corresponding to one set of external reluctances in which $\Delta R = 100$ per cent. Thus, for the point B_1H_1, the slope S_1 of OX is assumed to be 2.5 and the slope S_2 of OY is 5. For the point B_2H_2, $S_1 = 5$ and $S_2 = 10$, etc. The minor hysteresis loops and the demagnetization curves are drawn from test data. The curve at the right of figure 5 shows the relation between these BH values and the slope S_1, and indicates that for a value of S_1 between 10 and 15 the value of BH reaches a maximum. The slope, S, is here expressed as (gausses)/(oersteds).

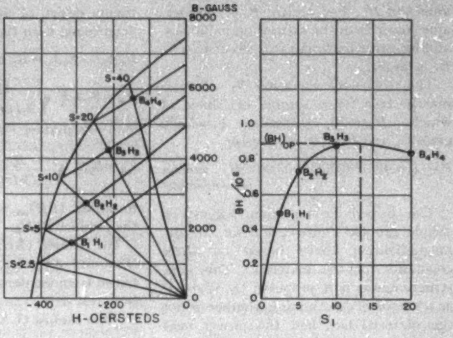


Figure 5. Curves showing values of BH for a sample of Alnico which can be obtained with a single set of external reluctance values by varying the magnet dimensions

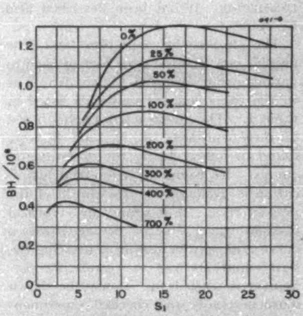

Figure 6. BH curves for a number of values of ΔR plotted as functions of S_1

In figure 6 similar curves are shown for a wide range of ΔR values, ranging from the constant reluctance conditions in which $\Delta R = 0$ to $\Delta R = 700$ per cent. Each of these curves is concave downward having a maximum value within the range plotted. In figure 7 the maximum values of BH, and also the values of S_1

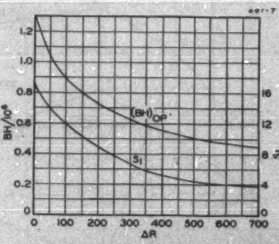

Figure 7. Curves showing the optimum value of S_1 and the optimum value of BH as functions of ΔR for a sample of Alnico

at which they occur, are plotted as functions of ΔR.

The data given by the curves of figure 7 may be used as a basis of design in which a magnet is to be fitted to an external magnetic circuit. The maximum and working reluctances of the external circuit are calculated, or otherwise determined, and ΔR calculated. The value of S_1 corresponding to ΔR in figure 7 will then determine the proportions of length and area of the magnet, and the value of BH will determine its volume.

Application of Minor-Loop Data to Design

For approximate calculation it may be assumed that the minor loop is a straight line in the demagnetization quadrant of the major hysteresis loop. On the basis of this assumption the induction in the permanent magnet may be calculated as follows:

Referring to figure 8 which is similar to figure 3 except for this approximation, the minor hysteresis loop is represented by the line $B_R'Y'X$. This line projected to the left intersects the H axis at some value, H_0, and has a slope $B_R'H_0$ which may be designated as μ_r.

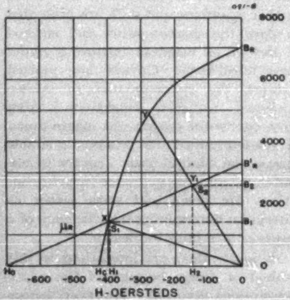

Figure 8. Demagnetization curve for a sample of Alnico showing a minor hysteresis loop replaced by a straight line

Assume that it is desired to determine the output of an Alnico permanent magnet which is to be subjected to open circuit before being assembled with the normal working gap. In figure 8 the slope of the open-circuit air-gap line, S_1, is a function of the permeance of the open-circuit leakage-flux paths, and the slope of the final or working air-gap line S_2, is a function of the permeance of the working gap in addition to the leakage paths. The permeance of the leakage paths may be determined by flux plotting of the stray field or by leakage equations of either an empirical or an analytical basis. Methods for calculating the leakage are given in Evershed's paper.[1] Another method of determining S_1 for certain magnets is given in appendix C.

The equation of the working air-gap line is

$$B_2 = S_2 H_2$$

And for the assumed straight-line minor loop is

$$B_2 = \mu_r(H_0 - H_2)$$

The solution of these two equations yields

$$B_2 = \frac{H_0 \mu_r S_2}{\mu_r + S_2} \tag{18}$$

The physical significance of equation 18 becomes apparent if it is put in slightly different form

$$B_2 = \frac{H_0}{\dfrac{1}{\mu_r} + \dfrac{1}{S_2}} \tag{19}$$

H_0 is the internal magnetomotive force per unit length, $1/\mu_r$ the unit internal reluctance, and $1/S_2$ the unit external reluctance. Hence the equation is simply the expression of Ohm's law for the permanent-magnet circuit and is expressed in a per-unit form.

In equations 18 and 19

B_2 = induction in the magnet during normal operating conditions

H_0 = fictitious "internal magnetomotive force" per unit length

μ_r = slope of assumed straight line "internal magnetization curve" or minor loop

S_2 = slope of working air-gap line

The value H_0 depends upon the location of the point X, figure 8, and hence upon the slope of the open-circuit air-gap line S_1. μ_r also varies somewhat for different values of S_1. These two quantities are plotted as functions of S_1 in figure 9 from test data obtained with a sample of Alnico.

The quantities S_1 and S_2 are calculated for the particular design, and μ_r and H_0 are read from the characteristic curves for the material (figure 9). Then by substitution in equation 18 the induction in the magnet is readily calculated. The density in the air gap is

$$B_g = B_2 \frac{A_m}{A_g K_1} \tag{20}$$

The magnetomotive force per unit length of Alnico for the normal operating air gap is

$$H_2 = \frac{\mu_r H_0}{\mu_r + S_2} \tag{21}$$

Then the available energy is given by

$$B_2 H_2 = \frac{\mu_r^2 H_0^2 S_2}{(\mu_r + S_2)^2} \tag{22}$$

The value of the available BH may be compared with the maximum available given by curve figure 7. The ratio of the available to the maximum available energy may be termed the "utilization" of the material, or symbolically

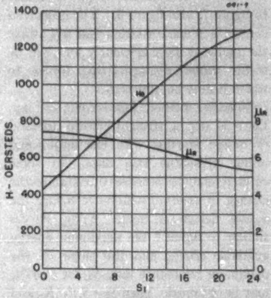

Figure 9. Curves showing values of H_0 and μ_r for assumed straight-line minor hysteresis loops

$$U = \frac{B_2 H_2}{(BH)_{op}} \tag{23}$$

This term is simply the ratio of the total available energy of the actual design to the maximum available energy obtainable for a given variation in external reluctance. It is a measure of how efficiently the material is being utilized.

The over-all efficiency of design is given by

$$E = \frac{B_2 H_2}{(BH)_{op} K_1} \tag{24}$$

This ratio shows the relation of the useful available energy to the maximum available energy obtainable. One hundred per cent efficiency is never obtainable but can only be approached, while 100 per cent utility is possible by correct design. The curve in figure 7 shows the maximum energy available, $(BH)_{op}$, and the optimum slope of the maximum demagnetization as functions of the change in external reluctance from minimum to maximum so that

$$\Delta R = \frac{100(R_1 - R_2)}{R_2} = \frac{100(P_2 - P_1)}{P_1}$$

in which

R_2 = minimum reluctance
R_1 = maximum reluctance
P_1 = minimum permeance
P_2 = maximum permeance

The converse of the problem of determining how efficiently a given magnet design will utilize the material is the problem of calculating a design which will utilize the material to the best advantage. The method is essentially one of cut and try and involves the use of curves similar to figure 7, also figure 9. The object, of course, is to make a design that will utilize the material most efficiently and will be stable under demagnetizing forces to which it may be subjected.

Since the method is one of cut and try, there is not a straightforward method of design starting with the major and minor hysteresis loop data. In some cases it may be possible to estimate the change in external reluctance before the actual design is made. From curves similar to figure 7 the maximum energy available $(BH)_{op}$ and the slope of the maximum reluctance line, S_1, for $(BH)_{op}$ may be obtained. Then $S_2 = S_1R_1/R_2$, and by the use of equations 18 and 20 and curves similar to figure 9, the size of the magnet may be calculated. From the dimensions of the first design the leakage factors may be obtained by calculation or from empirical data, and the actual change in external reluctance determined. The actual output of the magnet may then be calculated from the characteristic curves and compared with the desired output. This method should require but a few tries depending on how complicated the magnetic circuit is and the experience of the designer.

It might be observed that under certain conditions when the leakage is quite appreciable a design giving 100 per cent utility would not yield maximum efficiency, but that maximum efficiency would be obtained at a lower utility. However, the best procedure would probably be to design for maximum utility and then to make check calculations to determine if greater efficiency could be obtained for a design of slightly different dimensions.

Magnet Subjected to Varying Applied Magnetomotive Forces

In some cases the permanent magnet may be subjected to a variable applied magnetomotive force as well as a variable external reluctance. In a generator or motor excited by a permanent magnet such forces would result from armature reaction. Figure 10 illustrates the operation of a permanent magnet subjected to a variation in demagnetizing force from H_{D1} to H_{D2} and a variation in external reluctance ΔR defined by $100(S_2-S_1)/S_1$. Under such conditions the internal magnetomotive force of the magnet is reduced and the equations for magnet output under normal conditions are

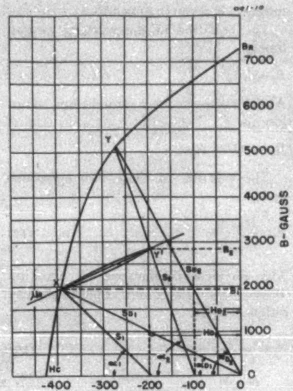

Figure 10. Demagnetization curve and minor hysteresis loop for a condition of combined variation in external reluctance and external demagnetizing force

$$B_2=\frac{\mu_r(H_0-H_{D2})S_2}{S_2+\mu_r} \tag{25}$$

$$H_2=\frac{\mu_r(H_0-H_{D2})}{S_2+\mu_r} \tag{26}$$

and the available energy is

$$(B_2H_2)=S_2\frac{\mu_r^2(H_0-H_{D2})^2}{(S_2+\mu_r)^2} \tag{27}$$

Under such conditions the slope of the maximum demagnetization line will not be S_1 but will be given by

$$S_{D1}=\frac{[\mu_r(H_0-H_{D1})-H_{D1}(\mu_r+S_1)]S_1}{\mu_r(H_0-H_{D1})} \tag{28}$$

Also, the slope of the normal demagnetization line will be given by

$$S_{D2}=\frac{[\mu_r(H_0-H_{D2})-H_{D2}(\mu_r+S_2)]S_2}{\mu_r(H_0-H_{D2})} \tag{29}$$

The ordinate of the curves in figure 7 must be interpreted in terms of the variation of an apparent reluctance which depends on the applied demagnetizing forces as well as the air-gap reluctance.

$$\Delta R'=\frac{100(S_{D2}-S_{D1})}{S_{D1}} \tag{30}$$

Similarly H_0 will be a function of S_{D1} rather than S_1, and the abscissa of figure 9 must be interpreted in terms of this quantity. S_{D1} and S_{D2} are best determined graphicallyas indicated in figure 10.

Summary and Conclusions

This paper presents the elements of permanent-magnet design based on the major and minor loop data and magnetic-circuit theory. For the general case of variable reluctance or applied magnetomotive force it has been shown that the permanent magnet can be treated as a path of almost constant permeability, μ_r, and a variable internal magnetizing force which is a function of maximum external reluctance or demagnetizing force.

Equations and methods for the design of permanent magnets having constant external reluctance or applied magnetomotive force are given based on certain assumptions regarding the shape of the demagnetization curve. Empirical relations of this type are given for a sample of average Alnico.

Since many permanent-magnet problems involve conditions of variable external reluctance or magnetomotive force, further equations and data are presented to show the characteristics and method of design of magnets operating under these conditions. Curves are plotted showing the characteristics of Alnico subjected to such conditions. From these curves the output of a magnet may be predetermined. Maximum available energy and "initial state" curves to obtain maximum energy under varying conditions are given and serve either as criteria for determining the efficiency of a design or as a basis for design.

Obviously there are limitations to this method of design because of the many assumptions involved. However, before attempting too great a refinement in permanent-magnet calculations it must be realized that exact field theory will, in the simplest cases, be too cumbersome to apply, and in general the complexity of the boundary conditions and the multiple-functioned relation of B and H render a mathematical solution hopelessly complicated. Furthermore, variations in magnetic quality of material among magnets and in the same magnet make exact calculations futile from a practical standpoint. The method of permanent-magnet design which has been outlined in this paper has been found sufficiently accurate for a wide variety of problems.

Appendix A

Analytic Determination of Permanent-Magnet Output

In terms of the slope of the air-gap line the equation of the demagnetization curve may be written as follows:

$$B=\frac{-\frac{B}{S}+H_c}{\frac{H_c}{B_r}-\frac{B}{B_g S}} \tag{31}$$

The solution of the above equation for B yields

$$B=\frac{B_g S}{2}\left\{\left(\frac{H_c}{B_r}+\frac{1}{S}\right)-\sqrt{\left(\frac{H_c}{B_r}+\frac{1}{S}\right)^2-\frac{4H_c}{B_g S}}\right\} \tag{32}$$

Since the available energy is defined as BH and since $H=B/S$, the following equation for available energy may be written:

$$BH=\frac{B_g^2 S}{4}\left\{\left(\frac{H_c}{B_r}+\frac{1}{S}\right)-\sqrt{\left(\frac{H_c}{B_r}+\frac{1}{S}\right)^2-\frac{4H_c}{B_g S}}\right\}^2 \tag{33}$$

Equations 32 and 33 are valid only for nonvarying conditions of external reluctance or applied magnetomotive force.

If the permanent magnet is subjected to variable conditions of external reluctance or applied magnetomotive forces, these relations no longer hold. Under such conditions the magnet acts as a path of almost constant permeability and as a source of variable magnetomotive force, both of which are functions of the maximum external reluctance to which the magnet is subjected. Then by equation 32 and the relation $H=B/S$ the equation for the maximum magnetizing force applied to the air gap may be expressed in terms of S_1.

$$H_1=\frac{B_g}{2}\left\{\left(\frac{H_c}{B_r}+\frac{1}{S_1}\right)-\sqrt{\left(\frac{H_c}{B_r}+\frac{1}{S_1}\right)^2-\frac{4H_c}{B_g S_1}}\right\} \tag{34}$$

It is easily shown by means of figure 8 that the internal magnetizing force is

$$H_0=\frac{H_1(S_1+\mu_r)}{\mu_r}$$

so that

$$H_0=\frac{B_g(S_1+\mu_r)}{2\mu_r}\left\{\left(\frac{H_c}{B_r}+\frac{1}{S_1}\right)-\sqrt{\left(\frac{H_c}{B_r}-\frac{1}{S_1}\right)^2-\frac{4H_c}{B_g S_1}}\right\} \tag{35}$$

Then by combining equations 35 and 18

$$B_2=\frac{B_g S_2}{2}\frac{(S_1+\mu_r)}{(S_2+\mu_r)}\left\{\left(\frac{H_c}{B_r}+\frac{1}{S_1}\right)-\sqrt{\left(\frac{Hc}{B_r}+\frac{1}{S_1}\right)^2-\frac{4H_c}{B_g S_1}}\right\} \tag{36}$$

Since $H_2=B_2/S_2$ the available energy under such conditions is given by:

$$B_2H_2=\frac{B_g^2 S_2}{4}\frac{(S_1+\mu_r)^2}{(S_2+\mu_r)^2}\left\{\left(\frac{H_c}{B_r}+\frac{1}{S_1}\right)-\sqrt{\left(\frac{H_c}{B_r}+\frac{1}{S_1}\right)^2-\frac{4H_c}{B_g S_1}}\right\}^2 \tag{37}$$

It will be seen by inspection of (36) and (37) that they reduce to equations 32 and 33 if $S_1=S_2$, which is the condition for a constant air gap.

If the magnet is subjected to a variable applied magnetomotive force as well as a variable air gap, S_1 and S_2 in the preceding equations must be replaced by S_{D1} and S_{D2} which depend both on the external reluctances and the magnitudes of the demagnetizing forces. These quantities are defined by figure 10 or by the equations 28 and 29.

Appendix B

Sample Calculation

The permanent-magnet design shown in figure 11 is used to illustrate the method of calculating the output of a permanent magnet subjected to variable conditions of external reluctance.

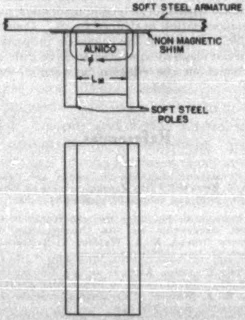

Figure 11. Sample Alnico magnet design. Magnet subjected to maximum reluctance when armature keeper is removed

The use of soft-iron pole pieces is a recommended type of permanent-magnet design for applications where the flux is to be concentrated in an air gap without affecting the flux density in the Alnico. If the pole pieces were of Alnico, the concentration of flux would result in a loss of magnetomotive force in the magnet poles.

The Alnico magnet shown in figure 11 is to be stabilized by being subjected to open circuit before being assembled, with a working air gap of 0.0105 inch. It is desired to find the air-gap flux density and efficiency of design with the normal air gap inserted in the magnetic circuit. The dimensions of the magnet are

$L_M=0.47$ inch $=1.19$ centimeters

$A_M=0.5\times1.75=0.875$ square inch $=5.64$ square centimeters

The dimensions of the working air gap are

$L_g=0.0105\times2=0.021$ inch $=0.0533$ centimeter

$A_g={}^1/_8\times1.75=0.219$ square inch $=1.41$ square centimeters

There is an additional air gap in the magnetic circuit equivalent to approximately 0.004 inch, due to the reluctance of the joints and keeper. This must be added to the working air gap.

Then

$L_g'=0.021+0.004=0.025$ inch $=0.0635$ centimeter

The equivalent working air-gap permeance is

$$P_g=\frac{A_g}{L_g'}=\frac{1.41}{0.0635}=22.2 \text{ centimeters}$$

and the dimensions ratio of the magnet is

$$\frac{L_M}{A_M}=\frac{1.19}{5.64}=0.211$$

By using the conductance formulas given in Evershed's paper[1] the approximate open-circuit and normal operating conductances were calculated:

$P_1=11$ centimeters

$P_2=48$ centimeters

The per cent change in reluctance from minimum to maximum, which is the same as the per cent change in permeance from minimum to maximum, is

$$\text{Per cent } \Delta R=100\frac{(P_2-P_1)}{P_1}=\frac{48-11}{11}=336 \text{ per cent}$$

The slope of the open-circuit line is

$$S_1=\frac{L_M}{A_M}P_1=0.211\times11=2.32$$

and the slope of the normal operating line is

$$S_2=\frac{L_M}{A_M}P_2=0.211\times48=10.13$$

From figure 9, with $S_1=2.32$

and

$\Delta_r=7.3$

$H_0=530$

Then by equations 18 and 21

$$B_2=\frac{7.3\times530\times10.13}{7.3+10.13}=2{,}250 \text{ gausses}$$

and

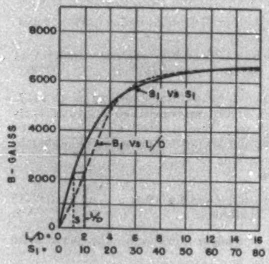
$$H_2=\frac{7.3\times530}{7.3+10.13}=222 \text{ oersteds}$$

Then by equation 20

$$B_g=2{,}250\times\frac{5.64}{1.41}\times\frac{22.2}{48}=4{,}160 \text{ gausses}$$

The available energy (stored in the air gap and leakage fields) per cubic centimeter of Alnico is

$$B_2H_2=2{,}250\times222=5\times10^5 \text{ ergs}\times8\pi$$



which may also be obtained directly from figure 6.

From the curve in figure 7 the maximum possible under the given condition is 5.9×10^6.

Hence by equation 23

$$U=\frac{5}{5.9}=0.847$$

and by equation 24

$$E=0.847\times\frac{22.2}{48}=0.392$$

The significance of U and E are explained in the main body of the paper.

Appendix C

Open-Circuit Demagnetization

If the magnet is of constant cross section and straight axis and has no soft-iron pole pieces when open-circuited, S_1 can be determined by a direct method without resorting to leakage calculations. It has been shown by Scott and others that the remanence or open-circuit residual, B_1, is a function of the dimension ratio, L/D (length/diameter) of the magnet and is very nearly independent of the actual size and shape provided a constant L/D is maintained.

A curve of S_1 as a function of L/D can be plotted from the relation between B_1 and L/D as determined by test, and from the relation between B_1 and S_1 as determined from the demagnetization curve of the material. Figure 12 illustrates this method as applied to a sample of Alnico.

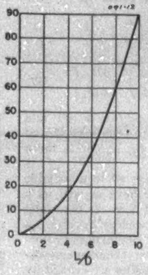


Figure 12. Curve relating slope of open-circuit demagnetization line to dimension ratio, L/D

Since $S_1=\frac{L_M}{A_M}P_1$, it should depend only on the geometry of the magnet and should be independent of the properties of the material. However, further study is necessary to determine if the relation between S_1 and L/D as found by tests on magnets of a certain material can be applied to magnets of other materials. The method has been applied to Alnico magnets of circular and rectangular cross section as a quick and fairly accurate means for determining open-circuit demagnetization as defined by S_1. Considerable variation in the magnetic properties between magnets appeared to have little or no effect on the relation between S_1 and L/D.

An Extension of the Method of Symmetrical Components Using Ladder Networks

WALDO V. LYON
FELLOW AIEE

Synopsis: The pictorial quality of equivalent circuits is often of considerable assistance in computing the performance of transformers and that of synchronous and induction machines. The principal object of this paper is to show how equivalent circuits are useful in extending Fortescue's method of symmetrical components to cases where the circuits on both sides of the air gap of either synchronous or induction machines are unsymmetrical. The analysis is developed for steady-state conditions but the method also may be useful in the analysis of transient conditions.

IN his now classical paper on symmetrical components Fortescue analyzed the behavior of synchronous and induction machinesoperating under unbalanced conditions. In this analysis Fortescue assumed that the stator and rotor windings themselves were symmetrical, that the rotor windings were either short-circuited or connected to balanced static circuits, and that the stator windings were connected to unbalanced circuits. Under these conditions there are unbalanced currents of a single frequency in the stator, and balanced currents of two different frequencies in the rotor. It has since been shown how the method of symmetrical components is applied when the rotor windings are connected to unbalanced circuits and the stator windings are connected to balanced circuits. Under these conditions there are unbalanced currents of a single frequency in the rotor, and balanced currents of two different frequencies in the stator.

The object of this paper is to show how the method of symmetrical components can be extended and applied when both the stator and rotor windings are connected to unbalanced circuits. Under these conditions there are unbalanced currents in both stator and rotor, consisting of infinite series of harmonic components. These harmonic components differ in frequency by a multiple of the frequency corresponding to the speed of the rotor. For example, if a synchronous generator is connected to an unbalanced static circuit, the unbalanced stator currents consist of fundamental, third, fifth, and all other odd-harmonic components, and the rotor currents consist of all the even harmonic components. If an induction motor has unbalanced static circuits connected to both stator and rotor windings, the angular velocities of the currents are $\omega \pm kn$; where ω is the angular velocity of the applied potential, n is the angular velocity of the rotor, and k is any even integer for the stator and any odd integer for the rotor. These conditions are well known, and special cases have been analyzed. Doherty and Nickle determined the currents during a single-phase short circuit on a synchronous generator. Wagner has recently determined the conditions existing when a synchronous generator is connected to an unsymmetrical capacitive load.

The proposed method of analysis can be applied only when the machine and its connected load can be represented by an equivalent circuit. This restriction, however, is not at all serious, since an equivalent circuit can always be found for a three-phase machine if the unbalanced static circuits connected to it are symmetrical about *one* phase. Most of the common unsymmetrical conditions are of this type. While it is true that any problem which can be solved with the aid of equivalent circuits can also be solved without using equivalent circuits, nevertheless the pictorial quality possessed by equivalent circuits has proved of considerable assistance in computing the performance of transformers and that of synchronous and induction machines.

The complete solution consists of two parts:

I. First there are the relations between the positive- and negative-sequence currents and terminal potentials of the *same* frequency. These relations depend upon the impedances of the unbalanced circuits connected to the terminals of the stator or rotor windings.

II. Secondly there are the relations between the currents and potentials of *different* frequencies. These relations depend upon the constants of the machine itself and upon its speed.

I. If, for example, Z_0, Z_1, Z_2 are the symmetrical components of three unbalanced impedances connected in Y to the terminals of a synchronous generator, the positive- and negative-sequence components of the potentials at the terminals of the Y are

$$V_1 = I_1 Z_0 + I_2 Z_2$$

$$V_2 = I_2 Z_0 + I_1 Z_1$$

where I_1 and I_2 are the positive- and negative-sequence components of the currents. If Z_1 equals Z_2 these equations are the equations of a coupled circuit which can be represented by figure 1. The positive- and negative-sequence components, Z_1 and Z_2, of the Y impedances are equal when two of the Y impedances are equal; that is, when the Y impedances are symmetrical about one phase. If the Y impedances are Z_a, Z, Z, the symmetrical components of Z_a are

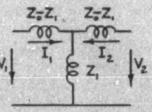

Figure 1

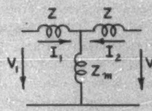

Figure 2

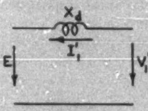

Figure 3

$$Z_0 = \frac{Z_a + 2Z}{3} \qquad Z_1 = Z_2 = \frac{Z_a - Z}{3}$$

Since $Z_0 - Z_1 = Z$, figure 1 can be labeled as in figure 2, in which

$$Z_m = Z_1 = \frac{Z_a - Z}{3}$$

Paper 40-98, recommended by the AIEE committee on electrical machinery, and presented at the AIEE summer convention, Swampscott, Mass., June 24-28, 1940. Manuscript submitted March 17, 1938; made available for preprinting April 23, 1940.

WALDO V. LYON is professor of electrical machinery, Massachusetts Institute of Technology, Cambridge.

1. For all numbered references, see list at end of paper.

In each of the following illustrations we shall assume that two of the three impedances connected to the stator or rotor windings are equal, since it is only then that the equivalent circuit of figure 2 can be used. Equivalent circuits like figure 2 show the relations among the positive- and negative-sequence potentials and currents of *each harmonic frequency*. The values of the impedances in each of these equivalent circuits are adjusted for the particular harmonic frequency considered.

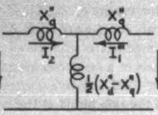

Figure 4

II. In setting down the relations between the currents and potentials of different frequencies, it is best to use a somewhat different procedure for the synchronous machine than for the induction machine. Consider first the synchronous machine. The analysis is somewhat simpler if the resistances of the stator and rotor are neglected, but the resistances can be taken into account if desired.

If the resistances in the machine and in the circuits connected to the machine are neglected, the relation between the excitation electromotive force, E, which is assumed to be sinusoidal, and the positive-sequence component, V_1', of the fundamental terminal potential is determined by the equivalent circuit of figure 3, in which X_d is the synchronous reactance in the direct axis. In all the following equivalent circuits the primes ('), triple primes ('''), and quintuple primes (v) attached to the potentials (V) and the currents (I) indicate the harmonic order of the potential and current. The arrows indicate the assumed positive direction of the current (I) and the fall in potential (V). The relation between the negative-sequence component, V_2', of the fundamental terminal potential of the armature and the reflected positive-sequence triple-frequency component, V_1''', of the terminal potential is determined by the equivalent circuit of figure 4,[1] in which X_q'' is the subtransient reactance in the quadrature axis, and X_d'' is the subtransient reactance in the direct axis. Likewise the relation between the negative-sequence triple-frequency component, V_2''', of the terminal potential and the positive-sequence fifth-harmonic component, V_1^{v}, of the terminal potential is determined by the same equivalent circuit (see figure 5). The equivalent circuits of figure 4 and figure 5 would not be exactly alike if the resistances of the armature and field circuits were taken into account. Note that each harmonic component of terminal potential is divided by the harmonic order.

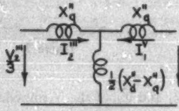

Figure 5

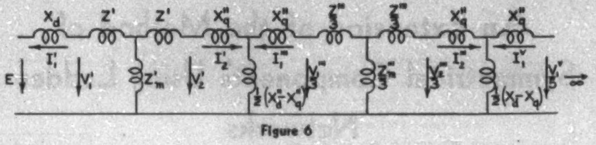

Figure 6

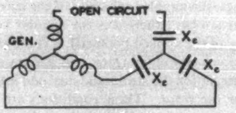

Figure 7a

It is readily seen the alternator and the unbalanced external circuits connected to its armature terminals can be represented by an equivalent circuit composed of units like figure 3, figure 4, figure 5, etc., connected by units like figure 2, as indicated in figure 6. The impedances in the successive units like figure 2 are for fundamental frequency, for third-harmonic frequency, for fifth-harmonic frequency, etc., and in each case the impedance is divided by the harmonic order of the frequency for which it is computed. Since the impedances and the terminal potentials both are divided by the harmonic order, the currents have their correct values. If the resistances, inductances, and capacitances in the external circuit are independent of frequency and are connected in series, dividing the impedances of the external circuit by the harmonic order divides the resistances by the harmonic order, does not alter the inductive reactances, and divides the capacitive reactances by the square of the harmonic order. This interconnection (figure 6) of the component equivalent circuits satisfies the requirement that for each frequency the positive- and negative-sequence potentials and currents at the terminals of the generator equal the corresponding potentials and currents in the external circuit. The network of figure 6 actually extends to infinity but it is usually necessary to include only a few units to attain the desired accuracy in the computation. Not only can the magnitude of the successive harmonic components of the current be determined, but their phase relations also can be computed and hence the wave form of the current. The phase relations of the fundamental and different harmonic components of the current determined from the equivalent circuit (figure 6) equal the phase relations of the rotating vectors representing these currents at the moment the phase of the armature winding for which the analysis is made is directly opposite a field pole; that is, at the moment the excitation electromotive force in that phase is passing through its zero value. At other moments in the cycle the third- and fifth-harmonic vectors have different phase relations with respect to the fundamental vectors, since they spin at different speeds.[1]

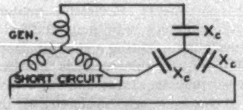

Figure 7b

We shall consider two special cases in which an alternator is delivering current to an unbalanced condenser load, representing a cable or long transmission line whose resistance is neglected. In figure *7a* one circuit breaker opens and in figure *7b* there is a line-to-line single-phase short circuit at the terminals of the alternator. The equivalent circuits are given in figure 8 and figure 9. First consider the conditions of figure *7a*. The impedances connected to the alternator terminals are, at fundamental frequency, $Z_a' = \infty$ and $Z' = -jX_c$. Consequently Z_m (figure 2) is infinitely great. In figure 8 note the capacitor reactances are divided by the *square* of the harmonic order. This is in accord with figure 6, since the actual capacitor reactances vary inversely as the harmonic order. For the conditions of figure *7b* the impedances connected to the

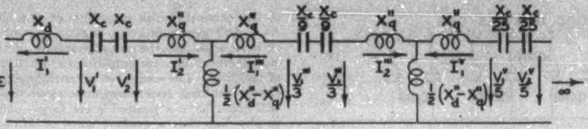

Figure 8

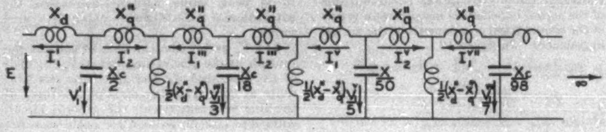

Figure 9

alternator terminals are, at fundamental frequency,

$Z_a'=-j3X_c/2$

and

$Z'=0$

Consequently

$Z_m=-jX_c/2$

In order to determine the currents in these networks (figure 8 and figure 9) the following procedure can be used. Since the capacitive reactances in figure 8 are divided by the squares of the harmonic orders, there will be a point beyond which these reactances can be neglected without introducing much error. If the capacitive reactances are neglected beyond a given point, the reactance of the entire network beyond this point is $\sqrt{X_d''X_q''}$.[1] In figure 9 it is evident there is a point beyond which the capacitive reactances substantially shortcircuit the network. Therefore there is a point in either network where the network may be assumed to terminate if there is connected to the network at this point either an impedance equal to $\sqrt{X_d''X_q''}$ or one equal to zero. The choice of this point depends upon the accuracy desired and the experience of the worker. The following numerical illustration is given of the single-phase short circuit of a 30,000-kva alternator without dampers supplying a capacitive load.

$X_d=1.15\quad X_q''=X_q=0.83\quad X_d''=X_d'=0.33$

from which

$X_2=\sqrt{X_d'X_q}=0.52$

$1/2(X_d''-X_q'')=-0.25$

Reactance of load $X_c=9\times0.52=4.7$ at fundamental frequency. Substituting these values of reactance in the ladder network of figure 9 gives figure 10. All resistances are neglected and the machine reactances are assumed independent of saturation. Applied electromotive force $E=1.0$.

Neglect the part of the ladder to the right of *k*. Apply the rules for computing the impedances and currents in series-parallel circuits. In table I, column 1 gives the reactances at the right and left of the points *j*, *i*, *h*, etc. Column 2 gives the currents in the series branches *ab*, *bc*, *cd*, etc. Column 3 gives the potentials at *a*, *c*, *e*, etc.

From figure 10 and table I, column 3, note that $V_1'=V_a$, $V_1'''/3=V_c$, $V_1^{v}/5=V_e$, $V^{vii}/7=V_g$. Consequently the positive-sequence-harmonic components of the terminal potential are

$V_1'=0.87$

$V_1'''=3\times(-1.74)=-5.22$

$V_1^{v}=5\times(-0.21)=-1.05$

$V_1^{vii}=7\times(-0.011)=-0.077$

The vector diagram of figure 11 can be drawn for the moment the excitation electromotive force, *E*, is passing through zero. The harmonic components are in opposition to the fundamental, and consequently the peak value of the positive-sequence electromotive force at the moment the fundamental is maximum is $0.87+5.22-1.05+0.077=5.12$ times peak value of *E*. With a line-to-line short circuit the peak value of the remaining line potential is three times the peak value of the positive-sequence line-to-neutral potential of the unshort-circuited phase or $3\times5.12=15.4$. This is $15.4/\sqrt{3}$ or 8.9 times normal maximum line potential. The condition chosen is so near resonance for the third harmonic that the resistances should not be neglected, particularly near the point *b* in figure 10, if more accurate results are required.

Table I

* This 0.05 is so small that considerable error is made by neglecting resistance.

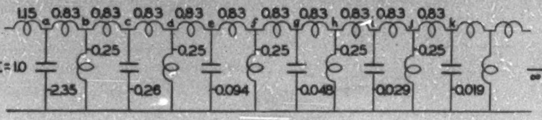

Figure 10

Appendix I

Resistance can be taken into account in the positive-sequence equivalent circuit of the generator, figure 3, by replacing X_d by R_a+jX_q and at the same time multiplying the excitation electromotive force E by

$$\frac{(X+X_q)^2+(R_a+R)^2}{X^2+X(X_d+X_q)+X_dX_q+(R_a+R)^2}$$

where R_a is the armature resistance and $R+jX$ is the complex ratio of fundamental positive-sequence potential V_1' to fundamental positive-sequence current I_1'. See figure 6.

Appendix II

When there is a neutral current so that the line currents have a zero-sequence component, a slightly different procedure is necessary. Let the three self-impedances connected between the lines and neutral be Za, Z, Z, their symmetrical components being $Z_0=(Z_a+2Z)/3$, $Z_1=(Z_a-Z)/3$, $Z_2=(Z_a-Z)/3$. The relations among the symmetrical components of potential, current, and impedance are

$$V_0=I_0Z_0+I_1Z_1+I_2Z_1 \qquad (1)[2]$$

$$V_1=I_0Z_1+I_1Z_0+I_2Z_1 \qquad (2)$$

$$V_2=I_0Z_1+I_1Z_1+I_2Z_0 \qquad (3)$$

Assume that the zero-sequence component of the terminal potential of the generator to which the impedances Z_a, Z, Z, are connected depends only upon the zero-sequence component of the current, or that the positive- and negative-sequence components of current cause no zero-sequence component of terminal potential. Also assume the zero-sequence component of current causes neither positive- nor negative-sequence components of potential. These necessary assumptions are often substantially true but may not be strictly true. Equation 1 can then be extended to include the effect of the impedance, Z_{g0}, of the generator to zero sequence

$$0=I_0(Z_0+Z_{g0})+I_1Z_1+I_2Z_1 \qquad (4)$$

Substitute the value of I_0 determined by equation 4 in equations 2 and 3.

$$V_1=I_1\left(Z_0-\frac{Z_1^2}{Z_0+Z_{g0}}\right)+I_2\left(Z_1-\frac{Z_1^2}{Z_0+Z_{g0}}\right) \qquad (5)$$

$$V_2=I_2\left(Z_0-\frac{Z_1^2}{Z_0+Z_{g0}}\right)+I_1\left(Z_1-\frac{Z_1^2}{Z_0+Z_{g0}}\right) \qquad (6)$$

These equations apply both to the equivalent circuit of figure 12 and to that of figure 13.

The impedances in the branches of these equivalent circuits can be expressed in terms of the actual impedances instead of in terms of the symmetrical components of the actual impedances. In figure 12,

$$Z_0-Z_1=Z$$

$$Z_1-\frac{Z_1^2}{Z_0+Z_{g0}}=\frac{(Z+Z_{g0})(Z_a-Z)}{Z_a+2Z+3Z_{g0}}$$

In figure 13,

$$Z_0+Z_1-\frac{2Z_1^2}{Z_0+Z_{g0}}=\frac{3Z_aZ+Z_{g0}(2Z_a+Z)}{Z_a+2Z+3Z_{g0}}$$

The equivalent circuits of figure 12 or figure 13 can be used to relate the positive- and negative-sequence components of the terminal potential of the generator for every harmonic frequency. It is necessary to know the values of Z_a, Z, and Z_{g0} for the fundamental and each odd harmonic frequency.

Figure 13

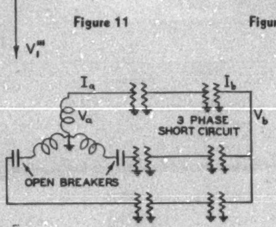

Figure 14

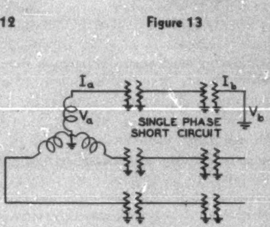

Figure 15

Having determined the positive- and negative-sequence components of current and potential of each desired frequency from the equivalent circuit, the corresponding zero-sequence component of current is determined by equation 4. The zero-sequence component of the terminal potential of the generator is

$$V_{g0}=-I_0Z_{g0} \qquad (7)$$

Appendix III

If a salient-pole generator without dampers is connected to a long transmission line, it is convenient to obtain a solution in terms of the general circuit constants of the line. As a first approximation neglect the effect of saturation on the magnetization of the transformers that are connected at each end of the line. The excessive potentials sometimes resulting from unsymmetrical faults will often have a peaked wave form. Due to the fact that a peaked wave of applied potential results in a flat wave of flux variation in the transformer, the peak value of the applied potential may well be twice the rated peak value without increasing the saturation of the transformer above its rated value.

Let V_a and V_b be the line-to-neutral potentials at the generating and receiving ends of the line, and I_a and I_b be the line currents at corresponding ends of the line. If the line is symmetrical, the general circuit equations can be written for each sequence and for each harmonic frequency independently. The equations for fundamental frequency are:

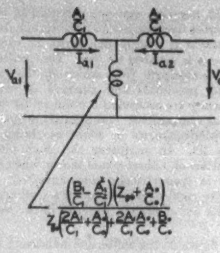
$$\text{positive sequence}\begin{cases} V_{a1}=AV_{b1}+BI_{b1} & (8)[3] \\ I_{a1}=CV_{b1}+DI_{b1} & (9) \end{cases}$$

$$\text{negative sequence}\begin{cases} V_{a2}=AV_{b2}+BI_{b2} & (10) \\ I_{a2}=CV_{b2}+DI_{b2} & (11) \end{cases}$$

$$\text{zero sequence}\begin{cases} V_{a0}=A_0V_{b0}+B_0I_{b0} & (12) \\ I_{a0}=C_0V_{b0}+D_0I_{b0} & (13) \end{cases}$$

The corresponding constants in the positive- and negative-sequence equations are equal, but are different from the constants in the zero-sequence equations, as indicated by the subscripts. There are corresponding equations for each harmonic frequency in which the general circuit constants are computed for each particular harmonic.

If the transformers at each end of the line are alike, the general circuit constants A and D are equal. Since it simplifies the expressions in the second illustration (figure 15) somewhat if $A=D$, we shall there assume that $A=D$. For simplicity assume the transformers are connected Y-Y with both neutrals grounded. The generator neutral is also grounded. In figure 14 there is a three-phase line-to-line short circuit at the



$\frac{A_1}{C_1}$
$\frac{A_1}{C_1}$

I_{a2}
V_{a1}
V_{a2}
$\frac{\left(\frac{B_1}{C_1}-\frac{A_1^2}{C_1^2}\right)\left(Z_{g0}+\frac{A_0}{C_0}\right)}{Z_{g0}\left(\frac{2A_1}{C_1}+\frac{A_0}{C_0}\right)+\frac{2A_1A_0}{C_1C_0}+\frac{B_0}{C_0}}$

Figure 16

far end which causes two of the breakers at the generator to open. In figure 15 there is a line-to-ground short circuit at the far end. In figure 14,

$$\left.\begin{aligned}&I_{a0}=I_{a1}=I_{a2}\\&V_{a0}+V_{a1}+V_{a2}=V_a\end{aligned}\right\}\text{ at generator}$$

$$\left.\begin{aligned}&I_{b0}=0\\&V_{b1}=0\\&V_{b2}=0\end{aligned}\right\}\text{ at far end}$$

On substituting these relations in the general circuit equations,

$$V_a=I_a\frac{1}{3}\left(\frac{2B_1}{D_1}+\frac{A_0}{C_0}\right)$$

Therefore the unbalanced impedances are

$$Z_a=\frac{1}{3}\left(\frac{2B_1}{D_1}+\frac{A_0}{C_0}\right)\text{, infinity, infinity}$$

Figure 12 should not be used, since each branch is infinitely great. In figure 13, $Z_0+Z_1-2Z_1^2/(Z_0+Z_{g0})$ reduces to $(1/2)\times(Z_{g0}+2B_1/D_1+A_0/C_0)$, so that there is a single through impedance $(Z_{g0}+2B_1/D_1+A_0/C_0)$ between the positive- and negative-sequence potentials V_1 and V_2. In order to preserve the correct phase relation between the harmonic components of different frequencies, the positive direction of the negative-sequence potentials and currents in figure 4 and figure 5 should be reversed and at the same time X_d'' and X_q'' should be interchanged. The component sections are then connected as in figure 6; that is, between V_1' and V_2' there is a single through impedance $(Z_{g0}'+2B_1'/D_1'+A_0'/C_0')$; between $V_1'''/3$ and $V_2'''/3$ there is a single through impedance $1/3(Z_{g0}'''+2B_1'''/D_1'''+A_0'''/C_0''')$; etc. In figure 15:

$$\left.\begin{aligned}&V_{b0}+V_{b1}+V_{b2}=0\\&I_{b0}=I_{b1}=I_{b2}\end{aligned}\right\}\text{ at far end}$$

Substitute these values in the general circuit equations and use the method of obtaining equations 4, 5, and 6. The resulting equivalent circuit relating the positive- and negative-sequence components of the same frequency is in figure 16.

Appendix IV. Induction Machines

Consider a three-phase induction machine having unsymmetrical circuits connected to both the stator and rotor windings, subject to the restriction that two of the branches of each unsymmetrical circuit are alike. The equivalent circuit representing either of these unbalanced circuits is in figure 2. The general equivalent circuit which determines the relation between the corresponding stator and rotor currents is in figure 17. Corresponding stator and rotor currents are balanced systems of currents of the same designated sequence which produce magnetic fields rotating in synchronism. In figure 17 it is assumed that balanced three-phase potentials, $V_{a\omega}$, of angular velocity $\omega=2\pi f$ are applied at the terminals of one winding (either the actual stator or the actual rotor). The leakage impedance of this winding at this angular velocity (ω) is $Z_{a\omega}$. The magnetizing reactance at this angular velocity (ω) is X_ω. The approximate effect of core losses can be included by replacing X_ω by Z_ω, the magnetizing impedance. The balanced currents, $I_{a\omega}$, in this winding produce a rotating magnetic field which has an angular velocity ω with respect to the winding, the direction of rotation depending upon the phase order of the currents. With respect to the winding *a*, the angular velocity of the winding (*b*) on the other side of the air gap is n. If n is a positive number, both the second winding (*b*) and the magnetic field rotate in the *same* direction with respect to the first winding (*a*), and n may be either greater or less than ω. If n is a negative number, the second winding (*b*) and the magnetic field rotate in opposite directions with respect to the first winding (*a*). In any case the relative angular velocity of the second winding with respect to the magnetic field is $\omega-n$. The leakage impedance of the second winding (*b*) at an angular velocity $(\omega-n)$ is $Z_{b(\omega-n)}$. In the equivalent circuit this impedance becomes $\omega\div(\omega-n)Z_{b(\omega-n)}$ and the terminal potential on this side of the equivalent circuit is $\omega/(\omega-n)V_{b(\omega-n)}$, where $V_{b(\omega-n)}$ is the actual terminal potential of the second winding. The subscript $\omega-n$ attached to V_b merely indicates the angular velocity of this terminal potential. These potentials are balanced and are said to have the same phase order as the potentials $V_{a\omega}$. The currents, $I_{b(\omega-n)}$ in the second winding also are balanced and of the same phase order as the potentials. They produce a magnetic field in the air gap rotating in synchronism with the field due to the currents $I_{a\omega}$.

X_ω
$\frac{\omega}{\omega-n}V_{b2(\omega-n)}$
$\frac{\omega}{\omega-2n}V_{a2(\omega-2n)}$

Figure 20

The usual definition of the slip, s, is $s=(\omega-n)/\omega$. If n is greater than ω, the slip is a negative number.

The more familiar form of the equivalent circuit is in figure 18. The leakage reactances $X_{a\omega}$ and $X_{b\omega}$ are both for the same angular velocity, ω. This assumes leakage inductance is independent of frequency. Since it is sometimes best to recognize the effect of frequency on resistance, the subscripts ω and $\omega-n$ are attached to the resistances to indicate the frequencies of the currents in them.

If the circuits connected to the second winding (*b*) are unsymmetrical, the currents in the second winding (*b*) are unbalanced and may be resolved into their positive- and negative-sequence components. The positive-sequence currents in the second winding (*b*) produce a magnetic field, rotating positively at an angular velocity $(\omega-n)$ with respect to the second winding and with an angular velocity ω with respect to the first winding. The relations of the positive-sequence currents in the two windings are determined by the equivalent circuit of figure 17. The negative-sequence currents in the second winding produce a magnetic field rotating at an angular velocity $(\omega-n)$ in the opposite direction with respect to the second winding and hence at an angular velocity $(\omega-2n)$ with respect to the first winding. This field induces a negative-sequence current of angular velocity $(\omega-2n)$ in the first winding. The relations of the negative-sequence currents in the two windings are determined by the equivalent circuit of figure 19.

If the terminal potentials and the impedances of figure 19 are multiplied by $\omega/(\omega-n)$ as in figure 20, the currents are unchanged.

If the terminal potentials and the impedances of figure 2 are multiplied by $\omega/(\omega-n)$, this circuit can be used to connect the equivalent circuits of figure 17 and figure 20 as in figure 21. Note, for example, that

$$\frac{\omega}{\omega-n}Z_{b(\omega-n)}=\frac{\omega}{\omega-n}r_{b(\omega-n)}+jX_b$$

Figure 23

Consequently each inductive reactance has the same value wherever it appears in the network, provided each phase of the circuits connected to the stator and rotor consists of a series combination of resistance and inductance. The resistance *at a frequency* $(\omega-kn)$ is multiplied by $\omega/(\omega-kn)$, where $(\omega-kn)$ is the angular velocity of the particular component current in the resistance being considered.

Consider the case in which a three-phase motor is operated from an infinite bus with one stator terminal free and only two of the three rotor terminals short-circuited. The unbalanced impedances connected to both stator and rotor terminals are then infinity, zero, zero, and the impedances of figure 2 are $Z=0$, $Z_m=\infty$. The positive-sequence equivalent circuit of figure 21 becomes the equivalent circuit of figure 22. The equivalent circuit showing the relations among the potentials and currents due to the application of negative-sequence potential of fundamental frequency (ω) at the terminals of the stator is exactly like figure 22 except that $-n$ is replaced by $+n$. The resultant equivalent circuit from which all the component potentials and currents of every frequency are computed is obtained by connecting the positive- and negative-sequence equivalent circuits in series as shown in figure 23. In analyzing the single-phase operation of a three-phase motor when the rotor is symmetrically short-circuited, the positive- and negative-sequence equivalent circuits are connected in series in the same way.[4]

In figure 23 the subscripts indicating the frequencies are omitted from the currents to simplify the notation, but the frequencies are indicated in the loops in which the currents flow. The total average torque developed is

$$\frac{550}{746}\frac{3p}{2\omega}\left\{[I_{b1}{}^2{}_{(\omega-n)}R_A+I_{a2}{}^2{}_{(\omega-2n)}R_B+\ldots\ldots]-[I_{b2}{}^2{}_{(\omega+n)}R_K+I^2{}_{a1(\omega+2n)}R_L+\ldots\ldots]\right\}$$

pound-feet

where R_A is the resistance of the entire positive-sequence equivalent circuit to the right of A, R_B is the resistance of the entire positive-sequence equivalent circuit to the right of B, R_L is the resistance of the entire negative-sequence equivalent circuit to the right of L; where p is the number of poles for which the motor is wound; and $\omega=2\pi f$ is the fundamental angular velocity.

Performance of Traveling Waves in Coils and Windings

REINHOLD RUDENBERG
MEMBER AIEE

THE reaction of coils and windings to traveling waves which impinge upon their terminals is an ever-important problem in electric power systems from both the practical and the scientific point of view. Transformers as well as alternators are used at increasingly higher voltages and their insulation is thus subjected to switching and lightning surges of ever-increasing severity. A simplified but nevertheless rigorous conception of the wave propagation within such windings may therefore be advantageous. It may be used for coils in communication circuits as well.

Previous investigations[1–5] show that in addition to the self-inductance and ground capacitance of the windings, the internal capacitance between turns or coils plays an important part in their behavior to surges. The various investigators differ, however, in defining the self- and mutual inductances of coils and windings under the conditions of rapid transients. By adopting in this paper a special method of deriving the differential equations of the system, the inductance can be related to well-known data of the winding.

Formerly, the effect of an incident steep wave front has been analyzed from the point of view of standing waves within the winding. This involves the numerical computation of many terms of an infinite series of waves, the series having slow convergence. It will be shown that the conception of traveling waves leads to a much simpler result as the problem can then be solved by a mathematical summation of the series of waves in a compact form. The results developed from the analysis given in this paper are verified by many experimental data, some of which have already been published while others are given here for the first time.

Inductive and Capacitive Coupling of Turns and Coils

Consider first a coil which consists, as in figure 1, of but one layer, the turns being wound fairly close together. A single turn has capacitance to ground and, in addition, to both adjacent turns. The capacitance with respect to any other turn, however, is always small compared with either of the capacitances just mentioned. Figures 1*b* and 1*c* represent the distribution of interturn and ground capacitances over the entire coil, both capacitances being uniform over all the elements. At the ends of the coil, however, the ground capacitance c increases and the turn capacitance k decreases because the external flat side of the last turn affects the ground capacitance, but not the turn capacitance. However, this can be taken into account when the boundary conditions of the coil enter into consideration.

Consider winding elements or turns of a length

$$\Delta x = w \tag{1}$$

x being the length co-ordinate of the conductor. The charging current in the ground capacitance of the nth turn is

$$i_{cn} = cw\frac{\partial e_n}{\partial t} \tag{2}$$

where e_n is the mean voltage of the nth turn, c its ground capacitance per unit length of the coil conductor, and t the time. Correspondingly, the charging current of the nth turn to both its adjacent turns is

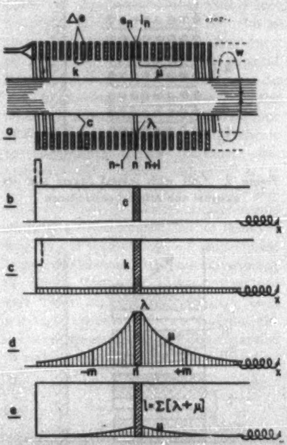

Figure 1. Cylindrical single-layer coil and spatial distribution of its capacitances and inductances

$$i_{kn} = kw\left[\frac{\partial(e_n - e_{n-1})}{\partial t} + \frac{\partial(e_n - e_{n+1})}{\partial t}\right]$$

$$= -kw\frac{\partial \Delta^2 e_n}{\partial t} \tag{3}$$

if we call k the turn capacitance of the unit length between adjacent turns and if the second *difference* of the voltages is abbreviated to

$$\Delta^2 e_n = e_{n+1} - 2e_n + e_{n-1} \tag{4}$$

The sum of both charging currents, as given in equations 2 and 3, is equal to the decrease of the current within the nth turn and the finite spatial alteration of current is thus

$$-\Delta i_n = cw\frac{\partial e_n}{\partial t} - kw\frac{\partial \Delta^2 e_n}{\partial t} \tag{5}$$

If, in addition to the capacitance to ground, there exists any other external capacitance, such as capacitance to conductors connected with the incoming line, its effect can be expressed by terms similar to the first term on the right-hand side of equation 5. This addition, however, does not alter the general character of the relations here derived.

The variation of the voltage along the coil is caused by the inductive effects of its magnetic field. Although in reality there is only one magnetic field, its action can be divided into the self-inductive effect of the turn under consideration and the mutual inductive action of the other turns. If we call λ the self-inductance per unit length of a single turn when separated from the coil, its self-induced voltage is

$$e_{\lambda n} = \lambda w\frac{\partial i_n}{\partial t} \tag{6}$$

where i_n is the mean current within the nth turn. The two immediately adjacent turns with their mutual inductance μ induce a voltage

$$e_{\mu n} = \mu w\frac{\partial(i_{n+1} + i_{n-1})}{\partial t} \tag{7}$$

and a similar voltage is produced by all other turns on both sides of the turn under

---

Paper 40-102, recommended by the AIEE committee on electrical machinery, and presented at the AIEE summer convention, Swampscott, Mass., June 24–28, 1940. Manuscript submitted June 26, 1939; made available for preprinting May 6, 1940.

REINHOLD RUDENBERG is professor of electrical engineering, Harvard University, Cambridge, Mass.

[1] For all numbered references, see list at end of paper.

consideration. However, μ decreases rapidly with the distance between the inducing turns, as shown in figure 1*d*, since for the very rapid variations in time considered here practically no flux can penetrate the laminated iron core of the coil, and mainly the air flux is effective. We exclude, therefore, any common core flux in our considerations in case there exists a closed steel core.

The sum of the currents in equation 7 is built up in a different manner from the sum of the voltages in equation 3. However, we can develop a mathematical expression similar to equation 3 if, within the bracket of equation 7, we add and subtract twice the current i_n of the turn under consideration. Then, for the two adjacent turns, there results

$$e_{\mu n}=2\mu w\frac{\partial i_n}{\partial t}+\mu w\frac{\partial(i_{n+1}-2i_n+i_{n-1})}{\partial t} \qquad (8)$$

and for all turns with any distances *m* from the turn under consideration the sum is

$$\sum_m e_{\mu n}=\sum \mu w\frac{\partial i_n}{\partial t}+\sum \mu w\frac{\partial\Delta^2 i_{n,m}}{\partial t} \qquad (9)$$

In the first term on the right-hand side of equation 9, the change of current is the same for every μ, and can therefore be put before the summation sign. In the second term on the right-hand side the change of current may be different for every μ.

The finite drop of voltage in the turn under consideration is now given by the sum of equations 6 and 9 as

$$-\Delta e_n=(\lambda+\Sigma\mu)w\frac{\partial i_n}{\partial t}+\Sigma\mu w\frac{\partial\Delta^2 i_{n,m}}{\partial t} \qquad (10)$$

if we neglect the small resistance of the conductors. If we consider the first term on the right-hand side of equation 10, we realize that it corresponds to the sum of λ with every μ in figure 1*d*. This, however, is the total self-inductance of the whole coil, related here to the length *w* of one turn. The sum

$$l=\lambda+\Sigma\mu \qquad (11)$$

is therefore the total self-inductance of the winding under consideration per unit length of its conductor.

The coupling effect of all turns with the turn under consideration is expressed mainly by the first term of the right-hand side of equation 10, while the second term, consisting of differences, is merely a remainder. For harmonic oscillations within the coil we can evaluate this remainder (see discussion) and we see then that its elements are mostly acting against one another. If the waves are not extremely short, the total summation will be very small and consequently we make only a small error if we neglect the second term on the right-hand side of equation 10 and confine ourselves to the first term only. If we do not neglect completely the last member of equation 10, but take into account only its largest term, corresponding to the turns immediately adjacent to those under consideration,[6] the result of the calculations would alter only very slightly.

For the change of voltage we now obtain the simple expression

$$-\Delta e_n=lw\frac{\partial i_n}{\partial t} \qquad (12)$$

where *lw* is the contribution of one turn to the total self-inductance of the coil.

Before we proceed further, it is useful to extend the sphere of validity of our derivations. If the coil under consideration has not only one layer, as in figure 1, but any number of layers, as in figure 2, the average voltage and current of every layer may be represented by e_n and i_n. Correspondingly, we denote by *c* the capacitance to ground of every layer and by *k* the capacitance between any two layers, *c* and *k* being related to the unit length of conductor, while the definition of the self-inductance *l* remains the same as before. Then we obtain exactly the same formal expressions 5 and 12, except that now *w* is the length of wire of every layer.

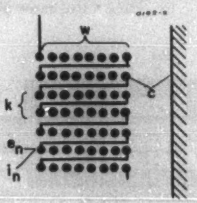

Figure 2. Coil with several layers and its external and internal capacitance

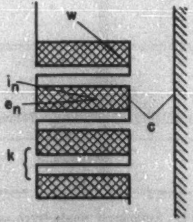

Figure 3. Winding consisting of several coils and its external and internal capacitance

If, finally, the winding is arranged in separate coils as in figure 3, we may relate these characteristic values to any coil, and equations 5 and 12 will now give the mean values of voltage e_n and current i_n of the successive coils.

Not only transformer coils and reactor coils, but also windings of generators or motors can be treated in the same manner. In every case we must take into consideration the wire length *w*, and corresponding capacitances *c* and *k*, over which the mean values of voltage and current are reckoned: the length of a coil for the gross distribution, the length of a layer for the finer distribution, the length of a turn for the very minute change of voltage and current.

Our final equations 5 and 12 are differential equations in time and difference equations in space. If we take the internal capacitance $k=0$, equations 5 and 12 change to the equations of the ordinary choke filter circuit with every turn or coil as an element, although with a different definition of *l*. If we decrease the turn length *w*, with the limit 0, we may write in consequence of equation 1 $w=dx$, and thus equations 5 and 12 change to the simpler differential equations

$$\left.\begin{aligned}-\frac{\partial i}{\partial x}&=c\frac{\partial e}{\partial t}-kw^2\frac{\partial^3 e}{\partial t\,\partial x^2}\\ -\frac{\partial e}{\partial x}&=l\frac{\partial i}{\partial t}\end{aligned}\right\} \qquad (13)$$

These are valid to a good degree of approximation if the number of turns, or layers, or coils is relatively large. As this is often the case with machines and transformers, we shall use this formulation (13) in most of our calculations. Then the term with *k* in equation 13 forms the sole difference in comparison with the well-known differential equations for smooth transmission lines.

Distribution of Standing and Traveling Waves

If we eliminate the current *i* from the two equations 13, we obtain

$$\frac{\partial^2 e}{\partial x^2}-lc\frac{\partial^2 e}{\partial t^2}+lkw^2\frac{\partial^4 e}{\partial t^2\partial x^2}=0 \qquad (14)$$

The same differential equation of the fourth order holds good also for the current *i*.

The simplest form of solution is

$$e=E\cdot\epsilon^{j\omega t}\cdot\epsilon^{j\alpha x} \qquad (15)$$

according to which a voltage with the amplitude *E* oscillates sinusoidally in time and also in space along the extension *x* of the coil conductor. ω is the angular frequency in 2π seconds, and α is the wave density along the wire of the coil expressed as the number of wave lengths in 2π cm of the wire. By introducing equation 15 into equation 14, we obtain

$$-\alpha^2+lc\omega^2+lkw^2\omega^2\alpha^2=0 \tag{16}$$

whereby frequency and wave density are correlated.

Instead of solution 15, which represents standing waves within the coil, we can solve the differential equation 14 by

$$e=E\cdot\epsilon^{j\omega\left(t-\frac{x}{v}\right)} \tag{17}$$

which represents traveling waves within the coil. They oscillate in time with the frequency ω, but propagate along the coil conductor with a velocity v. This solution is fully equivalent to the solution by equation 15. By substituting equation 17 in equation 14, we obtain

$$-\left(\frac{\omega}{v}\right)^2+lc\omega^2+lkw^2\omega^2\left(\frac{\omega}{v}\right)^2=0 \tag{18}$$

which connects frequency ω with velocity v of the traveling waves. Which of the two conceptions, standing waves and traveling waves, is simpler or more practicable depends upon the special physical problem under consideration.

We consider first the development of standing waves. From equation 16 we derive

$$\left.\begin{aligned}\alpha&=\sqrt{\frac{cl\omega^2}{1-klw^2\omega^2}}\\ \omega&=\frac{\alpha}{\sqrt{cl+klw^2\alpha^2}}\end{aligned}\right\} \tag{19}$$

For low frequencies the second term of the denominators is very small and therefore wave density and frequency are practically proportional. The second expression 19 shows that for greater wave density α the internal capacitance k forms an increasing additional capacitance to the external or ground capacitance c. The first expression 19 shows that with increasing frequency ω the wave density α increases rapidly and becomes infinitely great at a certain frequency, given by the zero value of the denominator as

$$\omega=\nu=\frac{1}{w\sqrt{kl}} \tag{20}$$

We call this value ν the critical frequency of the coil,[1] because it plays a critical role in the performance of the winding. It prevents the formation of standing waves for any exciting frequency ω which is equal to or larger than this limiting value ν, because α then becomes imaginary, so that the solution 15 is no longer valid.

We discuss first the subcritical range of frequencies. In each finite winding with open or closed ends, there can exist only a series of well-defined spatial waves which are determined by the boundary conditions at the ends. If m is the number of full waves over the total wire length a, only the wave lengths

$$\lambda=\frac{a}{m}\text{, with } m=\begin{cases}{}^1/_4\times 1, 3, 5, 7\ldots\\ {}^1/_4\times 2, 4, 6, 8\ldots\end{cases} \tag{21}$$

are compatible with the stated boundary conditions. Hence the wave density of such standing waves is given by

$$\alpha=\frac{2\pi}{\lambda}=\frac{2\pi}{a}m \tag{22}$$

If we introduce this expression 22 into the second equation 19, we obtain the only frequencies which can occur in natural oscillations:

$$\omega=\frac{2\pi\frac{m}{a}}{\sqrt{lc\left[1+4\pi^2\frac{k}{c}\left(\frac{w}{a}m\right)^2\right]}} \tag{23}$$

While in smooth lines the natural frequency is directly proportional to the number m of wave lengths and inversely proportional to the length a of the line, this relation may hold in windings only for small values of m and relatively large values of wire length a. However, if the quotient m/a increases, the intervals between successive natural frequencies become smaller. The natural frequencies are crowded together at last in a single point[2] at the value of the critical frequency ν, given by equation 20; this is shown in figure 4 for a critical frequency of five times the fundamental natural frequency.

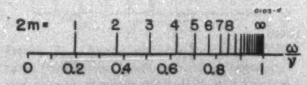

Figure 4. Spectrum of natural frequencies of a coil with internal capacitance

It is interesting to consider how the windings of transformers perform in view of these conclusions. Since it is difficult to co-ordinate natural harmonic frequencies[3] with definite values of m, it appears more conclusive to compare with equation 23 several measurements of fundamental frequencies for different lengths a of the winding. A single-phase power transformer with pancake winding of 16,660 kva with 11-kv low-voltage and 19-kv high-voltage windings, each winding consisting of two separate circuits on the same core for either parallel or series connection, was tested according to figure 5 with four different connections of each winding, the other winding always being grounded at both ends. Table I indicates the results of these experiments* which were carried out by a resonance method. Although the grounding of one terminal of the winding should halve the natural frequency, according to the usual conception, we see that this does not happen either with the high-voltage or low-voltage winding, whether the winding is in parallel or in series. This result is due to the effect of the denominator in equation 23. But if we consider the frequencies with the grounded parallel connection and the insulated series connection, as in figure 5*b* and *c*, we find that the measured frequencies are exactly the same. This is due to the fact that m/a is the same in both cases, thus keeping numerator and denominator of equation 23 constant.

In order to compare these results with equation 23, we use the abbreviation

$$K=2\pi\sqrt{\frac{k}{c}}w \tag{24}$$

and write equation 23 in the form

$$\frac{1}{\omega^2}=\frac{1}{\nu^2}+\left(\frac{a/m}{\nu K}\right)^2 \tag{25}$$

If we plot $1/\omega^2$ against $(a/m)^2$, we should expect that our measured points would lie on a straight line which intersects the axis of ordinates at the critical frequency $1/\nu^2$. We see from figure 6 that the high-voltage frequencies agree very closely with the theoretical relation, while the low-voltage frequencies show minor deviations. The critical frequencies of the two windings as determined from this figure are 90 kilocycles per second for the high-voltage and 130 kilocycles per second for the low-voltage winding.

Before proceeding to supercritical frequencies, we will consider the performance of traveling waves within the winding. From equation 18 we derive the velocity of their propagation

$$v=\sqrt{\frac{1}{cl}-\frac{k}{c}w^2\omega^2} \tag{26}$$

and recognize that this velocity approximates the limiting value

$$v_0=\frac{1}{\sqrt{cl}} \tag{27}$$

only for waves of very low frequency. But the higher the exciting frequency ω is chosen, the smaller the velocity v becomes, and as we approach the critical frequency given by equation 20, the veloc-

---

* The measurements have been made by Mr. J. S. Cliff at the Witton factories of The General Electric Company, Ltd., London.

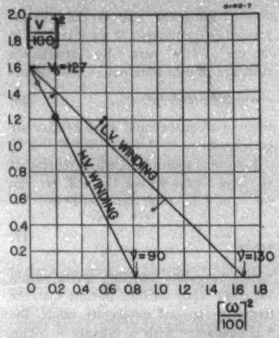

Figure 7. Wave velocity of the tested transformer plotted against natural frequency, both in square scale

ity decreases to zero, so that no propagation of this frequency or of any higher frequency can occur.

In order to determine how our experiments agree with this result, we write equation 26 in the form

$$\left(\frac{v}{v_0}\right)^2+\left(\frac{\omega}{\nu}\right)^2=1 \tag{28}$$

Table I contains the measured velocity of propagation within our transformer windings, determined by the product of natural frequency and actual length of the winding for each test and the numerical factor $1/m$, corresponding to the boundary conditions of the fundamental waves of figure 5 and equation 21. We recognize that the speed of propagation of the traveling waves decreases considerably with increasing natural frequency. In figure 7 v^2 is plotted against ω^2 and we see that the measured points lie on two straight lines in agreement with equation 28, the high-voltage points very closely and the low-voltage points with a fairly good degree of approximation.

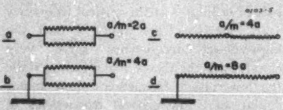

Figure 5. End connections for testing a transformer winding with various natural frequencies

From figure 7 we can determine the value of the limiting velocity of traveling waves for low frequencies as $v_0=127{,}000$ kilometers per second, for both high-voltage and low-voltage windings. If we take the average magnetodielectric constant $\epsilon\mu$ of the winding space as 4.5, the velocity of propagation of free electromagnetic excitations is

$$300{,}000/\sqrt{4.5}=141{,}000 \text{ kilometers per second}$$

independent of the design of the winding. Thus we realize that traveling waves of low frequency are propagated along the transformer wires with very nearly this fundamental velocity. Waves of higher frequency, however, travel substantially slower because of the effect of the internal capacitance.

Table II shows measurements made on transformer windings of different rated voltages. The first two transformers are single-phase with pancake and with concentric windings; the third transformer has three-phase windings in star and in delta connection; and the last apparatus is an air-core, steel-yoke reactor. Figure 8 shows the wave velocity in these differ-

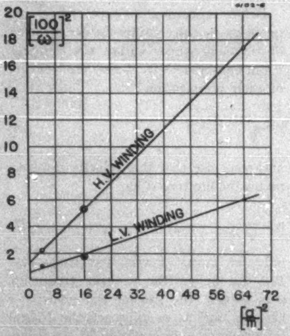

Figure 6. Reciprocal natural frequency of a transformer plotted against the equivalent wire length, both in scale of squares

Table II. Natural Frequencies and Wave Velocities of Transformer Windings of Various Types and Voltages

ent types of windings, beginning with small velocity at low rated voltages and approaching, at higher rated voltages, the electromagnetic velocity of light in oil transformer insulation.

If the velocity v of the traveling waves is known empirically for various types of transformers, it is easy to predict the natural frequency of any winding, which is simply

$$\omega = 2\pi m \frac{v}{a} \tag{29}$$

where a is the length of the winding and m is the number of wave lengths defined in equation 21. By comparing equation 29 with equation 23 it is evident that the denominator of equation 23 determines the velocity of waves for a given winding

$$v = \frac{v_0}{\sqrt{1 + 4\pi^2 \frac{k}{c}\left(\frac{w}{a} m\right)^2}} \tag{30}$$

If we determine the capacitive ratio k/c from the geometry of the winding, we may then find the velocity and the frequencies by mere calculation.

If the exciting frequency of the winding exceeds the critical frequency of equation 20, the wave density α in equation 19 becomes imaginary and it is better to write this relation as

$$\alpha = j\sqrt{\frac{cl\omega^2}{klw^2\omega^2 - 1}} = j\beta \tag{31}$$

Instead of by equation 15, the voltage is now given by

$$e = E \cdot \epsilon^{j\omega t} \cdot \epsilon^{-\beta x} \tag{32}$$

Thus for supercritical frequencies there no longer exist any standing or traveling waves within the winding, but only an exponential attenuation of the voltage from the terminals toward the interior. The space constant X of this voltage distribution at rest is, with use of equation 20,

$$X = \frac{1}{\beta} = w\sqrt{\frac{k}{c}\left[1 - \left(\frac{\nu}{\omega}\right)^2\right]} \tag{33}$$

Near the critical frequency ν the space constant X is fairly small, but X increases rapidly with higher exciting frequencies, approaching a maximum value

$$X_\infty = w\sqrt{\frac{k}{c}} \tag{34}$$

Figure 9 gives the variation of the space constant with frequency according to the circle equation

$$\left(\frac{X}{X_\infty}\right)^2 + \left(\frac{\nu}{\omega}\right)^2 = 1 \tag{35}$$

The current i in equations 5 and 13 denotes the conductor current within any winding element. At the terminal of the winding, however, there is collected by the external lead the sum of the last-turn current and the internal capacitive current which ends at this point, as it has no exterior adjacent turn in which to flow. The external terminal current is, therefore, using equations 3 and 5 for $n = 0$,

$$i_0 = i_n + i_{kn} = cw \sum \frac{\partial e_n}{\partial t} = c\int \frac{\partial e}{\partial t} dx \tag{36}$$

which is written in difference form as well as in differential form, the latter for large numbers of turns. If we evaluate the last integral, using the voltage of equation 15, we obtain for the terminal current

$$i_0 = c\frac{\omega}{\alpha} \cdot E\epsilon^{j\omega t} \cdot \epsilon^{j\alpha x} \tag{37}$$

an equation valid only for $x = 0$.

The surge impedance of any line is the ratio of the terminal voltage, according to equation 15, to the terminal current, according to equation 37. For our winding this is

$$\frac{e_0}{i_0} = Z = \frac{\alpha}{c\omega} = \sqrt{\frac{l/c}{1 - klw^2\omega^2}} = \frac{Z_0}{\sqrt{1 - \left(\frac{\omega}{\nu}\right)^2}} \tag{38}$$

where

$$Z_0 = \sqrt{\frac{l}{c}} = \sqrt{\frac{L}{C}} \tag{39}$$

is the surge impedance for low frequency, being identical with the expression commonly used for smooth lines. Since we have defined l as the self-inductance L of the whole winding divided by the total length of the winding, and c as the capacitance C of the whole winding to ground divided by the total length of the winding, we realize that Z_0 can be computed easily from the total inductance and total capacitance of the winding, a consideration which is of some value for a simple calculation of practical cases. For increasing frequency the surge impedance of the winding increases according to equation 38 and approaches infinity as the frequency approaches the critical value.

For supercritical frequencies the voltage-current ratio of equation 38 becomes imaginary and we write inverted therefore the ratio

$$\frac{i_0}{e_0} = \frac{\omega c}{\alpha} = j\omega w\sqrt{kc\left[1 - \left(\frac{\nu}{\omega}\right)^2\right]} = j\omega C \tag{40}$$

We see that here the winding acts as pure capacitance C, which is, however, small for frequencies in the neighborhood of the critical value but increases rapidly with higher frequencies up to a maximum

$$C_\infty = w\sqrt{kc} \tag{41}$$

This value is in accordance with the resultant capacitance of a long chain of series capacitances k and ground capacitances c, each extended over a length w.

Figure 9 represents the variation of all characteristic values of the winding which we have derived: traveling velocity v and surge impedance Z for the subcritical range, and space constant X and terminal capacitance C for the supercritical range. For very low and very high exciting frequencies, the winding

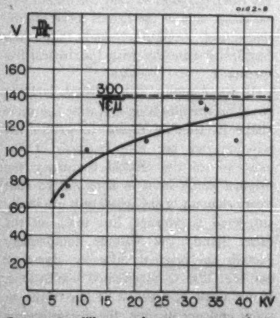

Figure 8. Wave velocities measured in various transformer windings of different rated voltage

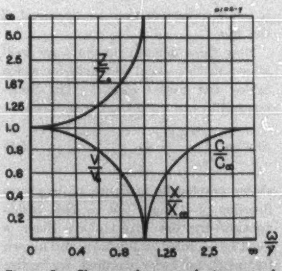

Figure 9. Change of wave velocity v, and surge impedance Z, with subcritical frequency and change of space constant X, and terminal capacitance C, with supercritical frequency, all expressed in relative values

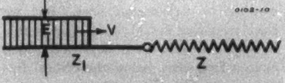

Figure 10. Steep-front wave impinging on a winding from a line

performs regularly like an ordinary smooth line or like an ordinary capacitance chain. In the neighborhood of the critical frequency, however, the characteristic values approach zero or infinity, which means that then the winding is in a kind of resonance state which is due to oscillations of its single elements against one another.

Summation of Subcritical and Supercritical Waves

It is seldom that a transformer, or other machine winding, is excited with a single definite frequency. For the most part traveling waves of any shape, nonsinusoidal in form, impinge from the system lines upon the winding, as shown, for example, in figure 10. However, according to Fourier's theorem, any such wave form can be regarded as a summation of sinusoidal oscillations with every frequency from zero to infinity, each frequency having a definite amplitude. The rectangular wave shown in figure 10, consisting of an abrupt jump at its front and a constant value thereafter, is expressed by the Fourier integral:[7]

$$e=\frac{E}{2}+\frac{E}{\pi}\int_0^{\infty}\frac{\sin\omega t}{\omega}\,d\omega \tag{42}$$

It contains a constant term $E/2$, which makes the wave shape dissymmetrical to the zero line, and an integral which expresses the summation over all frequencies of oscillation with amplitudes inversely proportional to the frequency. The spectral distribution of amplitudes is shown in figure 11.

If such a wave form were to impinge from one smooth line on another smooth line, it would penetrate as a whole into the second line without changing its shape and undergo only refraction according to well-known laws. But we have seen that a coil or winding is able to propagate only those oscillations which have a frequency below the critical frequency ν. Therefore, only those partial waves, shaded horizontally in figure 11, can penetrate the transition point between the two lines and travel on through the winding. All partial oscillations above the critical frequency ν, shaded vertically in figure 11, cannot penetrate deeply into the winding. They excite only standing exponential distributions within the first elements of the winding and are therefore reflected back to the original line.[1]

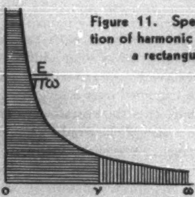

Figure 11. Spectral distribution of harmonic amplitudes of a rectangular-front wave

This splitting of incident waves into two distinct parts is the main difference between the performance of windings and of smooth lines with respect to traveling waves. We recognize therefore that of the entire expression 42 only the first term and the part of the integral up to the frequency limit ν

$$e'=\frac{E}{2}+\frac{E}{\pi}\int_0^{\nu}\frac{\sin\omega t}{\omega}\,d\omega \tag{43}$$

is traveling through the winding, while the second part of the integral with the higher frequencies above ν

$$e''=\frac{E}{\pi}\int_{\nu}^{\infty}\frac{\sin\omega t}{\omega}\,d\omega \tag{44}$$

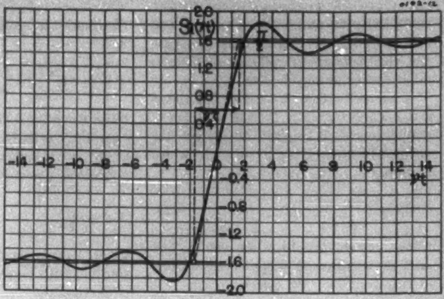
is totally reflected, as at an open end of the line.

Now these definite integrals are well-known mathematical functions for which tables and curves exist.[16] The "sine-integral"

$$Si(\nu t)=\int_0^{\nu}\frac{\sin\omega t}{\omega}\,d\omega \tag{45}$$

shown graphically in figure 12, is a pure function of νt, since the variable ω disappears by the integration. Since ν must be regarded as a definite and known frequency for every winding, we realize that this function remains for every case dependent solely on time t. Thus we see that from the original abrupt jump on the line there remains within the winding only a less steep ascent, as in figure 12 with some residual oscillations on either side of this ascent.

Figure 12. Graphical representation of the "sine-integral"



The sine-integral has very simple asymptotic approximations: for small values, up to $\nu t \cong 0.5$,

$$Si(\nu t)=\nu t \tag{46}$$

and for large values, upwards from $\nu t \cong 4$,

$$Si(\nu t)=\frac{\pi}{2}-\frac{\cos\nu t}{\nu t} \tag{47}$$

If we express the steepness of this sine-integral function by the tangent through the origin, we see from figure 12 that the time τ of the ascent of the voltage is given by the intersections of this tangent with the positive and negative final values. We have, therefore, using equations 46 and 47,

$$\nu\tau=2\frac{\pi}{2}=\pi \quad\text{or}\quad \tau=\frac{\pi}{\nu}=\pi w\sqrt{kl} \tag{48}$$

and realize that the time of ascent is determined solely by the value of the critical frequency of the winding. We see from equation 47 that the oscillations on either side of the ascent have rapidly decreasing amplitudes and that their frequency coincides with the critical frequency ν.

If we compare the original incident jump on the incoming line with the wave shape in time of figure 12 within the winding, we see that because of the existence of the critical frequency the original steep front is flattened so that every element of the winding is gradually subjected to voltage, but that, on the other hand, the voltage temporarily exceeds the original value by about 12 per cent due to attenuated oscillations. If we draw the shape of the wave in space and not in time, the discontinuous jump of figure 13*a* splits into the flattened wave of figure 13*b*, which travels through the winding, and the remainder of figure 13*c*, which is reflected at the transition point. Figure 13*b* contains all subcritical oscillations, while figure 13*c* is made up of all supercritical oscillations.

Although the shape of the front of the penetrating wave of figure 13*b* is determined by the value of the critical frequency, the wave as a whole contains, as we see from figure 11, preponderantly lower frequencies. Since these lower frequencies travel with the common speed v_0 of equation 27, the spatial head-length H can be expressed to a good approximation by

$$H_0 = v_0\tau = \pi\frac{v_0}{\nu} = \pi w\sqrt{\frac{k}{c}} \qquad (49)$$

in which the critical frequency of equation 20 is introduced. We see that the length of the flattened front is a multiple of the wire length w of each winding element, if the internal capacitance k is larger than the ground capacitance c. The wave travels with this compact form through the whole winding. We realize, therefore, that the final effect of the interaction of all turns and coils of every winding consists in the flattening of the wave front by cutting off the steep portions of the original wave. The laws that hold for the traveling of waves within the extension of the winding and for their refraction and reflection at the ends remain the same as the well-known laws for smooth lines.

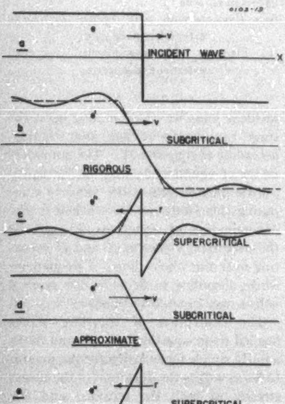


Figure 13. Subcritical and supercritical components of a steep-front wave

To follow the course of the waves graphically, it is not always convenient to draw the exact curved shapes of figures 13*b* and *c*, but it appears expedient to approximate them by the broken straight lines of figures 13*d* and *e*. These indicate that the subcritical penetrating wave contains mainly an inclined front H with a constant tail, and show that the reflected supercritical part consists chiefly of a short duplicate stroke with the original jump in its center.

With these preparations, it is easy to picture the performance at the beginning of a winding if a steep wave impinges upon it. We have only to superimpose at every instant the traveling wave e' within the turns, including the voltage $E/2$ at rest, and the exponential distribution caused by the reflected wave e'' within the end turns. For simplicity, we take as space constant for this reflected distribution the asymptotic value of equation 34, since the preponderant amount of the supercritical oscillations is co-ordinated with this fixed value. The ratio of the head length of the penetrating wave to the space constant of the reflected wave is then, using equations 34 and 49,

$$H_0 = \pi X_\infty \qquad (50)$$

Figure 14*a* represents the propagation of the voltage e' in several steps through the terminal. Figure 14*b* shows the attenuation of the reflected voltage e'' within the end turns for the same times. Corresponding, however, to the simplified straight-line representation of the wave shapes, the spatial attenuation is also linearized to straight lines with the space constant X_∞. In both graphs all states previous to time zero are drawn as dotted lines. Figure 14*c* represents the combined effect of both transmitted and reflected voltages and shows that with entrance of the original jump at time zero the voltage in the end turns suddenly jumps to an attenuated broken distribution, and also shows that the flat wave front then dissolves itself gradually and travels undisturbed from this time on throughout the winding.

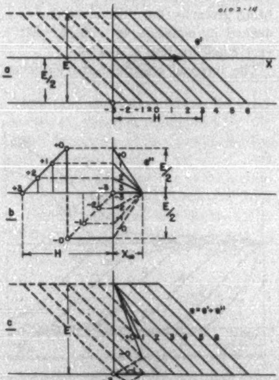

Figure 14. Entrance of a steep-front wave into a winding, in simplified form

We can now complete the picture by using the exact curves of the sine-integral function corresponding to figure 13*b* and *c* rather than figure 13*d* and *e*. Figure 15 shows the result. The small voltages preceding the arrival of the jump wave are now much more rounded. They are dotted also in this representation since they are caused mainly by our approximations, particularly of a constant speed v_0 for the complete wave, a supposition to which we shall return. We recognize from figure 15 that the wave within the winding forms at time zero an attenuated distribution with an initial space constant which is larger than X_∞ by 22 per cent. This voltage appears instantaneously with the arrival of the original jump wave at the terminal and is caused physically by the combined effect of the internal and ground capacitance of the winding. At first slowly and then progressively faster, there emerges from this initial shape a traveling voltage wave of smooth form which always keeps the terminal voltage constant but swings within the winding by 12 per cent below and above its final values. As a result not only the ends but also the interior of the winding are exposed to a considerable excess strain over the steady-state voltage stresses.

It is assumed in these drawings that the refraction factor for the traveling wave and the reflection factor for the reflected wave are equal. For most cases the surge impedance Z of winding is larger than that of the feeding line and Z increases, according to figure 9, even further as the critical frequency is approached. The refraction factor, there-

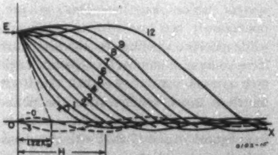

Figure 15. Distortion of a steep-front wave within the winding, in rigorous form

fore, approaches the value 2. The terminal capacitance, on the other hand, which loads the open end of the feeding line for supercritical frequencies, starts with small values, according to figure 9, for the neighborhood of ν and approaches a moderate value for most types of windings. Thus the reflection factor also approaches the value 2. Exact calculations show that the small differences caused by the finite values of Z and C do not distort our general picture. But naturally the final voltage E within the winding compared with that on the feeding line E_1 is always

$$\frac{E}{E_1}=\frac{2Z}{Z+Z_1} \tag{51}$$

Z_1 being the surge impedance of the line.

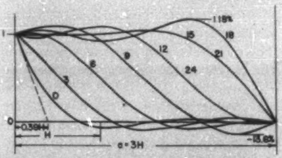

Figure 16. Arrival and reflection of the flattened wave at the grounded end of a winding

If the flat-headed traveling wave approaches the far end of the winding, perhaps the neutral point of a three-phase winding, it is reflected here according to familiar laws. Figure 16 represents several steps of such reflection for a grounded end and figure 17 for an insulated end, if we take arbitrarily the front length of the traveling wave as one-third of the whole phase length. If the winding is subdivided into only a moderate number of coils, the wire length w of each one is a considerable fraction of the phase length. We see then from equation 49 that the head length may become even larger than the phase length, depending entirely on the square root of the capacitances. The reflections which appear concentrated in figures 16 and 17 may thereby become more distributed over several phase lengths. This is preponderantly the case with transformers, while machine windings for the most part have so large a number of coils and such high ground capacitance that the front length is much smaller than the phase length. At all events, we recognize from figures 16 and 17 that with grounded end, the internal strain of the windings near the neutral is doubled, while with insulated end the strain to ground is doubled. By action of the overswinging of the sine-integral curve, as in figure 12, there are created excess voltages of 18 per cent over the final state with both grounded and insulated neutral. In every case small forerunner voltages precede the traveling front of the wave and cause negative stresses of 10–20 per cent at or near the neutral point. The shape and the speed of the traveling-wave front do not remain so uniform in the neighborhood of the neutral point as in the free portions of the winding, since the reflected forerunner voltages cause some distortion of both shape and speed.

If we compare these calculated distributions of voltage with the well-known results[13,14] of cathode-ray oscillograms, we realize that not only the general performance of figures 16 and 17 is in good agreement with the experimental results, but that even refinements, such as the often observed negative voltage forerunners of the penetrating waves, are well given by our representation.

The formulas and figures developed until now represent the voltage stress to ground of every point of the winding. The straining of the internal insulation, however, is determined by the voltage between adjacent turns, layers, or coils. If we reckon these internal voltages over the wire length w of each element, the maximum internal stress caused by the traveling wave with a front length H_0 is

$$\epsilon'=\frac{w}{H_0}E=\frac{E}{\pi}\sqrt{\frac{c}{k}} \tag{52}$$

Every internal element of the winding is successively exposed to such excess voltage, the duration of the exposure being given by the time of ascent τ, as defined by equation 48, τ being only a very small fraction of a second.

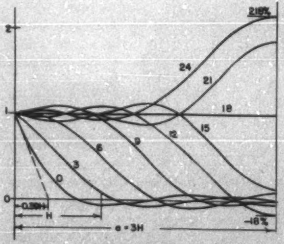

Figure 17. Arrival and reflection of the flattened wave at the insulated end of a winding

The terminal coils or turns, however, are exposed, in addition, to the strain of the standing exponential distribution which has, according to figure 14b and c, a space constant X, and an amplitude $E/2$. Its maximum stress is therefore

$$\epsilon''=\frac{w}{X}\frac{E}{2}=\frac{E}{2}\sqrt{\frac{c}{k}} \tag{53}$$

and thus the combined value of the stress near the terminal is

$$\epsilon=\epsilon'+\epsilon''=\left(\frac{1}{2}+\frac{1}{\pi}\right)E\sqrt{\frac{c}{k}}=0.818E\sqrt{\frac{c}{k}} \tag{54}$$

while its ratio to the internal stress has the fixed value

$$\frac{\epsilon}{\epsilon'}=1+\frac{\pi}{2}=2.57 \tag{55}$$

The duration of the terminal excess strain is only $\tau/2$, since we see from figure 14b and c that it lasts only half the time required by the wave head traveling over the junction.

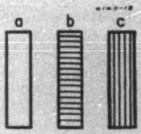

Figure 18. Cross sections of windings

(a)—Given area
(b)—Elements with small internal and large external capacitance
(c)—Elements with large internal and small external capacitance

In every case, we have to remember that E is the final voltage of the refracted wave within the winding which may approach twice the voltage E_1 of the incident jump wave, depending upon the surge impedances of line and winding, according to equation 51. The numerical factor of equation 54 may be in reality a little greater than 0.818, since in computing this factor we have taken in the denominators of equations 52 and 53 the maximum values of X and H occurring over the whole range of frequencies while, according to figure 9, the average values may be slightly smaller.

The conception of traveling waves has led us in equations 48, 52, and 54 to a fairly simple formulation for the magnitudes as well as the durations of the excess stresses of both the terminal and the interior elements. Large internal capacitance reduces the stresses but increases the duration, while small ground capacitance decreases the stresses without influencing the duration. Thus, for extensive self-protection of the winding every turn, every layer, and every coil should extend toward its neighbors with flat sides as wide as possible and toward ground with narrow sides as small as possible. If the winding area is oblong, as in figure 18*a*, it is evidently better to arrange the elements not short sided as in figure 18*b*, but long sided as in figure 18*c*. If by large internal capacitance k the head length H and the space constant X become much larger than the winding length a, the excess voltages decrease towards zero and the problem of the distribution of voltage thus becomes a static one. This is the aim of every surge-proof design of windings.

If an incident wave has not a discontinuous front, as in figure 10, but an already flattened head, its spectral distribution differs somewhat from figure 11; but as long as its front is steeper than the head H which enters the winding, only the higher frequencies above the critical frequency are influenced. The subcritical frequencies retain the same amplitudes as in figure 11 and travel undisturbed through the winding. Thus we recognize that for any incident wave shape those parts which are steeper than corresponds to the critical head length H are cut off and reflected at the terminal.

A capacitance C_p connected to the junction[13] of figure 10 smooths off every steep jump to a gradually ascending front with the well-known time constant

$$T=\frac{C_p}{\dfrac{1}{Z_1}+\dfrac{1}{Z}} \tag{56}$$

We can produce, therefore, protection against the terminal excess stresses e'' by choosing such capacitance that T becomes equal to or larger than the time τ of ascent. Then there remains only the traveling part of the wave with uniform impulse strain over the whole winding. By putting equation 56 equal to equation 48, we obtain as minimum amount of such protective capacitance

$$C_p=\tau\left(1+\frac{Z}{Z_1}\right)w\sqrt{ck} \tag{57}$$

We see that this value is a multiple of the apparent terminal capacitance C_∞ of equation 41.

Flattening of the Propagating Wave Front

The traveling velocity v of every partial oscillation within the winding depends upon its frequency ω, and thus composite waves in coils exhibit the phenomenon of dispersion. While long waves with low frequency, according to equation 26, run with a definite high velocity, the faster oscillating partial waves travel with slower speed and remain therefore behind the longer waves. Although it is possible to formulate mathematically an integral which takes account of the influence of this dispersion on the front shape, it seems impossible to give this a practically useful form. We will follow here, therefore, a geometrical presentation which supplies us, if not with a rigorous, at least with an approximate solution which is simple and easy to survey.

Table III. Flattening of the Wave Front H_x With Traveled Distance x

H_x/H_0	1	1.1	1.2	1.5	2	3	5	8	10	15
x/H_0	1	1.88	2.66	5.8	15	53	250	1,020	2,000	6,750

If the front of our uniformly ascending wave, according to figure 19, travels over a winding length x, it will become distorted, as only the fast-running waves with the speed v_0 carry forward the beginning of the ascending head. In a certain time t the first point of the wave front has moved over a distance

$$x=v_0t \tag{58}$$

During the same time all slower-moving oscillations, however, as for example, one of the frequency ω and the velocity v, have moved only over a distance x_ω which is, using equations 26 and 28,

$$x_\omega=vt=v_0t\sqrt{1-\left(\frac{\omega}{\nu}\right)^2} \tag{59}$$

Therefore the head in front of the distance x_ω will not contain any oscillation of frequency higher than ω. The length of this head, figure 19, is, using the last two equations,

$$H_x=x-x_\omega=x\left[1-\sqrt{1-\left(\frac{\omega}{\nu}\right)^2}\right] \tag{60}$$

Now the head length of our flattened wave is in principle determined by the highest frequency of the partial oscillations contained within the wave. For the critical frequency ν the co-ordination is given in equation 49, where the front H_0 corresponds to all oscillations up to the frequency ν, as shown in figures 11 and 12. But if the head of the wave is built up only by oscillations up to a frequency ω, as in figure 20, the head length is correspondingly

$$H_x=\frac{\pi v_0}{\omega}=\frac{\nu}{\omega}H_0 \tag{61}$$

where the last term expresses the ratio to the head length H_0 at the terminal of the winding. If we insert now the frequency ratio of equation 61 in equation 60, we obtain for the head length

$$H_x=x\left[1-\sqrt{1-\left(\frac{H_0}{H_x}\right)^2}\right] \tag{62}$$

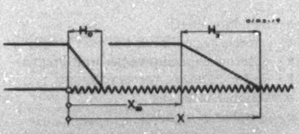

Figure 19. Further flattening of the propagating wave front along the winding

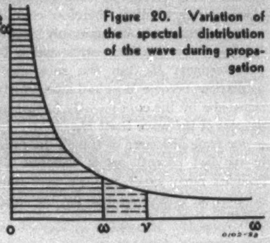

Figure 20. Variation of the spectral distribution of the wave during propagation

This relation contains only the original front length H_0, the distorted front length H_x, and the distance x through which the beginning of the wave has traveled over the winding. The equation is of the fourth degree in H_x and therefore difficult to solve. However, if we determine the distance x in units of the original front length H_0, we obtain the much simpler relation

$$\frac{x}{H_0}=\frac{\dfrac{H_x}{H_0}}{1-\sqrt{1-\left(\dfrac{H_0}{H_x}\right)^2}}$$

$$=\left(\frac{H_x}{H_0}\right)^2\left[1+\sqrt{1-\left(\frac{H_0}{H_x}\right)^2}\right] \tag{63}$$

We see that the original front length $H_x=H_0$ is related in this representation to the traveling distance $x=H_0$ of the fast-traveling waves at the beginning of the head. Table III shows some related values of head length H_x and traveled distance x and we see that the head length increases only very slowly with greater traveled distance. It needs to travel over a winding length of 15 original head lengths in order to flatten out the wave front to twice its original length; and for increasing the front length considerably it needs to travel over some hundred and even some thousand original head lengths.

The initial head length of waves in transformer or machine windings is usually between a large fraction and a small multiple of the winding length. The progressive flattening of the wave front is therefore moderate while traveling to and fro over only one phase length. If, however, we pursue the repeated travel of such a wave over the winding with numerous reflections at its ends, we see that the wave will become flatter and flatter. Free voltage or current oscillations of such windings therefore contain more or less sharp corners only during the first few oscillations corresponding to the steepness H_0, but the subsequent oscillations become more and more nearly sinusoidal by the continuously increasing flatness of the wave front H_x.

For large distances of travel, the ratio in the last parentheses of equation 63 becomes fairly small, and we may thus develop an approximation for the head length

$$\frac{H_x}{H_0}=\sqrt[3]{\frac{1}{2}\frac{x}{H_0}} \qquad (64)$$

which shows that the flattening effect increases as the cube root of the distance. Accordingly, the internal stresses of the insulation between turns and coils, which are inversely proportional to the front length, become approximately

$$\frac{\epsilon_x'}{\epsilon_0'}=\frac{H_0}{H_x}=\sqrt[3]{2\frac{H_0}{x}} \qquad (65)$$

Their exact distribution is shown in figure 21, where over the first head length H_0 there is added the exponential distribution of the reflected wave, according to equation 55. The total curve follows closely the numerous experimental results concerning the internal stresses in uniformly distributed windings of transformers and machines.

If one tries to determine experimentally the traveling speed of waves of any shape, it is necessary to be very cautious because, according to our conclusions, only the beginning of the front has a definite and constant velocity. The center or the end of a wave front, and similarly any other part of a more complex wave has, however, a decreasing speed along the winding, depending on the position of the point in question within the wave. Only sinusoidal waves have a well-defined velocity as determined by equation 26 and they are therefore particularly suited to determine the velocity of propagation.

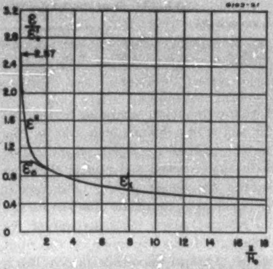

Figure 21. Distribution of internal stresses, caused by an impact, over the length of a winding

Summary

On the basis of a new investigation of the electromagnetic coupling of turns and coils, a differential equation of far-reaching validity is derived in which the inductive and capacitive effects of windings for rapid transients are related to the steady-state values. The spatial behavior of standing and traveling waves is considered, showing the existence of a critical frequency beyond which no harmonic oscillation can penetrate deeply into the winding. This causes a decrease with frequency of the traveling speed of waves which is verified by experiments on transformers.

By action of the critical frequency, an incident steep impact penetrates into the winding with a flattened front while the rest of the wave is reflected, causing a steeper terminal distribution of voltage. The reflection, at the neutral point of windings, of the traveling wave with its oscillating forerunners is derived and is found to be in accordance with many experimental results. Propagation through long uniform coils causes a continuous further flattening of the wave front.

List of Special Symbols

a —winding length
c —ground capacitance per unit length
k —internal capacitance per unit length
l —self-inductance per unit length
m—number of waves
n —number of element
r—reflected wave
v—wave velocity
w—wire length of element
H—head length
K—abbreviation
T—time constant
X—space constant
α—wave density
β—attenuation factor
ϵ—internal voltage
λ—self-inductance of single element
λ—wave length
μ—mutual inductance of elements
ν—critical frequency
τ—time of ascent

The Type CB Impregnated-Paper Cable

SAMUEL J. ROSCH
ASSOCIATE AIEE

SINCE the importance of low dielectric loss in impregnated-paper cable was first recognized,[1] attention has been constantly directed to securing lower power factor during the life of the cable. Although considerable progress has been made by close co-operation between cable manufacturer and supplier of the basic ingredients, instability of the insulation may result from:

(*a*). Abnormal increases in power factor and dielectric loss.

(*b*). Metallic soaps, due to the catalytic action between the impregnating compound and the metals within the cable.[2–8]

(*c*). "Wax" due to internal ionization.[9–11]

(*d*). Abnormal ionization forming configurations referred to as "tree" discharges.[12]

Some of the means advocated in the past for overcoming insulation instability were the use of:

1. An anti-oxidant within the impregnating compound.[13]
2. A tin coating on the conductor to retard catalysis.[14]
3. Rosin blended with mineral oil.[15]

It is the object of this paper to present a progress report on a new method for attacking the problem of insulation instability by the use of carbon-black protected (or type *CB*) cable.[16]

Theory

The electrical characteristics of an insulating oil can be improved by contact with activated carbon during filtration.[17] Carbon black of the adsorbent type, added to an insulating oil and the mixture agitated also improves the electrical properties by imparting a purifying effect and retarding the formation of deteriorating bodies.[18]

Although initially of high quality, the oil when placed under heat and electrical stress becomes subject to deterioration due to the fact that nearly all antioxidants are solid bodies which may be partially but not completely soluble in oil. When the insulation consists of paper impregnated with oil containing an antioxidant, the paper may act as a partial filter for these solid bodies.

To secure definite chemical and electrical stabilization, the means employed should be effective during the life of the cable and remain in its original position. One means for accomplishing this is to incorporate highly adsorbent carbon black into paper during the pulp stage and to place this carbon-black paper in the cable structure. Standard methods of cable processing are then followed. Inherently, the carbon-black paper tapes shield from the electric field all materials which they may adsorb. In addition, they tend to smooth out the configuration of stranded conductors and thereby reduce the maximum stress. This is the fundamental design of the type *CB* cable.

Experimental Verification of Theory

Test 1. Effect of Carbon-Black Paper on Oil and Impregnated Paper Stability

To determine the protective effect of the presence of carbon-black paper on impregnating oil, three beakers were filled with standard cable impregnating compound. Into one beaker was placed a small strip of carbon-black paper; into the second, standard insulating paper; while the third beaker contained only oil. In this condition, the three beakers were placed in an aging oven and exposed to the oven atmosphere for ten days at 85 degrees centigrade.

Table I. Effect of Presence of Standard Versus Carbon-Black Paper on Stability of Oil and Impregnated Paper

Aged Ten Days at 85 Degrees Centigrade

Aging Condition	Power Factor at 85 Deg C 50 Volts Per Mil (Per Cent)	Insulation Resistivity at 85 Deg C (Megohms $\times 10^6$ Cm)
Oil initially	0.2198	127.0
Oil aged alone	0.6407	29.7
Oil aged with standard cable paper	0.4690	45.8
Oil aged with carbon-black paper	0.3930	50.0
Impregnated paper before aging	0.25	10,000
Impregnated paper after aging alone	0.715	2,270
Impregnated paper after aging in presence of carbon-black paper	0.664	4,600

Similar tests were conducted with strips of five-mil impregnated wood-pulp paper. To one of the beakers was also added a small strip of five-mil carbon-black paper.

The results are given in table I. The data indicate that the presence of carbon-black paper tended to retard the normal rate of deterioration of oil and impregnated paper.

Test 2. Effect of Carbon-Black Paper With Stranded Conductors

Four cable models similar to those used by Whitehead[19] were made with conductors of highly-polished, number 4/0 American wire gauge 19-strand bare copper cables having 14 layers of 5-mil wood-pulp paper. On two models the first two tapes were of five-mil carbon-black paper, thereby these two models were deprived of 10-mils of insulation. However, all models were considered to have 70 mils of insulation for stress and other computations.

Set *A*, consisting of a standard and a carbon-black paper model was aged for ten days at 100 degrees centigrade and 100 volts per mil. Set *B* was aged for 20 days at 85 degrees centigrade to more nearly approach maximum operating temperatures. (For further details on the construction of models and technique of measurements, refer to the appendix.)

Test results are given in table II. The data indicate pronounced stabilizing effect of the two carbon-black tapes next to the conductor. After the severe aging at 100 degrees centigrade (set *A*), the power factor of the *CB* model is only half that of the standard while the insulation resistance is four times as high.

The same stabilizing tendency is evident with 20 days aging at 85 degrees centigrade (set *B*). The power factor of the *CB* model is less than one-third while the insulation resistance is approximately twice that of the standard.

The models were not carried to failure, to permit tape-by-tape examination. Figure 1 illustrates paper tapes taken from set *A*. In the standard model, pronounced stress marks are visible in all of the tapes up to the tenth from the conductor. In the *CB* model, none of the tapes shows overstressing. Tapes from the standard model also show marks parallel to the horizontal axis of the tapes,

---

Paper 40-121, recommended by the AIEE committee on power transmission and distribution, and presented at the AIEE summer convention, Swampscott, Mass., June 24–28, 1940. Manuscript submitted April 12, 1940; made available for preprinting May 20, 1940.

Samuel J. Rosch is manager, insulated products development, Anaconda Wire and Cable Company, Hastings-on-Hudson, N. Y.

The author is very grateful for the assistance received in the preparation of this paper from the members of the engineering, laboratory, and testing staffs of his company and wishes to make specific acknowledgments to A. C. Connell, B. Jove, and E. W. Greenfield.

[1] For all numbered references, see list at end of paper.

which correspond to overstressing in the butt spaces between adjacent convolutions.

Tapes from set *B*, showed no stress markings on either model. On the conductor of the standard model there were black helical lines due to overstressing of the oil in the butt spaces, as shown in figure 2.

Test 3. Effect of Carbon-Black Paper Versus Tinning of Conductor

A study was made of the relative protective effects in cable models of carbon-black paper versus conductor tinning. Cable models were prepared with number 4/0 American wire gauge, stranded conductors. The standard model had each strand double tinned; the *CB* model had bare strands.

Both models were aged for ten days at 125 degrees centigrade and 125 volts per mil. The aging conditions were made severe to accelerate the formation of deteriorating bodies due to catalysis, oxidation, electronic bombardment, or other effects.

Figure 3 demonstrates the superiority of the carbon-black tapes when compared to double tinning of the conductor.

A study of the radial power factor after aging was made since this method has been proposed for determining distribution of deterioration through the insulation.[20, 21] The results in figure 4 indicate that double tinning of the conductor afforded very little protection. These results substantiate findings reported in the literature.[22]

Table II. Aging Characteristics of Standard and CB Models With Stranded Conductors

Aging (Days)	Temperature (Deg C)	Standard Model: Power Factor (Per Cent) 50 Volts Per Mil	Standard Model: Power Factor (Per Cent) 100 Volts Per Mil	Standard Model: Insulation Resistance (Megohms ×10⁵ Cm)	CB Model: Power Factor (Per Cent) 50 Volts Per Mil	CB Model: Power Factor (Per Cent) 100 Volts Per Mil	CB Model: Insulation Resistance (Megohms ×10⁵ Cm)
Set A—Aged 10 days at 100 degrees centigrade and 100 volts per mil							
Initial	22.0	0.369	0.387	6,000	0.307	0.316	6,721
	100.8	0.600	0.715	3,120	0.549	0.587	4,270

	100.0	2.210	2.211	171	0.834	0.703	310

Test 4. Effect of Carbon-Black Paper With Smooth Cylindrical Conductors

Since all of the preceding tests had been conducted on models made with stranded conductors, it was considered desirable to conduct similar tests on highly-polished, bare solid copper conductors. This serves to eliminate strand stress considerations and also reduces copper-oil interface area.

Accordingly, standard and *CB* models were prepared with highly-polished number 4/0 American wire gauge, bare solid conductors. These models were subjected to aging at 100 degrees centigrade and 100 volts per mil for 41 days. The results are plotted in figure 5.

Figure 5 shows that at 100 degrees centigrade there is a definite superiority in the *CB* construction. At room temperature the power factor remained about the same.

Test 5. Effect of Adsorptive Index on the Protective Powers of Carbon-Black Tapes

Colloidal carbon, or "carbon black" is the result of impinging a natural-gas flame against a relatively cool surface.[23] The colloidal size can be varied over a considerable range by control of several factors such as the nature of the gas, size and shape of flame, distance from impinging surface, etc. Changing the colloidal size and surface complex of the carbon-black particle will also change a number of its properties such as, conductivity, adsorptive index, and pH values. As an illustration, the pH values of carbon black can be varied from 2 to 11.[24]

Table III. Construction Details of Standard and CB Cables

Single Conductor, 350,000 Circular Mils, 19/64 Inch Paper, 7/64 Inch Lead

		Number of Carbon-Black Tapes**	
Length No.	**Shielding Tape***	**Adjacent to Conductor**	**Adjacent to Sheath**
1	None	None	None
2	None	3	None
3	None	None	2
4	None	3	2
5	Copper tape	None	None
6	Copper tape	3	None
7	Copper tape	3	1

* The shielding tape consisted of a 0.003-inch bare perforated copper tape intercalated with a 0.005-inch high-density manila rope paper tape on lengths numbers 1 to 6 and with a 0.005-inch carbon-black paper tape on length number 7.

** The over-all diameter of each insulated conductor was the same. Each carbon-black paper tape therefore displaced a similar number of insulating tapes.

To determine the relative effectiveness of various grades, carbon-black papers were produced with a range of adsorption index and particle size. Models were made having these different types of carbon-black tapes applied in two layers directly over the conductors. Model *E*-1 was made with standard insulating tapes only. The models were aged for ten days at 100 degrees centigrade and 100 volts per mil.

Figure 6 represents the before and after power factor values of the various models plotted against the adsorption indices of the carbon blacks used. This figure not only brings out the extent of the protection afforded by the various carbon-black tapes in contrast with the unprotected *E*-1 model, but also illustrates the remarkable stabilizing effect afforded by the higher-adsorptive-index carbon-black tapes used in models *E*-2 and *E*-5.

Reduction of Theory of Practice

Test 6. Effect of Positioning of Carbon-Black Paper on Dielectric Properties of Single-Conductor Cable

A study was made of the effect on the dielectric properties of a series of cables containing carbon black at different portions of the cable structure. Table III shows the construction details. Table IV shows the results of the high-voltage time tests.

Table IV indicates that the constructions which had carbon-black tapes adjacent to the conductor, namely, lengths numbers 2, 4, 6, and 7, gave the highest voltage life. Length number 4, which had no shielding tape but had three *CB* tapes adjacent to the conductor and two adjacent to the sheath, yielded the highest equivalent one-hour dielectric strength ("life") of all the constructions tested. This is of interest when it is considered that it contained five carbon-black tapes which displaced five insulating tapes, so that compared to lengths numbers 1 and 5, it had only 91 per cent effective insulation thickness.

Figure 7 shows the initial power factor-temperature characteristics. Figure 8 gives the radial power-factor measurements made on samples from these cables *after* they had been subjected to the high-voltage time tests.

In figure 7, it is noted that the cables which had carbon-black tapes adjacent to the conductor show the lowest power factor at elevated temperatures.

In figure 8, a steep rise in power factor is noted adjacent to the *conductor* of lengths numbers 1, 3, and 5, which had no carbon-black tapes applied over the con-

Smooth cylindrical conductors

Standard versus *CB* models

ductor. Lengths numbers 2, 4 and 7 showed practically no rise. Adjacent to the *sheath* where carbon-black tapes were present, no rise in radial power factor is noted. Lengths numbers 4 and 7 with the maximum number of carbon-black tapes exhibited the most uniform radial power-factor characteristics.

Test 7. Effect of Carbon-Black Paper in Three-Conductor 28-Kv Shielded Cable

To study the effect of carbon-black paper on the electrical characteristics of three-conductor cable, two lengths of three-conductor 350,000-circular-mil sector shielded-type cable were made, each conductor insulated with 20/64-inch total wall of paper. Length *A* was of standard construction. Length *B* had the three tapes adjacent to each conductor replaced by carbon-black tapes. The intercalation of the shielding and binder tapes of length *B* was carbon-black paper; length *A*, manila-rope paper. Lengths *A* and *B* were impregnated in the same tank after which they were covered with an 8.5/64-inch wall of lead.

Figure 9 shows typical power factor versus temperature and ionization curves.

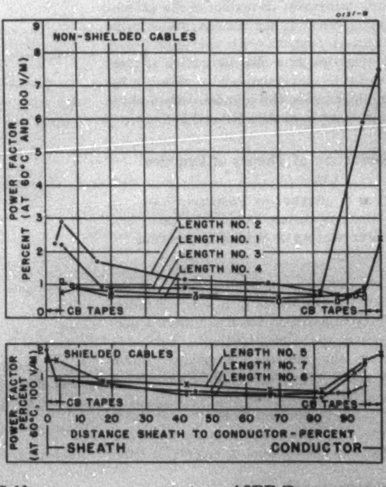

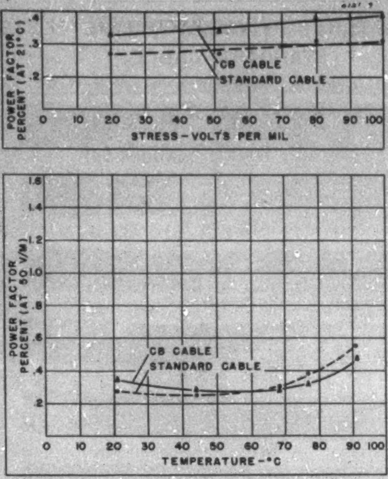

Figure 9. Ionization and power factor characteristics—unaged

Three-conductor, 350,000-circular-mil, sector, 28-kv shielded

Standard versus *CB* cables

Both constructions have excellent initial power factor values.

Figure 10 shows the appearance of some of the tapes removed from both cables after the high-voltage time test of 350 volts per mil applied until breakdown. The standard cable failed under the lead after 155 minutes and the *CB* cable had a terminal failure after 490 minutes.

Figure 11 shows radial power-factor measurements on the cables *after* they had been subjected to the high-voltage time test. In the standard cable, a rise in power factor is noted adjacent to the conductor. In spite of the considerably longer time at which the *CB* cable was subjected to the 350 volts per mil stress (490 versus 155 minutes), the tapes taken from the same region show uniformly low values with no upward trend. The reasons for these results are demonstrated in figure 10.

Test 8. Cyclic Aging Data on Three-Conductor, 28-Kv Shielded Cables

To further study the effectiveness of carbon-black tapes in maintaining insulation stability, two 45-foot lengths of three-conductor cable described in test 7 were subjected to a cyclic aging test.

After the ends were fitted with oiltight terminals, the two lengths were laid in separate wooden troughs supported in a horizontal position about three feet above a concrete floor. Combination vacuum and pressure gauges were attached to the respective sheaths at the center and at each end below the terminal. About one foot of each cable protruded from the trough at each end in a drooping position. The ends of each trough were sealed by tightly packing with glass wool. Thermocouples were attached at five points on the sheath of each cable and connected to a Leeds and Northrup Micromax temperature-recording instrument. The conductors of each cable were connected in series so that the loading current would be the same for both cables. Power-factor readings were made on each cable in three-minute intervals by a Leeds and Northrup recording power-factor bridge having a double scale with ranges in power factor of 0 to 5 per cent and 0 to 20 per cent. The shift from the low to the high scale is automatic.

387	1.15	0.83	0.32
394	0.80	0.65	0.15
401	0.95	0.77	0.18

The procedure consisted in the continuous application of 31.3 kv between each conductor and sheath and a simultaneous current loading which was maintained for 8 hours during each 24-hour cycle. The test voltage corresponded to an average stress of 100 volts per mil on the basis of total paper thickness.

The test results are given in figure 12. The cables under test are shown in figure 13 and the recording instruments in figure 14.

The cyclic-loading test was started on February 20, 1939. The standard cable failed during the 202d day which occurred on Saturday, September 9, 1939. The insert in the upper right-hand corner of figure 12, shows the rise in power factor and sheath temperature just prior to failure as recorded by the recording instruments. At the time of writing this paper, the type *CB* cable was still on test.

The published literature on cyclic-loading tests of cable indicates that the maximum sheath temperature generally used was 65 degrees centigrade, with many of the tests between 40 and 50 degrees centigrade. It is, therefore, apparent that, since the average sheath temperature was about 75 degrees centigrade with some

days as high as 90 degrees centigrade, this cyclic-aging-test was very severe. A conservative estimate would place the average conductor temperature of both cables at about 90 degrees, with high points of about 105 degrees during the days when the sheath temperature was between 85 and 90 degrees centigrade.

In general, correlation can be noticed between the rise and dip of the sheath temperature, pressure, and power factor curves of the standard cable during each cycle. The power factor of the type *CB* cable, both before and after heating, is practically constant up to the 215th day and from then on, there is a period in which the sheath temperatures were maintained at their highest values (between 85 and 90 degrees centigrade). It is at the beginning of this period that the power-factor values seem to follow the rise and dip of the sheath temperatures. However, the "before heating" power-factor values remain substantially constant until the 342d day when the values shifted to a higher level.

Table V shows ionization factors of the type *CB* cable from the 318th day at the end of the cooling cycle.

Some ionization was noted from the 346th day and by examining the corresponding period in figure 12, it will be seen that this coincides with the shift in power factor. From the 359th day, the ionization factor has been continuously decreasing thus indicating that the stability has not been impaired.

The cyclic aging of the type *CB* cable will be continued until evidences of instability have been detected or the test has to be discontinued.

Test 9. Data on Commercial Order of Three-Conductor 15-Kv Type CB Shielded Cable

An overlength of 250 feet was added to an order of 10,000 feet of three-conductor, 600,000-circular-mil sector type *CB* shielded cable for 15-kv grounded neutral. The insulation on each conductor included three carbon-black tapes adjacent to the conductor and 2 adjacent to the shielding tape, the carbon-black tapes being considered part of the total required thickness of 203 mils. The cable was covered with a 125-mil wall of lead.

Figure 15 contains the results of power factor and dielectric loss determinations.

Test 10. Data on Commercial Order of Three-Conductor 35-Kv Type CB Shielded Cable

An overlength of 80 feet for Association of Edison Illuminating Companies sample tests was added to a commercial order of three-conductor 350,000-circular-mil sector type *CB* shielded cable rated at 35-kv grounded neutral. The insulation design was the same as for test 9 except the total paper thickness was 375 mils. The cable was covered with a 125-mil wall of lead.

The power factor and dielectric loss values are given in table VII. The results of the high-voltage time test are given in table VIII.

Test 11. Data on Three-Conductor 13-Kv Type CB Shielded Cable With 130 Mils of Insulation

The high dielectric strength and remarkable stability obtained with type *CB* cable have indicated a possibility of a reduction in present insulation thickness. A length of three-conductor 500,000-circular-mil sector type *CB* shielded cable with 130-mil total paper thickness was furnished to the Commonwealth Edison Company for experimental purposes. From the results of tests on this and other thicknesses, data are being secured to determine the proper thickness for 13-kv grounded-neutral operation. The standard thickness of insulation for this voltage is 172 mils. The number of carbon-black tapes applied was the same as that described under tests 9 and 10. The data reported below were obtained in the Commonwealth Edison laboratories.

Cyclic aging tests were conducted on a 111-foot length of this cable from October 9 to November 6, 1939, and consisted in the continuous application of 24 kv, three-

phase, for 28 days with superimposed load cycles. Figure 16 shows the data obtained as reported by Herman Halperin. For comparison, similar data obtained on standard belted cable are reproduced from his recent AIEE paper.[25]

The power factor and ionization curves given in figure 16 for the belted cable, both before and after each heating cycle, are typical of excellent quality of cable, especially when consideration is given to the high temperatures to which this cable was subjected. However, when these data are compared to those on the type *CB* shielded cable, the superiority of the latter is readily apparent.

Figure 17 represents the composite power factor-temperature relation taken at all the temperatures during the cyclic aging test including the initial values. This indicates remarkable stability.

Future Work

This paper is a progress report. Additional work is under way to apply the fundamental principle of carbon-black protection to the solution of insulation stability problems of other types of insulated conductors and electrical equipment.

Conclusions

The use of carbon-black paper offers a simple and unique practical means for increasing the useful sphere of solid-type impregnated-paper-insulated cable.

Appendix

Model Accelerated Test Unit. A standardized cable model 16 inches in length having a number 4/0 American wire gauge conductor and a 60 to 75-mil wall thickness of insulation is used as a basis of all constructions. Conductor shape is optionally round or sector and either stranded or solid. Insulation wall is lathe wound, butt lapped with 60/40 overlay. Seven inches precalculated sloped end reinforcements permit maximum operating voltage of 30 kv. The measuring electrode is 5 inches in length provided with $1^{1}/_{2}$-inch overlapping guards.

Treating and Testing Equipment. Monel-metal storage and degasser tanks equipped with vacuum pump, heaters, resistance thermometers, and atomizing device are used for properly storing, degassing, and dehydrating the impregnant. The treated oil is piped to four horizontal monel-metal tanks in which the dry models are mounted. Once the models are installed and sealed in these test tanks all operations of drying, impregnating, and testing are controlled by external means.

Dielectric Measurements. Power-factor and dielectric-constant measurements are made using a Leeds and Northrup modified Schering bridge: power-factor accuracy, 0.00001 ± 0.000005; power-factor sensitivity, 0.000005; capacitance accuracy, ±0.25 per cent. Insulation resistance measurements are made with a guarded high-sensitivity d-c galvanometer circuit readable to 5×10^{6} megohms.

Tape-by-Tape Tests. Tape power-factor measurements are made at 100 volts per mil stress and at 60 degrees centigrade using a balance-pressure type cell with rigid six by three-eighths inch guarded measuring electrode.

Cyclic Aging Measurements. Measuring equipment in the cyclic-aging laboratory is built around the Leeds and Northrup automatic power-factor recorder having two scales: 0 to 5 per cent and 0 to 20 per cent. Low-scale accuracy is ±0.03 per cent with sensitivity at 0.01 per cent. High-scale accuracy is ±0.15 per cent and sensitivity, 0.1 per cent. A Leeds and Northrup 16-point recording thermocouple potentiometer records sheath temperatures to a maximum of 100 degrees centigrade.

A Study of Short-Time Ratings and Their Application to Intermittent Duty Cycles

R. E. HELLMUND
FELLOW AIEE

P. H. McAULEY
ASSOCIATE AIEE

VARIOUS American standards for electrical apparatus provide, in addition to continuous ratings, certain short-time ratings, based on 5-, 15-, 30-, and 60-minute runs with the apparatus starting cold. Usually these short-time runs do not correspond to conditions met in service; for example, a motor very seldom starts cold, operates for a limited period of time, and then remains at rest until it has cooled to ambient temperature. Often these short-time ratings are applied to intermittent loads, such as shown in figure 1, in which T represents the total time for each cycle of operation; $T_r = kT$, the running time; and $T_i = (1-k)T$, the time the motor stands still. Since the short-time ratings do not indicate the type of operating cycle with varying values of T, k, and operating current I, for which these ratings are suitable, suggestions have been made from time to time to establish standard intermittent load ratings, especially for motors. Efforts along these lines have so far not led to any definite action because it is difficult to find practical standard provisions applicable to the many variations encountered in operating cycles. Furthermore, the present standard short-time ratings are so simple and convenient for acceptance-test ratings that there naturally is considerable hesitancy in adopting a complicated system of intermittent ratings. This raises the question of the possibility of devising various reasonably simple means for applying short-time ratings to intermittent load conditions without resorting to time-consuming temperature calculations, for instance, those used in the application of railway motors. In many industrial applications the cost of these calculations would be entirely out of proportion to the total cost of the motor and any slight saving in the size and cost of the motor resulting therefrom.

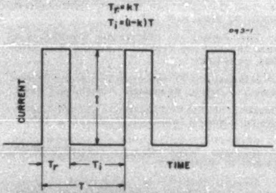

Figure 1. During the operating cycle of total time, T, the running period is $T_r = kT$ and the idle period is $T_i = (1-k)T$

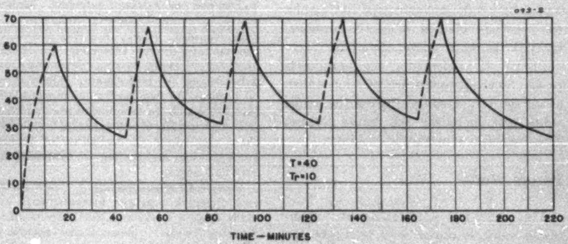
Therefore, this paper discusses a method for applying short-time ratings to intermittent service. It will also very briefly touch upon another application problem, namely, the co-ordination of the control and similar auxiliary apparatus and the wiring for short-time rated apparatus used for intermittent loads. To arrive at a solution of the problem, a few limiting values, somewhat arbitrary but at the same time reasonably logical, will be selected. The first is that the rms current I during the operating period of the cycle should be substantially that for the short-time rating, or at least not exceed it appreciably. With this assumption, the variables are reduced to the total time T of the cycle and the ratio $k = T_r/T$. Also for the purpose of this analysis, applications are divided arbitrarily into three main types of duty cycle.

Time-Temperature Curves

Figure 2 represents an attempt to determine by test an operating cycle giving the same maximum temperature rise as that specified for the short-time rating. A motor susceptible to various ratings between $^3/_4$ and 1.1 horsepower was tested to give 60 degrees centigrade temperature rise by resistance for a 15-minute period. Subsequently the motor was operated at the same current with an idle period of 30 minutes and a running period of 10 minutes. During subsequent cycles the maximum temperature rise gradually increases to about 70 degrees centigrade. The cycle must be changed

Figure 2. The duty cycle for this temperature test at the 15-minute rating current consisted of a 15-minute run followed by a cycle with T = 40 and k = 0.25. The heating sections of the curve are interpolated



Paper 40-93, recommended by the AIEE committees on electrical machinery and standards, and presented at the AIEE summer convention, Swampscott, Mass., June 24–28, 1940. Manuscript submitted April 23, 1940; made available for preprinting May 20, 1940.

R. E. HELLMUND is chief engineer for the Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.; P. H. MCAULEY is in the engineering laboratories and standards department of the same company.

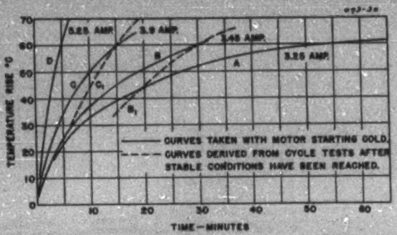


Figure 3a. The heating curves of a motor for 5, 15, 30, and 60-minute ratings starting cold are shown. When the motor parts are heated to stable operating conditions, the dotted curves apply for the same currents

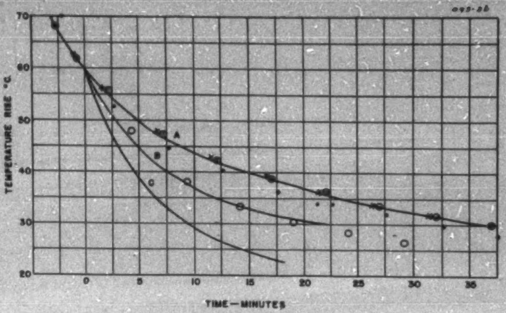

Figure 3b. The cooling curves depend on the time from a cold start, as well, the rate of cooling depending on the running time and on temperature conditions throughout the motor

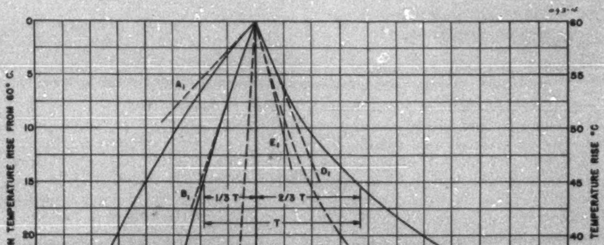
C—Following continuous test at 5.25 amperes lasting 5 minutes

if the limiting temperature rise of 60 degrees is not to be exceeded. An attempt to obtain data for a great many different load conditions by such a "cut and try" method of testing would be very costly and time-consuming and for a comprehensive study, various derivations should be made from suitable time-temperature curves.

Figure 3*a* shows time-temperature curves obtained by test for 5-, 15-, 30 , and 60-minute ratings based on a temperature rise of 60 degrees centigrade by resistance. This temperature rise was chosen because, with an ambient temperature of 40 degrees centigrade and the usual hot-spot allowance, it gives a hot-spot temperature of 105 degrees centigrade, which is the generally adopted limit for class *A* insulation. However, the analytical methods apply equally well to any temperature rise selected. Although tests are required to determine the current values for the various short-time ratings, the full-line curves shown are not suitable for the study of sustained cyclic loads, because, after the short-time run started with cold motor parts, many of the parts (the frame for example) are still relatively cool and absorb considerable heat. This naturally tends to reduce the rate of rise of the winding temperature. To obtain suitable curves, a number of tests as shown in figure 2 must be made with varying time and current values. Values of the rate of temperature rise must be taken from the cycles toward the end of a test when fairly stable temperature change rates in all parts of the machine have been established. The dotted curves B_1 and C_1 in figure 3*a* have been determined in this manner for the currents corresponding to the 30- and 15-minute rating respectively. Figure 3*b* shows a number of time-temperature cooling curves taken after the various runs indicated and with the motor at rest. Here again it is necessary to select for our study a curve taken after fairly stable conditions prevail.

For greater convenience, representative time-temperature curves were replotted in figure 4 to start from the common point of 60 degrees centigrade to show the temperature changes from that point in terms of the time in minutes. If we now wish to find the heating cycle for an "on" period of $T_r = (^1/_3)T$ and an "off" period of $T_f = (^2/_3)T$ at the 15-minute rating current, we locate on curves *B* and *D* of figure 4 a temperature which shows this particular ratio of time. The zigzag curve *A* in figure 5 has been derived in this manner. It is seen that the temperature rise during each load cycle reaches a maximum of 60 degrees, which is the established temperature rise for the 15-minute rating. This, then, represents an ideal application for the motor and corresponds to a total time *T* of 14.55 minutes for each cycle with one-third time on and two-thirds time

Figure 4. The curves of figure 3 have been replotted in terms of the variation from a temperature rise of 60 degrees centigrade



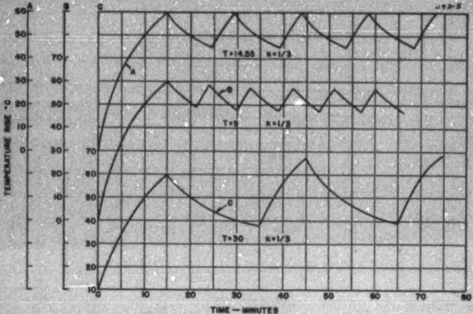


Figure 5. The time-temperature curves for different running cycles may be derived from the curves of figure 4

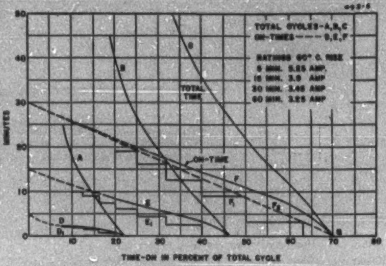

Figure 6. Curves derived from figure 4 show the limiting values of the cycle T and the "on" time T_r for different short-time rating currents to produce a rise of 60 degrees centigrade or less

off. Curve *B* in figure 5 was constructed by using portions of the curves in figure 4, with *T*=nine minutes for each cycle and with the same ratio of time on and time off as before. It will be seen that after uniform conditions have been established, the maximum temperature rise is only 57 degrees, which, although not quite utilizing the full capacity of the motor, is a satisfactory application. Curve *C* of figure 5 is derived for a total time of 30 minutes per cycle, again for the same ratio of the on and off periods; in this case a maximum temperature of 69 degrees is obtained. It follows from these considerations that, for any ratio of on and off time, there is a maximum time per cycle which leads to the limiting temperature rise of 60 degrees, while for longer periods the temperature limit will be exceeded. The plotting of curves as shown in figure 5 is of advantage for illustrative purposes but is not necessary for determining the limiting values.

Class I Applications

For many intermittent loads that can be handled advantageously with motors of short-time ratings, the running time for each cycle is not only relatively short but also definitely limited to a maximum set by the driven device. Examples of this are: hoists, cranes, elevators, door-openers, etc., with which the "on" time is limited by the maximum possible travel of the driven device. Another application is that for gasoline filling stations, where the running time is limited by the largest size of auto tank to be serviced. For these (class I applications), the analysis can be simplified if it is assumed that the maximum running time is limited to a small percentage, say 10 per cent, of the time used as a basis for the rating, giving maximum running times of 0.5, 1.5, and 3 minutes for the 5-, 15-, and 30-minute ratings respectively. For these short intervals the curves of figure 4 can be considered straight lines near the limiting temperature rise of 60 degrees. Curve *A* applying to the 30-minute rating shows a temperature rise from $56^1/_4$ degrees to 60 degrees, that is $3^3/_4$ degrees in a time interval of 3 minutes. Curve *D* shows that after this running period, a cooling time of 1.5 minutes is required to reduce the temperature to $56^1/_4$ degrees. It follows that the 60-degree limit will never be exceeded if the running time is 3 minutes or less and if it is not more than 67 per cent of the total time per cycle. Similarly, it can be shown that a 15-minute rating is suitable for loads with running periods of 1.5 minutes or less, if the running time does not exceed 44 per cent of the total time per cycle. Thus, for this very common type of application, the selection of the proper short-time rating is exceedingly simple if the curves of figure 4 are available.

Class II Applications

For applications where the running time exceeds 10 per cent of the rating time (class II applications), correct results cannot be expected by the method just discussed. However, complete curves as in figure 6 can be derived from figure 4. Tabulations as given in table I, which applies to the 15-minute rating, will be found convenient for deriving the curves of figure 6.

Table I

Change in Temperature (Deg) From 60 Deg	Time on (Curve B)	Time off (Curve D)	Total Time	Time on in Per Cent of Total Time
5	1.6	2.05	3.65	43.8
10	3.2	4.75	7.95	40.2
15	4.65	8.9	13.55	34.3
20	6.0	15.0	21.0	28.6
25	7.25	24.25	31.5	23

Curve *B* in figure 6 shows the values of column 4 against those of column 5. Curve *E*, showing the values of column 2 against those of column 5, gives the maximum permissible running time per cycle. Similarly, curves *A* and *D* apply to the 5-minute rating, and curves *C* and *F* to the 30-minute rating. These curves show the maximum permissible time (minutes) per cycle as well as the permissible running time plotted against the ratio (*k*) of the on time to the total time of the cycle. For instance, with one-third of the time on and a 15-minute rating, the maximum permissible time per cycle is about 14.5 minutes and the permissible running time is 4.8 minutes, corresponding to the case illustrated by curve *A*, figure 5. It is evident from the curves of figure 6 that each of the three ratings is suitable for a certain limited range of the ratio of on time to the total time, and also for certain limited values of running time. Figure 7 gives 30-minute rating data similar to figure 6 for a standard open squirrel-cage motor suitable for ratings between 5 and 7.5 horsepower.

The considerations and results up to this point are theoretically correct. The accuracy is dependent in actual practice only upon the test errors in the time-temperature curves and the selection of the proper curves. However, abnormal rises always can be avoided by using for the derivation of figure 6 a temperature-rise curve slightly steeper than the test curve, and for the cooling curve one slightly flatter than that observed.

It remains now only to put the results into the most convenient form for practical use and to introduce approximations leading to simplicity. Instead of using curves, tabulations as in table II may prove convenient.

Table II

Per Cent of Running Time ($k \times 100$)	Permissible Running Time (T_r) in Minutes for: 5-Minute Rating	15-Minute Rating	30-Minute Rating
8	2		
10	1.8		
12.5	1.6	10	
16.0	1.2	9	
20.0	0.5	7.5	
25.0		6	19
31.5		4.5	16
40		2.5	12.5
50			9
63			3

The values in the first column are chosen from the ten series of preferred numbers, and the values of the other columns are chosen with some margin of safety below the curves of figure 6. The step curves F_1, E_1, and D_1 in figure 6 are from table II. All applications not exceeding these values will have temperature rises below the assumed limit of 60 degrees centigrade.

Another convenient approximation can be made by assuming a straight line F_2 in figure 6 to replace curve F for instance. Here, F_2 simply provides a better margin of safety than F. A straight line from the point (a) to the time value of the short-time rating does not always fall below the corresponding curve for its entire length. This is true for curve D in figure 6, and for curve F in figure 7. To retain a sufficient margin of safety for the higher values of k, the straight line should be drawn to a somewhat smaller value of k, as for F_2 in figure 7; here the value k_{a1}, corresponding to point a_1, has been set at 90 per cent of the calculated value for point a. If the straight line is above the curve for the lower values of k, as shown for F and F_2 in figure 7, applications according to the F_2 values are still satisfactory for the following reason. For low values of k, the temperature peaks are by necessity limited to very small portions of the total time, and rather low temperatures prevail during a large percentage of the time. Normal insulation life can be expected with temperature peaks somewhat in excess of the temperature value which may be considered satisfactory for continuous operation. Therefore, this simplified approximate method will be satisfactory if it is understood that it avoids unsafe operating conditions but does not limit temperature rises to a definite maximum value. Approximations of this kind are essential if reasonably simple methods are to be evolved.

The point a for C and F can be determined by entering the tangents A_1 and D_1 through the limiting temperature rise of 60 degrees for curves A and D of figure 4. The rate of temperature rise (r) and temperature drop (d) for the tangents A_1 and D_1 follow directly. To maintain constant temperature, the drop for each cycle must equal the rise. We thus have $T_i d = T_r r$, or, if we introduce the ratio R of the rate of drop (d) to the rate of rise (r), as $R = d/r$, we have

$$T_r = T_i R \tag{1}$$

Further, since $T_r = kT$ and $T_i = (1-k)T$, we find for the point a the value

$$k_a = \frac{R}{1+R} \tag{2}$$

If, now, T_s is the time basis for the short-time rating, we find the permissible running time from the equation for the line F_2, which is

$$T_r = T_s\left(1 - \frac{k}{k_a}\right) \tag{3}$$

(As indicated before, k_a in equation 3 should be somewhat smaller than calculated from equation 2 to provide a sufficient margin of safety for the higher values of k.)

We thus have a very simple equation (3) to find for any value of k the permissible running time if one characteristic value, namely, the ratio R, has been determined from tests for the particular short-time rating of the machine. The derivation of the curves in figures 6 and 7 can be avoided entirely if this approximate method is used.

The exact conditions indicated in figures 4, 5, and 6 illustrate the method and apply, of course, only to the particular motor tested, which was a three-phase, splash-proof, wound-secondary motor with a small fan at the rear end of the armature. Conditions vary with the size, speed, and type of ventilation of the machine. This is seen by comparison with figure 7.

It is interesting to compare the results of this analysis with the rms current method for applying motors to intermittent loads. This consists of calculating the rms current for the particular load cycle and comparing it with the current at which the motor can operate running continuously. For the smaller motor considered here, the continuous rating current for 60 degrees centigrade rise is 84 per cent of I the 15-minute rating current. For a cyclic load at current I, the rms currents, in per cent of I, for different values of k are given in curve A of figure 8. For $k = 0.25$ the limiting length of the cycle is 27 minutes from figure 6. Yet from figure 8, the rms current for $k = 0.25$ is only 50 per cent of the 15-minute rating current compared to a value of 84 per cent running with continuous load. Curve B in figure 8 shows the rms current permissible with

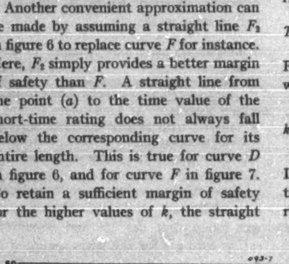

Figure 7 (left). A similar analysis gives the limiting cycles based on the 30-minute rating of a larger motor

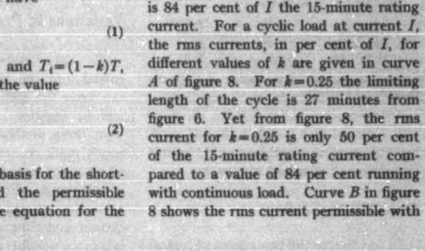
Figure 8 (right). The rms values of current for different duty cycles are shown



a continuously running motor, obtained by multiplying curve *A* values by the ratio of the rating currents. Comparing curve *B* and the value *C*, it is seen that, in basing applications on the conventional rms calculations, appreciable allowances must be made to avoid overheating. The causes are the reduction in ventilation during the idle periods and because, with varying temperatures, as in figures 2 and 5, the maximum rise rather than the average rise should be considered.

For standardization purposes, it is of course impractical to use for each size and type of motor the specific value of *R* applying to the motor. An inspection of equation 3 indicates that satisfactory values for T_r will be obtained as long as the ratio *R* in the motor is larger than the value of *R* used in the formulas. With this in mind, two courses are possible for standardization purposes:

1. Groups of motor ratings of a certain type, each group extending over a certain range of ratings and speeds, can be selected. (If the smallest value for *R* applying to any motor in the group is selected for the calculations, safe results will be obtained for all motors of the group.)
2. Certain bands of values for *R* may be selected to establish classes of motors, as in table III.

Table III

Range of Factor R*	Class	Approx. Value of k_s
6.3 to 4	*A*	0.80
4 to 2.5	*B*	0.70
2.5 to 1.6	*C*	0.60
1.6 to 1.0	*D*	0.50
1.0 to 0.63	*E*	0.38
0.63 to 0.40	*F*	0.28
0.40 to 0.25	*G*	0.20

* Figures in column 1 correspond to the five series of preferred numbers.

It is believed that testing a limited number of typical machines will permit classifying all standard motors.

Class III Applications

In addition to the two classes of typical intermittent loads (class I, short-time cycles, and class II, longer-time cycles), there is another class of considerable practical importance. This general type (class III) of application occurs with pumps, compressors, etc. The normal load is intermittent, but there is often a prolonged period of initial operation, to fill an empty tank or to bring a cooling system to the condition of normal operation. The initial periods of operation, which as a rule start with a cold motor, are often more severe than any subsequent intermittent service and therefore may have an important, if not a governing, influence upon the selection of the motor rating. For this purpose the nominal short-time rating may furnish considerable guidance.

With pumps and air compressors the load during the initial period may be the same as or even less than the load during normal operation. Cases are conceivable where the initial period lasts about an hour or more, dictating the choice of a 60-minute or even a continuous rating, where possibly a 30-minute rating would be sufficient for the subsequent intermittent load. For refrigeration and air conditioning the load during the initial stage may be double the operating load, decreasing gradually to $1^1/_2$ times load, and then to full load; the entire period may last from one to eight hours or longer. In these cases the initial operating period determines thermal rating, while the normal operating load is considered for satisfactory efficiency and power factor. Where such initial operating conditions occur very rarely, it will be practical and economical to allow temperature rises in excess of normal values during these periods. Even then this period of operation may govern the selection of the motor rating. (For refrigerator machinery, where the motor is located inside the refrigerator, many of the previous considerations cannot be applied directly because the density of the gases cooling the motor varies during different periods of operation.)

Variations in Practice

The three classes of application discussed and the conclusions reached do not cover the great variety of conditions met in practice. The data obtainable from these methods supply, however, a bench mark or starting point by use of which many variations can be calculated or estimated. Frequently the cycles in operation are not uniform but vary in current and time values; in these cases is is often possible to estimate an average or typical cycle for use with this method of analysis. The current during the "on" period frequently is not uniform, as assumed in figure 1, but these cases can be treated by using the rms current for the "on" period in the calculations; sometimes the appreciable effect of the starting current of squirrel-cage motors can thus be taken into account. Applications where the motor keeps running light between load periods can be made the subject of a similar but modified analysis. The principal difference is that the cooling curves must be obtained with the motor running. Actually, the variations encountered in practice are infinite and these few examples are cited merely to indicate how many of the variations can be treated. In certain special and important cases, more extensive calculations or tests may be the best solution.

Wiring and Control

The wiring used for machines with short-time ratings employed for intermittent loads can be analyzed by the same methods. (Since the ventilation of the wiring does not change with operating conditions like the machine, the rms current can be used as a basis for application if the operating cycles are very short.) Proposed standards for wiring provide a number of continuous ratings for each size of wire and cable, depending upon the grade of insulation and the method of installation of the conductors; as many as 15 different ratings are given for some of the wire sizes. It is obviously impractical to assign short-time ratings and give application data for intermittent ratings to all these variations in wire and methods of installation. Appreciable simplifications obtained through reasonable approximations must be introduced to obtain practical methods.

In order to obtain an idea of the time constants of wire, some tests were made on number 14 wire, which has approximate ratings corresponding to the larger motor tested (curves of figure 7). The time intervals required to reach maximum temperature were:

5 minutes for bare wire installed in open air
10 minutes for insulated wire (50-degree-centigrade Code grade) installed in open air—isolated
40 minutes with four of the same wires in a single metal duct
140 minutes with the motor of figure 7

These relative values seem to indicate a complicated situation. However, it was found that the 15- and 30-minute rating currents for the wires mounted in a conduit, if applied to bare wire or to the same insulated wire mounted in open air, would not give temperature rises exceeding the standard value when operated continuously. This suggests the idea that standards could be set for wires in conduit only, because this is the usual method of installation; operation would, however, be satisfactory if the same wire is used in open air. Many other simplifications could be suggested, but the discussion of these possibilities should be deferred until more basic test data of the kind described here are available, permitting a more comprehensive study of the proper co-ordination of wiring and machines having short-time ratings. The methods outlined also can be used for analyzing the performance of switching and control devices and their co-ordination with the apparatus controlled. In addition, it will be necessary to study in more detail the proper practices for applying thermal protective devices for both the wiring and the machines.

Conclusions

The considerations outlined in this paper seem to indicate that the standardization of a limited number of intermittent ratings for applications with the motor at rest during the off period would be of little assistance. On the other hand, it seems that reasonably simple guiding rules for the application of the present short-time ratings to many such installations can be devised. To just what extent approximations should be introduced to facilitate simplification is, of course, a matter of judgment. Following is an example of a simple type of statement which would lead to satisfactory applications and result in reasonable all-round economy in motor applications:

> "Open induction motors in the range from . . . . to . . . . horsepower inclusive, with a 30-minute short-time rating, do not exceed limiting temperature rises if the rms current during the operating period does not appreciably exceed the rated current and if the running time does not exceed 50 per cent of the total time of the operating cycles. The limit for the "on" time (T_r), in minutes, during the cycle is given in the following equation
>
> $$T_r = 30(1-2k)$$
>
> (This corresponds to equation 3 for $k_a = 0.5$. In both equations k is the ratio of running time to total time per cycle.)
>
> "With operating currents below the rated current, T_r may be increased. If T_r is appreciably smaller than calculated, currents somewhat in excess of the rated current are permissible."

The studies made also indicate that reasonably simple guiding rules can be worked out for the proper co-ordination of machines or apparatus and their control, their protecting devices, and the wiring of the circuits. This paper should not be construed as indicating that intermittent ratings cannot be used to good advantage. In certain specific applications, they may serve a very useful purpose.

Discussion

For discussion, see page 1221.

Some Problems in the Standardization of Temperature Ratings of Fractional-Horsepower Motors

CYRIL G. VEINOTT
MEMBER AIEE

Synopsis: In this paper statistical data are given on comparisons between different methods of temperature measurement in fractional horsepower motors. For such motors it is shown that surface thermocouple readings tend to give as much, or slightly more temperature rise than resistance measurements. For this, and other reasons, it is proposed, for fractional horsepower motors, that the surface thermocouple method be recognized as a distinct method of temperature measurement, instead of classifying it with the thermometer method, as the present standards do; it is suggested that the rating limits for the surface thermocouple be the same as those for the resistance method. It is pointed out that the surface thermocouple method is often the most convenient one to use in fractional horsepower motor application tests, and that it is used by the Underwriters' Laboratories, particularly in their standards on inherent overheating protective devices, the function of which is briefly discussed. Also, the effect of voltage variation upon fractional horsepower single-phase induction motors is discussed.

At the winter convention of the AIEE in New York in January 1939, there were presented a number of papers on temperature rating of electrical apparatus.[1–4] Since that time AIEE Standards No. 1 has been tentatively revised to favor the resistance method for determining the temperature rise and changing the limits for this method from 55 degrees to 60 degrees centigrade. Little data have been published on how the proposed changes in standardization might affect fractional-horsepower motors. For this reason the study outlined in this paper was undertaken. It is hoped that the information given herein will be of some assistance in standardization problems affecting fractional-horsepower motors. It is further hoped that others who have similar data on fractional-horsepower motors will make them available, regardless of whether they may support or differ with the data in the paper, in order that correct information representative of the industry may be available to those who make the standards, or any future revision of them.

Temperature Rises and Methods for Their Determination

The revised AIEE Standards No. 1 gives three methods for the determination of temperature rises:

1. Thermometer or surface thermocouple
2. Resistance
3. Embedded detector

The resistance method is indicated as the preferred method for most insulated windings because the much greater use of enclosed or protected type of electric motors seems to make a change from the thermometer to the resistance method logical. Although the standard gives certain definite values for temperature rises suitable for the majority of machines and apparatus, the necessity for departures from such values for individual types of apparatus is recognized. It also indicates that since temperature-rise values generally used for electrical apparatus at the present time, are the results of long experience and have proved reasonably satisfactory, major changes in these satisfactory standards should be avoided. From this, it may be concluded that whenever a change is made from the thermometer to the resistance method, values of limits used should be in accord with those found satisfactory in the past. It is obvious, therefore, that if a change in method of temperature-rise measurement is to be made, it is essential to know how the actual test results taken by the two methods compare. Data of this nature are given

---

Paper 40-95, recommended by the AIEE committees on electrical machinery and standards, and presented at the AIEE summer convention, Swampscott, Mass., June 24–28, 1940. Manuscript submitted April 22, 1940; made available for preprinting May 23, 1940.

Cyril G. Veinott is electrical development engineer, small-motor engineering department, Westinghouse Electric and Manufacturing Company, Lima, Ohio.

The author wishes to acknowledge with thanks the permission of the Westinghouse Electric and Manufacturing Company to publish the data herein presented. He is further obligated to J. E. Mulheim for assistance in collecting and recording some of these data, and also to R. E. Hellmund for many helpful suggestions in the preparation of the paper.

[1] For all numbered references, see list at end of paper.

in this paper and it is hoped that they will be of assistance in applying these broad principles to fractional-horsepower motors. (Similar data have been given by Summers[8] for motors from 10 to 1,000 horsepower in rating.)

In figures 1 to 6 inclusive are shown the result of 585 temperature tests taken on fractional-horsepower motors by different means of temperature measurement. These temperature runs are all continuous runs and were taken over a period of from seven to ten years on various ratings and different mechanical constructions of fractional-horsepower motors. The results were all taken by standard test procedure by testers generally skilled in the art. The tests shown were selected purely at random from a number of tests taken over this period and were not selected with any particular reference to accuracy. Even some tests of doubtful accuracy have been purposely included to show what magnitudes of variations might be expected in temperature measurements of this sort. In some cases, a special mechanical construction made to suit a particular customer's requirements, makes the problem of locating thermometers difficult.

The surface thermocouples used for these tests were located in the hottest spot of the winding accessible to thermocouples; in single-end ventilated machines, this point will be on the exhaust side. The small size of the thermocouples often makes it possible to put them between strands of wire or between two coils. This procedure was followed in installing "surface" thermocouples; but in all cases, the thermocouples were installed in completed motors, after the windings were impregnated and baked.

To determine the relationship between rise by resistance and rise by thermometer in capacitor-start, split-phase, and d-c motors, the results of many continuous runs were plotted in figures 1 to 4, inclusive. It will be noted that the temperature-rise measurements include a wide range of temperature (because overload temperature runs are included) and that the points are so scattered it would be difficult, with only a few points, to draw a representative curve giving the relationship between rise by resistance and rise by thermometer. For this reason, many points were plotted. It is more or less tacitly assumed, however, and it seems reasonable to suppose that the relationship of rise by resistance to rise by thermometer is a simple proportionality that can be represented by a straight line passing through the origin. (And the data indicate that assumption is probably more reasonable than any other; in other words, the actual differential between the two methods of measurement is proportional to the total temperature rise.) This straight line is so located that there are as many points above as below the line. If each point is considered to represent a ratio of two temperature rises, the slope of the line just constructed represents the median value of the numerous ratios and represents the sought-for relationship between rise by resistance and rise by thermometer. (This median line is the solid line in the figures.) The dotted lines are drawn to show variations that may be expected and include 90 per cent of the points plotted.

In figure 5 the surface-thermocouple method is compared with the thermometer method, and in figure 6, with the resistance method.

The results of these tests are summarized in table I.

Table I. Comparison of Three Methods of Measurement of Temperature Rise

Methods Being Compared	Number of Tests	Ratio of First Method to Second Method: Median Ratio	Maximum Ratio*	Minimum Ratio*
Resistance versus thermometer				
Capacitor-start motors	129	1.16	1.45	0.88
Split-phase motors	102	1.16	1.43	1.00
D-c motor armatures	116	1.61	2.11	1.22
D-c motor fields	116	1.62	2.29	1.08
Surface thermocouple versus thermometer				
A-c motors	66	1.19	1.48	0.94
Surface thermocouple versus resistance				
A-c motors	56	1.04	1.37	0.78

* Excluding 5 per cent of the tests.

From these curves and table I, a number of interesting conclusions may be drawn:

For fractional-horsepower a-c squirrel-cage motors with the primary winding on the stator, the temperature rise by resistance averages 16 per cent higher by resistance than by thermometer. This figure is based upon the results of 231 continuous temperature tests on split-phase and capacitor-start motors. (Figures 1 and 2.) The values of 16 per cent are reasonably consistent with the value of 20 per cent following from the figures given in Standard No. 1. It is to be expected that for small machines such as fractional-horsepower motors, the difference in temperature will be somewhat smaller than that for larger machines. In order to avoid odd values of temperature rise, a value of 50 degrees centigrade by resistance might be substituted for motors previously based on the 40-degree-centigrade standard by thermometer. In fractional horsepower motors such a change would be tantamount to raising the temperature-rise-by-thermometer limits 3 degrees centigrade, certainly a minor and insignificant change, particularly in view of improvements made in insulating materials since the figure of 40 degrees centigrade was initially set.

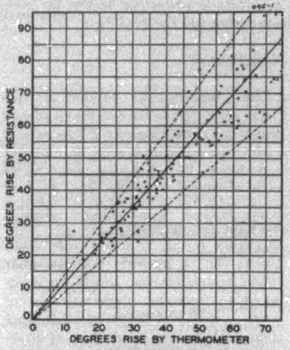


Figure 1. Temperature-rise tests on capacitor-start motors ranging from one-eighth to one horsepower in rating, comparing resistance method with thermometer method (129 tests)

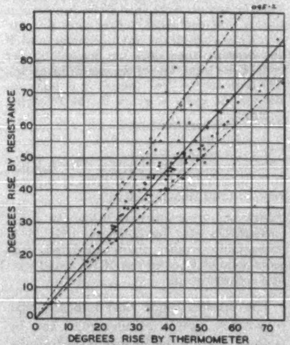

Figure 2. Temperature-rise tests on split-phase motors ranging from 1/30 to 1/2 horsepower in rating, comparing resistance method with thermometer method (102 tests)

For fractional-horsepower d-c motors, the temperature rise of either the armature or of the field is approximately 61 to 62 per cent greater when measured by the resistance method than when measured by thermometer. This difference between figures obtained by the two methods seems to be the same for both armature and field measurements and is based on the results taken separately from both fields and armatures for 116 different d-c motors. (Figures 3 and 4.) In armature temperature measurements, the large difference between the thermometer and resistance readings is likely due to a number of factors: the impossibility of supplying internal ventilation to the armatures makes the temperature rise high; furthermore, the thermometers can only be applied after the machine is shut down and the mass of these armatures is so small that the windings have had time to cool appreciably before thermometers can be installed and reach their final temperature.

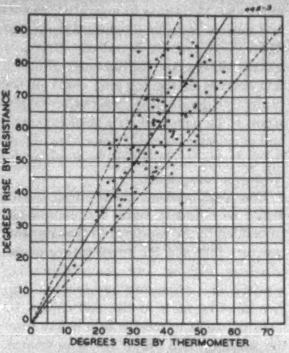

Figure 3. Temperature-rise tests on the armatures of d-c motors ranging from 1/20 to 1 horsepower in rating, comparing resistance method with thermometer method (116 tests)

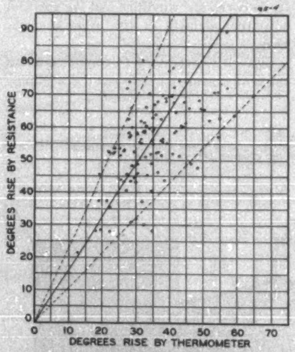

Figure 4. Temperature-rise tests on the field windings of d-c motors ranging from 1/20 to 1 horsepower in rating, comparing temperature rise by resistance with thermometer method (116 tests)

The ratio of rise by resistance to rise by thermometer appears to be subject to greater variations in individual cases of field temperature measurements than in individual cases of armature temperature measurements, although the average of a large number of points is substantially the same. Some fractional horsepower d-c motors have series fields and some do not. When a series field is used it is often wound on top of the shunt coil and the two taped together, making it difficult to determine by which field a thermometer reading is most affected. Different strengths of series fields and different degrees of overload would exaggerate these discrepancies. The resistance to heat flow between the windings and core of an a-c motor is relatively small, because most of the winding is embedded in slots which afford a large area and short length of path for the transfer of heat; also, the cross-sectional area of the coil is limited by the size of a single slot and is, therefore, relatively small. On the other hand, in a d-c motor there is relatively high resistance to heat flow from the field windings to iron parts because the winding for each pole is concentrated in a single coil, of relatively large cross-sectional area, and not in particularly good thermal relationship with the iron parts of the motor. Consequently it is not surprising to find large differences between rise by resistance and rise by thermometer in measurements of d-c fields.

As a result of the foregoing discussion, it is to be concluded that if the standard basis for rating fractional-horsepower d-c motors is to be changed from thermometer to rise by resistance, the 40-degree-centigrade limit should be changed to 60 degrees centigrade. Since figures 3 and 4 show that a rise of 60 degrees centigrade by resistance corresponds to approximately 37 degrees centigrade by thermometer, a rating of 60 degrees by resistance actually is slightly more conservative than the old rating of 40 degrees by thermometer. A figure of 60 degrees by resistance is, therefore, in harmony with the previously expressed principle that there should be no major change in the present time-tried ratings. Actually, a limit of 65 degrees centigrade by resistance would correspond more closely to the present figure of 40 degrees centigrade by thermometer.

Some interesting conclusions regarding the use of surface thermocouples for measurement of temperature rise of fractional-horsepower a-c motors became apparent from a study of figures 5 and 6. The temperature rise by surface thermocouple is seen to be 19 per cent higher than the rise by thermometer and 4 per cent higher than the rise by resistance. This finding is particularly significant in view of the fact that the present AIEE standard recognizes no distinction between surface thermocouple readings and thermometer readings of temperature rise.

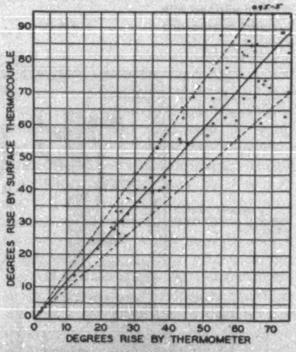

Figure 5. Temperature-rise tests on split-phase and capacitor-start motors ranging from 1/30 to 1 horsepower in rating, comparing rise by surface thermocouple with thermometer (66 tests)

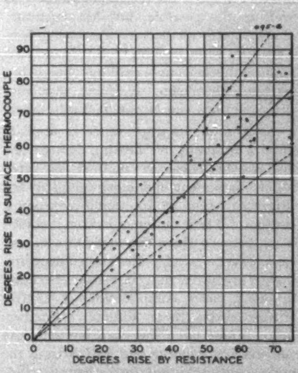

Figure 6. Temperature-rise tests on split-phase and capacitor-start motors ranging from 1/30 to 1 horsepower in rating, comparing rise by surface thermocouple with resistance method (56 tests)

Here is an anomaly which needs correction in any future revision of AIEE Standards No. 1.

As far as fractional-horsepower motors are concerned, the surface-thermocouple method should be considered as a method separate and distinct from the thermometer method, and different limits of rise for the two methods should be established; it would be in accord with the findings in this paper if the limits for the surface thermocouple were made the same as for resistance.

Emphasis has been placed upon the foregoing because of the importance of surface-thermocouple temperature measurements of fractional-horsepower motors. In applying inherent overheating protective devices, temperature rises in the order of 100 to 125 degrees centigrade may be encountered; for such high temperature rises, the use of surface thermocouples is virtually indispensable, and the standards of the Underwriters' Laboratories for these devices are based upon this method of temperature measurement. There are two important reasons why the surface-thermocouple method is best in such cases: (1) the high temperature rises encountered make it essential that an accurate method be chosen, involving as little difference as possible between "hot spot" and observed temperature; this consideration rules out use of the thermometer; (2) moreover, in applying these devices it is most desirable, from an engineering standpoint, to measure temperatures while the motor is running, and part of Underwriters' standards are based on temperatures taken *while the motor is running;* this consideration precludes the use of the resistance method, as well as the possible, but less accurate, thermometer method for measuring temperatures while running. It is found that surface thermocouple readings change but little on shutdown, signifying that running readings can be satisfactorily taken.

Aside from its importance in application of inherent overheating devices, the surface-thermocouple method is often most convenient and most suited in application tests of fractional-horsepower motors. These motors are often installed in appliances where thermometers cannot be applied or read. Resistance measurements are often not convenient because, in many cases, complications of control wiring make them difficult. Furthermore, it may not always be easy to isolate the starting winding and switch from the main winding circuit for resistance readings. Moreover, use of the surface-thermocouple method affords a means of following the motor temperature of various conditions of load imposed by the appliance *without shutting down the machine.*

It is for the reasons given above, that the author believes that the surface-thermocouple method should be given recognition in AIEE standards as a distinct method of temperature-rise measurement.

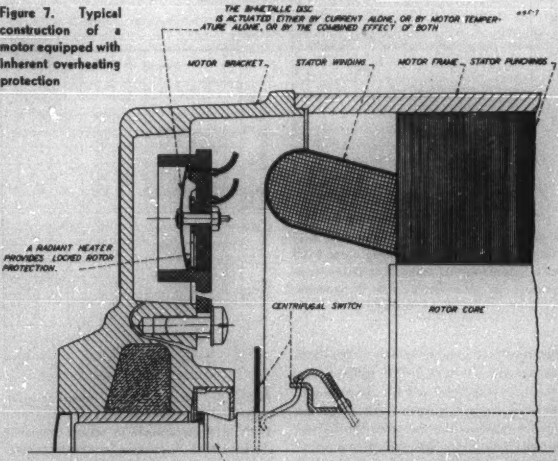
Inherent Overheating Protection

In earlier days fractional-horsepower motors were protected by external devices which would trip on any continuous current exceeding the "ultimate tripping current" of the thermal relay. Since it was assumed that the *temperature rise* of a motor is a function of the motor current, these external relays really limited the temperature rise of the motors. In recent years, however, there has been a rapidly growing tendency to incorporate the protective device inside the motor to obtain inherent overheating protection. These devices are designed to limit the *total temperature* and not the *temperature rise* of the winding. The standards of the Underwriters' Laboratories for these devices[8] specify that, under no condition of running overload, shall the *total* temperature of the windings, as measured by surface thermocouples, exceed 125 degrees centigrade and that, with a locked rotor, the total temperature of the windings shall not exceed 150 degrees centigrade nor shall there be any excessive smoking indicative of permanent injury to the windings. (Moreover, the device must be able to provide locked-rotor protection for 15 days.) These two figures represent the essential temperature requirements of the Underwriters' standards for these devices.

The figure of 125 degrees centigrade is somewhat above the limiting hot-spot temperature of 105 degrees established for class *A* insulation by AIEE. However, since variations in individual motors and devices must be downward from that figure, and since it is unlikely that any motor will operate continuously within a few degrees of the tripping point of the protective device, the Underwriters' limit seems to be tempered by a good economic and engineering sense. Some idea of how these devices function will be given in the following paragraphs.

The ideal inherent overheating device would be infinitely small and completely embedded in the windings so that its temperature followed the temperature of the windings without any temperature lag whatsoever. However, any practical device must be finite in size and cannot be mounted so as to receive heat solely from the windings and follow the temperature of the latter without an appreciable lag; the greater the current flowing through the windings, the greater will be the lag. In a practical device it is therefore necessary to compensate for the temperature lag between the windings and the thermal actuating element of the protective device.

Since it is necessary to compensate for the temperature lag between the windings



THE BIMETALLIC DISC IS ACTUATED EITHER BY CURRENT ALONE, OR BY MOTOR TEMPERATURE ALONE, OR BY THE COMBINED EFFECT OF BOTH

and the device anyway, the latter is often mounted in the end bracket (or end bell) of the motor for the sake of convenience, as shown in figure 7. Here the thermal actuating element is a bimetallic disk set to trip when the temperature of the disk reaches 120 degrees centigrade. (For example, if the entire motor without any current passing through it, were placed in an oven and heated, so slowly that all parts were the same temperature, the disk would trip open when 120 degrees was reached.) In close proximity to the disk is a radiant heater so designed as to compensate for the temperature lag of the bracket temperature behind the winding temperature. The heater is also designed so as to protect the motor against locked-rotor conditions, as will be discussed later.

How the heater provides compensation for the temperature lag of the bracket behind the windings may perhaps be better understood by reference to figure 8. Curve 1 shows the ultimate tripping currents of the thermostat plotted as abscissas against the actual ambient temperature surrounding the thermostat. This curve shows that the higher the temperature surrounding the thermostat, the lower the ultimate tripping current. This same curve also represents the ultimate current necessary to trip the thermostat for any given bracket temperature. The actual temperature of the disk is, of course, higher than that of its surroundings because of the heat generated in the auxiliary heater. The temperature rise of the disk above the bracket is plotted in terms of the current flowing through the heater and is seen to be proportional to the square of the current in the heater. The opening temperature of the disk itself is constant as shown in curve 3. Numerous temperature tests were taken on the motor for which this particular device is used and it was found that the temperature rise of the winding above the bracket, as measured by surface thermocouple, was almost solely a function of the motor current and independent of the bracket temperature. The results are plotted as curve 4 and it is seen that the temperature rise of the windings above the bracket is also proportional to the square of the stator current. By adding curve 4 to curve 1, curve 5 is obtained and this curve represents the actual temperature of the winding when the thermostat trips. Note that for different currents the temperature of the bracket may vary from 120 to 50 degrees centigrade, but for these same conditions, the actual hot-spot temperature of the winding will only vary between 120 and 110 degrees centigrade. To summarize, it may be said that the temperature of the motor which directly affects the inherent overheating device is the temperature of the bracket and the difference in temperature between the windings and bracket is compensated for by the auxiliary heater through which the stator current flows.

From the foregoing it can be seen that by a proper selection of the operating temperature of the device and by using an auxiliary heater of the right proportions, the temperature of the operating element or disk can be made to follow the winding temperature quite closely for various sustained load conditions which do not cause a tripping of the device. For very severe loads of short duration, the thermal device tends to overprotect, since it has less mass and less thermal capacity than the motor as a whole, and hence, reaches its final temperature more quickly than does the entire motor. Actual temperature measurements of the disk and of the windings under various continuous load conditions insufficient to cause tripping, verify this fact that, when properly applied, the disk does actually follow the winding temperature within a few degrees. For such tests, surface thermocouples have been found indispensable because of their convenience and accuracy.

Under locked-rotor conditions, the device operates on current alone, like any current-operated device. If the device is arranged to reset automatically, as does the thermostat in figure 7, it will cycle on and off automatically if the rotor is locked. During the on period, a large amount of heat is generated in the windings, but during the longer off periods, the temperatures tend to equalize partially, so that the temperature of the entire motor, including the end brackets is elevated. As the temperature of the end bracket increases the reclosing time of the thermostat increases, particularly as the reclosing temperature of the thermostat is neared. Thus, after an hour or two, the cycling time of the thermostat, the frame temperature, and the cyclic varia-

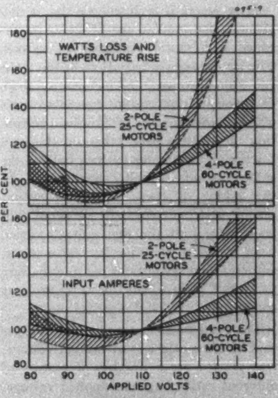

Figure 9. Effects of variation of applied voltage upon capacitor-start motors when developing full-load torque

tions in winding temperature stabilize. The total integrated watts consumed by the motor then becomes equal to the watts that can be dissipated by the motor with no ventilation, which is necessarily small. Inasmuch as the peak winding temperatures reached under locked-rotor conditions will never be maintained continuously, a figure of 150 degrees centigrade for locked-rotor condition, as required by the Underwriters' seems wholly reasonable. In actual practice, this temperature is probably seldom reached.

It is hoped that the foregoing discussion will help to clarify certain aspects of inherent overheating protection with particular reference to temperature measurement considerations. In the author's opinion, it further emphasizes the need for recognition of the surface thermocouple method of temperature measurement.

Effect of Voltage Variations on the Performance of Induction Motors

The effect of a variation of the line voltage upon the operation of fractional-horsepower single-phase induction motors is of considerable interest in setting standards for allowable voltage variations, as well as being of interest to power companies and also users of these motors. There has been a great reluctance on the part of motor manufacturers to make categorical statements as to the general effect of variation in line voltage, because of the enormous number of types and their ramifications which are involved. For these same reasons, it is with some reluctance that the data given in figures 9 and 10 of this paper are presented.

It is generally well known that variations in line voltage are of small importance to a motor operating at no load. The importance of variations in line voltage increases with an increase in load. However, to obtain some measure of this effect a large number of "full-load saturation" tests have been taken on standard fractional-horsepower motors, both of the split-phase and capacitor-start types. In the taking of these tests, the output torque was held constant at rated full-load value and the line voltage varied from 80 volts to 140 volts. The watts, amperes, and revolutions per minute were measured, from which the watts loss was computed.

The total watts loss, expressed as a per cent of the watts loss at normal voltage, was plotted for a number of motors of different ratings against applied voltage. As might be expected, these curves did not all fall directly on top of one another so limiting curves were drawn, between which lay all the curves plotted. The curves for four-pole 60-cycle capacitor-start motors all fell within the limits of the indicated shaded areas. Similar limits for the full-load saturation curves for two-pole 25-cycle capacitor-start motors of the same horsepower ratings were established and also indicated in figure 9. Similarly, on figure 9 is shown the variation in current, expressed as a per cent of full load current at rated voltage, for 60-cycle, and also for 25-cycle, capacitor-start motors.

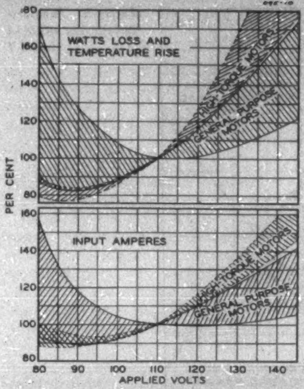

Figure 10. Effects of variation of applied voltage upon split-phase motors when developing full-load torque

The curves of total watts loss versus voltage are of interest, not only from the standpoint of voltage standardization but also from a consideration of temperature rise, since the temperature rise is very closely proportional to the total watts loss. Thus, it can be seen from the curves that if the full-load temperature rise of a capacitor-start motor is 50 degrees centigrade at 110 volts and rated output, the corresponding temperature rise at 125 volts would be from 117 to 121 per cent of this value, that is, from 58 to 61 degrees centigrade. However, if it were a 25-cycle motor under consideration, a 50-degree rise at full load on 110 volts would be increased 40 per cent to 56 per cent, giving a rise of 70 to 78 degrees at 125 volts. Twenty-five-cycle motors, because of higher saturations, are thus seen to be more sensitive to overvoltage than are 60-cycle motors. The curves for 50-cycle motors were not plotted but would probably fall between the 25- and 60-cycle curves.

However, a word of caution must be given in connection with the operation of capacitor-start motors on overvoltage. The limiting feature may be the voltage on the capacitor and not the full-load temperature rise.

In figure 10 are shown curves similar to those of figure 9, except that these are for split-phase motors. This type has been classified into two groups, namely (1) general-purpose motors, and (2) high-torque motors such as used on washing machines. It will be noted that the effect of voltage variation on general-purpose split-phase motors is subject to wider individual differences primarily because of the greater diversity of ratings which are covered and because the design of some of the ratings is influenced by the necessity of meeting the NEMA starting-current requirements. It will be noted that the high-torque motors are more susceptible to overvoltages than are the general-purpose split-phase motors, though the latter may be more susceptible to reduced line voltages.

The variation in current is shown for both types of motors in figures 9 and 10 because it is thought that it may be of some interest in connection with control and in connection with the application of external current-operated thermal overload devices.

No curves are shown for variation in torques as these vary directly as the square of the applied voltage.

It should be pointed out that the curves shown represent the effect of variation of voltage when the motors are operating at full-load torque and are not representative of other load conditions. Qualitatively, it may be stated, the higher the overload, the less relative effect that overvoltage has and the more relative effect that an undervoltage has.

From these curves it does not appear necessary to make any changes in the present standards for permissible voltage variation of plus or minus ten per cent.

A word relative to the much-discussed subject of changing of the present standard voltage rating from 110 to 115 volts may be in order here. One possibility is to design all the motors to give, on 115 volts, the same performance they now have on 110 volts, the curves shown in figures 9 and 10 would all be shifted to the right five volts without an appreciable change in shape. However, a change of this nature means that the torques of the motor would be reduced to $(110/115)^2 =$ 91 per cent of the present torques and the ability of the motor to start the load at reduced voltages would be impaired. The locked-rotor and full-load currents would be reduced in the ratio of 110 to 115.

Another possibility to be considered is

that of simply changing the name-plate stamping of the present motors. In such a case, the curves of figures 9 and 10 would not change, nor would the torques of the motors but the full-load performance of the motors would be changed. Also, the locked-rotor currents would be increased in the ratio of 115 to 110. In any case, however, it would be necessary to redesign some motors, such as two-pole 25-cycle capacitor-start motors and high-torque split-phase motors, to limit the temperature rises, on voltages ten per cent above the new rating and to redesign some capacitor-start motors to limit the voltage on the capacitor to a safe value.

Thus, it can be seen from the two preceding paragraphs, that the problem of changing the voltage rating is not a simple one, involving as it does the ultimate user and the manufacturer, as well as other standards.

Conclusions

The important conclusions of this paper, all of which relate only to fractional-horsepower motors, are:

1. The temperature rise of single-phase induction motors measured by surface thermocouple averages as much or more than the rise by resistance.
2. The surface thermocouple method of temperature measurement should be recognized as a distinct method instead of classifying it with the thermometer method as done in the present AIEE Standard No. 1. For purposes of rating, the limits assigned to this method may be the same as those assigned to rise by resistance.
3. If the method of determining the temperature rise of single-phase induction motors is to be changed, the present limit of 40 degrees centigrade by thermometer could be changed to 50 degrees by resistance or 50 degrees by surface thermocouple, without appreciably affecting actual temperature rises.
4. If the method of determining the temperature rise of d-c motors is to be changed, the present limit of 40 degrees centigrade by thermometer could be changed to 60 or 65 degrees centigrade by resistance without appreciably affecting actual temperature rises.
5. Use of the surface thermocouple is necessary to determine if inherent overheating protective devices comply with Underwriters' standards. Their use in application tests is indispensable.
6. Present standard limits of voltage variation of plus or minus ten per cent are satisfactory from the standpoint of motor performance. But a change in the present standard voltage rating of 110 volts is not a simple problem.

New Instruments for Recording Lightning Currents

C. F. WAGNER
FELLOW AIEE

G. D. McCANN
ASSOCIATE AIEE

IN the early days of lightning investigations surge voltages on transmission lines were measured by a relatively crude device consisting of a number of parallel gaps with different spacings. The maximum gap broken down, which was indicated by markings on a thin piece of paper placed within the gap, was a measure of the voltage. Peters,[1] by applying the phenomenon of Lichtenberg figures to photographic films, then developed the instrument called the klydonograph. Much information concerning the magnitude and frequency of voltage surges on systems was obtained with this instrument. At about this time the cathode-ray oscillograph was just emerging from its laboratory stage of development and several investigating groups adapted it to field work. A number of records were obtained with this device which showed the rate of rise of the voltage wave, its crest, and a limited amount of information regarding its tail. However, the quantity of data secured by this means was quite small, largely because of the initial cost of the instrument and the necessity of constant attendance for operation and maintenance.

Because of the variable nature of lightning it is desirable that many readings of its properties be made so that its statistical nature with regard to magnitude, rate of rise, and duration may be adequately studied. The surge-crest ammeter,[2] because of its simplicity and cheapness, has provided an enormous amount of information relating to the magnitude and polarity of lightning currents. However, there still remains much to learn regarding the wave shape of lightning currents, particularly their duration and initial rate of rise.

The records of wave shape obtained by the cathode-ray oscillograph indicated that the currents in a lightning stroke were essentially dissipated or spent in a time of a hundred microseconds. Lightning arresters and other protective equipment were therefore designed and tested on the basis that they would be called upon to discharge surges of this duration in service.

In parallel with the work being done on transmission lines and the like in the measurement of voltages and currents, photographic records were being made by means of the Boy's camera, a camera in which the lens and film move relative to each other either by movement of the film or by movement of the lens system. Schonland[3,4,5] and his associates in Africa had by this means shown the general nature of propagation of the discharge from the cloud to earth and the subsequent return streamer of high intensity. Their work also indicated the

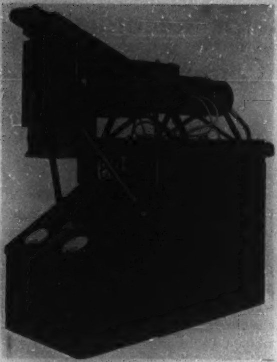

Figure 1. General view of automatic cathode-ray oscillograph

presence under certain conditions of long duration strokes, longer than the 100 microseconds which previously had been regarded as typical. Steknolnikov and Valeev[6] in Russia, Norinder[7] in Sweden, and McEachron[8] in this country with his work on the Empire State Building, likewise supplied fresh evidence that the tail of the current wave might persist at a low value for a long time.

The foregoing evidence therefore suggests the need for additional statistical knowledge of lightning currents, both in the stroke and in stricken equipment, particularly, with respect to the wave shape for periods of time in excess of 50 microseconds. It is the purpose of this paper to describe some new instruments recently developed to accomplish this result.

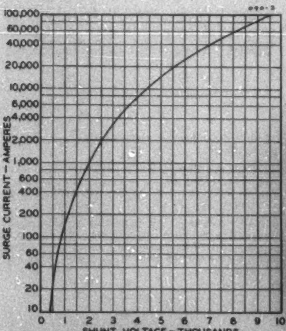

Figure 2. Calibration curve of cathode-ray-oscillograph shunt

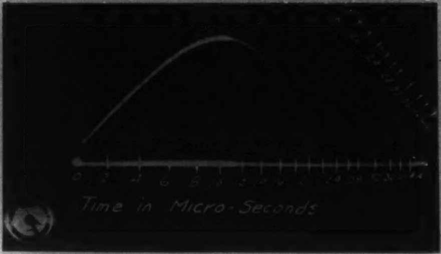
Figure 3. Laboratory record obtained with cathode-ray oscillograph under fully automatic conditions



Automatic Cathode-Ray Oscillograph

In the past the cathode-ray oscillographs used in lightning investigations were of the pumped type. A cathode-ray-oscillograph tube of sufficient writing speed which is sealed off and therefore does not require pumping is now available. A laboratory oscillograph utilizing this tube has been described by Kuehni and Ramo.[9] Being sealed off, this tube with suitable auxiliary circuits provides a device which lends itself readily for placement in the field for automatic operation without the constant attendance of an operator. Figure 1 shows a general view of the developed instrument. It is portable and operates from any 110-volt a-c lighting circuit. The tube is of the hot-cathode type and requires a potential of 15,000 volts to accelerate the electron beam which impinges upon a willemite screen. The image thus produced is photographed upon a light-sensitive film through a compound lens system. An auxiliary grid within the tube controls the electron beam so that under normal conditions the beam is not "on". In this manner fogging of the film is prevented. Upon the occurrence of a surge the control grid automatically initiates the beam and permits recording of the phenomenon.

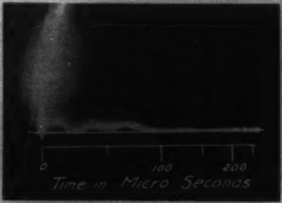


Figure 4. Field record obtained with cathode-ray oscillograph

The photographic film is mounted on a disk which rotates at a speed of five rpm. This is sufficiently slow that during the time of recording of a particular surge the film may be regarded as essentially stationary, but in the event of more than one surge occurring at different times a different surface of the film will be exposed. In order to identify individual records and determine their time of occurrence the face of an electric clock is focused at a point diametrically opposite from the record and is flashed simultaneously with the operation of the control grid of the cathode-ray tube.

The range of currents in which one is interested in this work is enormous as the discharge current of a stroke may vary from a few amperes to more than 150,000 amperes and may persist for a considerable time at small magnitudes. In order to cover this range as well as possible a nonlinear shunt whose resistance is variable and decreases with increasing current is utilized. Figure 2 shows the characteristic of this shunt in the form of a calibration curve plotted as total current in amperes for the ordinate and shunt voltage for the abscissa.

A typical oscillogram obtained in the

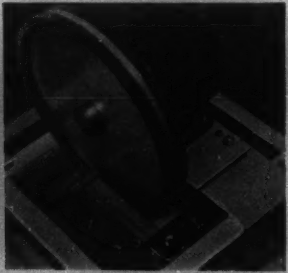

Figure 5. "High-speed" fulchronograph showing wheel

Figure 6. "High-speed" fulchronograph showing coils

laboratory with this instrument under fully automatic conditions is shown in figure 3. A number of oscillograms have also been obtained in the field of which figure 4 is an example.

Fulchronograph

The relatively high cost of the cathode-ray oscillograph and its complexity limits its use for the collection of statistical information regarding the characteristics of lightning currents. The need exists for a simple and less expensive instrument which can be distributed in greater numbers at different locations. A new device to which the name "fulchronograph*" has been given has recently been developed which the authors believe meets these requirements.

The essential part of the fulchronograph is a slotted aluminum wheel which, in one type, the "high speed", rotates at 3,450 rpm and in another type, the "slow speed", at approximately 60 rpm. Figure 5 shows one of the wheels mounted on the high-speed fulchronograph. The slots are filled with three nine-mil permanent-magnet-steel laminations, which project from each side. These projections are made to pass between narrow coils, see figures 6 and 7, through which flows the current to be measured. As a particular set of laminations spans the gap between the coils, the laminations are subjected to a radial magnetizing force proportional to the current at that instant. By measuring the retentivity or residual flux in the laminations it is possible to reconstruct a graph of the current as a function of time. The device functions in a manner similar to the surge-crest ammeter except that the element of time has been introduced by the rotation of the wheel. The two sides of the wheel are designed to cover two ranges of current. On one side the coil has a purely air core except for the magnetizable laminations and covers a current range of from 1,000 to 50,000 amperes; on the other side the magnetic circuit is completed through a Hipernik core with a partial air gap and the sensitivity in this manner is increased to cover a range of from approximately 100 to 6,000 amperes. A single wheel can thus record a range from 100 to 50,000 amperes. The calibration curves for the two sides are shown in figure 8.

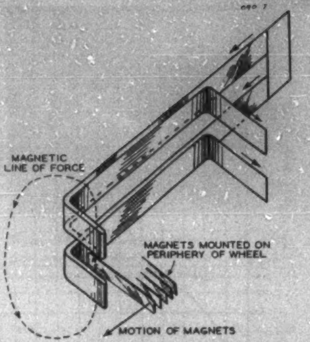

Figure 7. Diagram showing relation between one set of laminations and the coils on one side of the wheel

There are 408 slots in each wheel, so, for the "high speed" fulchronograph, the time element between slots corresponds to approximately 43 microseconds and for the "slow speed" to $^{1}/_{400}$ second. The total time for one revolution of the wheel is, for the "high speed", 0.017

Figure 9. Curves showing the distribution of flux between adjacent slots of fulchronograph wheel

* This name was obtained as a combination of the Latin word *fulmen* meaning *lightning*, and the Greek words *chrono* meaning *time*, and *graph* meaning *to write*.

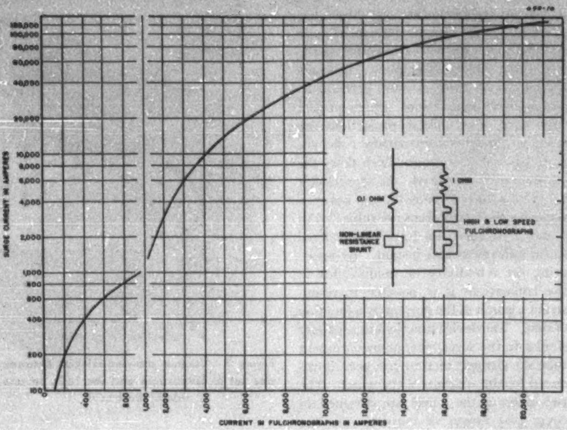

Figure 10. Calibration curve of fulchronograph shunt

second, and, for the "slow speed", 1.0 second.

There are several conceivable methods for utilizing the principle of remanent magnetism. A thin continuous disk of permanent magnetic steel in which the magnetizing force is directed by high-permeability steel to a very narrow region in a lateral direction has the advantage of possibly permitting finer resolution of the record. The pickup device in this construction would probably lead to considerable complexity. After consideration of a number of different schemes the form described here was built. Due to the close proximity of adjacent slots and their laminations, the magnetizing coil has a tendency to spread its effect over several slots. This spread can be determined by surging the coil with the wheel stationary, for various positions of one of the slots relative to the axis of the coil. The resultant current indications as a function of slot pitch and maximum current are shown in figure 9 for both the high-current side and the low-current side. A rate of change of current in excess of the slope of the distribution curves indicated in this figure cannot be determined. For values of current in excess of 30,000 amperes the spread is too great for the degree of resolution ordinarily desired. A specific application of these curves in interpreting a record will be illustrated later.

Results of magnetic-link investigations have shown that arresters are rarely called upon to discharge currents in excess of 10,000 amperes. Therefore, for the determination of arrester currents an upper range of 30,000 amperes is sufficient for this application. For measuring the current in direct strokes which may exceed this value a combination of ordinary resistors and nonlinear resistors is used. Figure 10 shows a calibration curve, for the shunt combination indicated in the insert, in which the maximum current in the fulchronograph is 20,000 amperes for 120,000 amperes of total current.

The purpose of two devices rotating at different speeds is to cover a greater range of time than would be possible with a single high-speed wheel. As stated previously, the high-speed fulchronograph covers a total time of approximately 17,000 microseconds in intervals of 43 microseconds and, of course, runs continuously. The slower speed device covers a time interval of approximately one second. As observed by Schonland, multiple-stroke discharges rarely last longer than one second. Therefore, for a multiple stroke, the slow-speed device measures the maximum value of each component and the time interval between the components. It cannot, however, tell definitely which one was the first and to this extent the time interval, between strokes is ambiguous. Perhaps from the nature of the current which may, for example, be continuous at a small value between successive strokes, it will be possible to differentiate the first from the others. Experience might

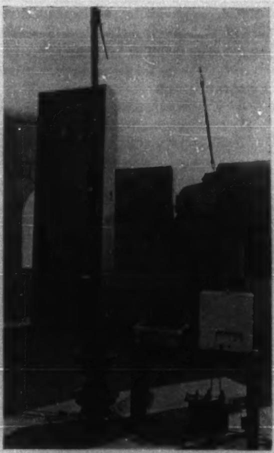

Figure 12. Installation on top of Cathedral of Learning of the University of Pittsburgh

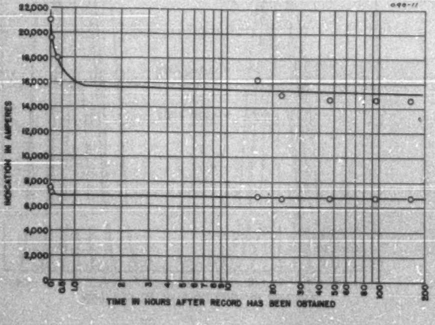

Figure 11. Demagnetizing effect of continued operation of high-speed wheel of high range after record has been obtained

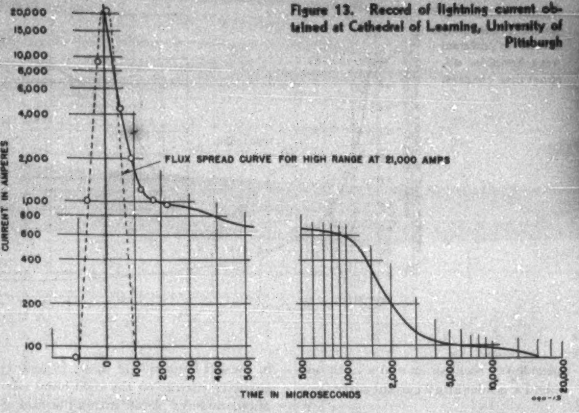

Figure 13. Record of lightning current obtained at Cathedral of Learning, University of Pittsburgh

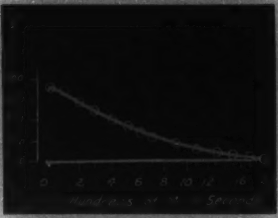

Figure 15. Comparison between fulchronogram and cathode-ray oscillogram for laboratory current surge

indicate the desirability of a different speed for the slow-speed wheels. The high-speed wheel permits of the expansion of the individual waves so that their shapes are discernible. The probability of the high current components of the individual strokes overlapping is not very great. This statement is based on the assumption that the higher-current components have a duration of the order of a few hundred microseconds which covers only a few per cent of the periphery of the wheel.

The presence of the coils for the production of the magnetomotive force naturally raises the question of the impedance of the device and its ability to withstand the voltages that might appear across it when a steep wave front of current is applied. Precautions were taken in its design to limit the inductance by making the distance between the two sides of the loop as small as possible. The coil inductance is equal to 4.0×10^{-7} henry, and its d-c resistance is 0.007 ohm. The device has successfully withstood a current rise of approximately 20,000 amperes per microsecond, and a maximum of 120,000 amperes which represents the limit of test facilities available at the time. The physical forces involved in this kind of structure are too large to be withstood without special bracing. For this reason the windings are substantially supported by blocks of Micarta which completely surround them. These blocks are visible in figure 6.

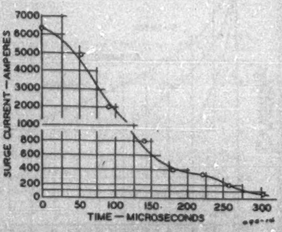

Figure 14. Typical lightning-arrester discharge current at the Gulfport substation of the Mississippi Power Company

The physical arrangement of the magnetic laminations constitutes a very good centrifugal fan which loads the driving motor enormously. To break up the fan effect a strip of paper is cemented to the inner edges of the plates.

Mechanical vibration has a tendency to demagnetize any permanent magnet. Continued operation of the fulchronograph after a record has been obtained has a similar effect. However, the composition and treatment of the magnetic material was selected with this point in mind and it has therefore been kept to a minimum. The curve of figure 11 shows this effect upon a particular wheel for the high range side taken for two degrees of magnetization. Below 10,000 amperes, the effect is relatively unimportant but at 20,000 amperes it is of the order of 20 per cent. However, by insuring that the wheel runs at least one hour before removing, this decrease which becomes constant thereafter can be included in the calibration of the steel.

The current which produced the magnetization is determined by measuring the remanent or residual magnetism in the laminations. At the present time the group of laminations in each slot are removed and measured as a group. The measuring instrument is in turn calibrated against known magnetizing currents. The number of laminations removed is dependent upon the character of the wave. When the rate of change is small it is necessary to remove only every tenth or twentieth group. The region magnetized can be located by means of a small exploring compass. The accuracy of the device is of the order of ten per cent.

A number of fulchronograph installations have been placed in the field for a part of the 1939 lightning season. One of them was placed on the roof of the Cathedral of Learning of the University of Pittsburgh. Atop this 530-foot structure a 50-foot insulated mast was placed and the fulchronographs connected between the mast and the grounded structural iron work. A photograph of this installation is shown in figure 12. One of

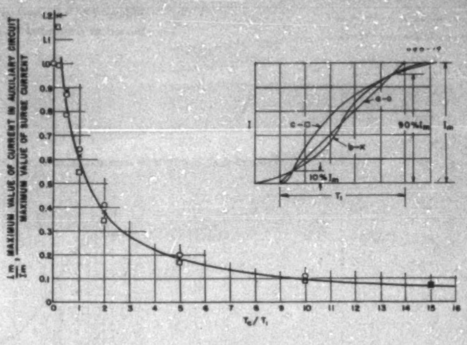
and the abscissas beyond 500 microseconds are logarithmic scales. Below 500 microseconds the abscissa is a Cartesian scale.

In figure 13 the observed points for the first few slots are shown together with the distribution curve from figure 9 corresponding to 21,000 amperes, the crest of the current wave. The zero point of time was determined by fitting the distribution curve for 21,000 amperes to the upward side of the observed readings. A fit indicates a surge front which lies within the envelope of the distribution curve. The observed point at 50 microseconds lies just about on the distribution curve for 21,000 amperes. A curve drawn through the observed points at 90 and 50 microseconds and the current for zero time forms a smooth curve which justifies the original curve drawn. For all other points the distribution curves fall within the observed curve and therefore do not influence its shape.

A typical record showing a lightning-arrester discharge current is shown in figure 14. This was obtained at the Gulfport substation of the Mississippi Power Company.

The accuracy with which a faithful record is obtained is indicated in figure 15, which shows a comparison between a

Figure 19. **Response of auxiliary circuits to different wave fronts for different time constants**



cathode-ray oscillogram and a fulchronogram for a laboratory current surge.

Magnetic Surge-Front Recorder

The principal disadvantage of the fulchronograph is its inability to measure high rates of rise of the front of waves. Devices for measuring the maximum rate of rise have been available for some time. J. F. Peters in the early investigations with the klydonograph first suggested the use of this instrument connected in a loop inductively coupled with the circuit carrying the surge current. Berger[10] later applied the method and published some data. This method gave a reading proportional to the maximum instantaneous rate of rise of current. A quantity probably of greater importance than the maximum rate of rise is that of the average rate of rise such as may be defined by a straight line drawn through the points having values 10 per cent and 90 per cent of the crest value. This is shown in figure 16*a*.

The magnetic surge-front recorder for which a schematic diagram is shown in figure 17 is a device for recording this property of lightning currents. It consists of three circuits containing resistance and inductance having different time constants which are connected across an inductance carrying the main surge current. A photograph of this coil is shown in the left-hand side of figure 18 and its auxiliary circuits on the right-hand side. Magnetic links placed within the field of the inductors of these three circuits serve to record their maximum currents, i_m.

Referring to figure 17 it may be seen that if the resistance of the main coil is negligible, the voltage across it is proportional to the rate of change of the surge current and its inductance L. If the inductances L_1, L_2, and L_3 of the auxiliary circuits are equal to zero the currents in these circuits are all proportional to the voltage across the inductance L and will have the wave shape indicated by the dotted line in figure 16*a*. In this case the maximum currents in all three auxiliary circuits are proportional to the maximum instantaneous rate of rise of the main surge current.

By the introduction of the inductances L_1, L_2, and L_3 the maximum currents in the auxiliary circuits are made to indicate, not the maximum instantaneous values of rate of rise of the surge current, but the average value given by the line *aa′* in figure 16*a*. The current in the auxiliary coils is then of the general form

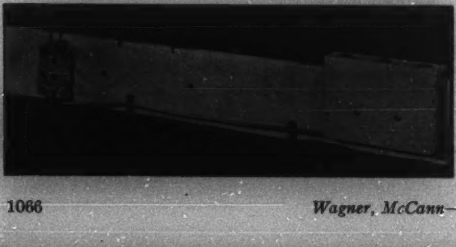


Figure 18. **Magnetic surge-front recorder**

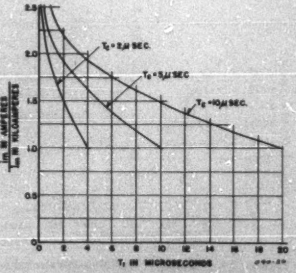

Figure 20. **i_m/I_m as a function of T_1 for fixed values of L, R, and T_c**

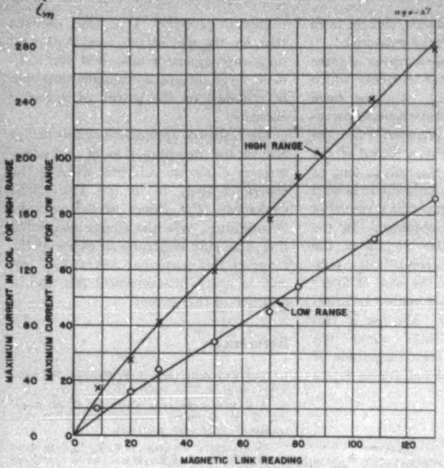

Figure 21. Calibration curves of magnetic links in magnetizing coils

of figure 16*b* varying with the circuit under consideration.

From figure 17 if *I* is the main surge current; i_1, i_2, and i_3 the instantaneous currents in circuits 1, 2, and 3, respectively; and R_1, R_2, and R_3 their respective resistances; then for any of the auxiliary circuits such as circuit 1, a voltage equation such as the following can be written:

$$L\frac{dI}{dt}=R_1i_1+(L+L_1)\frac{di_1}{dt}$$

The solution of this equation in terms of the maximum value of i_1, namely i_{m1}, can be expressed in the form

$$i_{m1}=\frac{L}{R}I_mF\left(\frac{T_{c1}}{T_1}\right)$$

where

I_m = maximum value of I

T_{c1} = time constant of circuit 1 including the inductance L

$= \frac{L+L_1}{R_1}$

T_1 = time to crest of the straight line passing through the 10 per cent and 90 per cent values of current as defined in figure 16

Speaking generally, the extent to which i_m is affected by the nature of the wave front is shown in figure 19. In this figure i_m/I_m is plotted as a function of T_c/T_1 for the three different wave shapes shown in the insert which have the same values of T_1. As T_c/T_1 approaches zero the response i_m/I_m approaches more and more a value corresponding to the maximum instantaneous rate of change of *I* and the spread for the three different waves becomes greater. However, for all practical purposes i_m/I_m is independent of wave shape for values of T_c/T_1 greater than 0.5.

For the specific values of *L*, *R*, and T_c used in the instruments, i_m/I_m can be expressed as the functions of T_1 shown in figure 20 for the range in which T_c/T_1 is greater than 0.5. It can be seen from these curves that if i_m and I_m are known, the duration of the front of the wave, T_1, can be determined. The calibration curves for obtaining i_m from the magnetic-link readings are given in figure 21. It is planned to use this device in conjunction with the fulchronograph which would supply the value of I_m. The purpose of using three circuits instead of one is to increase the accuracy of the instrument. The three curves terminate at values of T_c/T_1 equal to 0.5, because of the inaccuracies mentioned in connection with figure 19 for ratios below 0.5. A similar device can be developed in which the inductance *L* is replaced by a mutually coupled loop.

The foregoing analysis has been based upon neglecting the negative values of dI/dt on the tail of the wave. Since the readings of the magnetic links are dependent to some extent upon reversal of current in the auxiliary coils a limit must be placed upon the permissible negative slope for which sufficient accuracy is attainable. This value is set at a tail slope of about 20 per cent of that of the front slope, a value believed to be greater than that characteristic of most lightning currents.

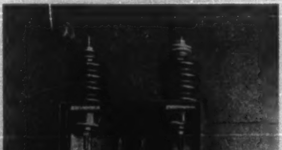

Figure 22. Magnetic surge integrator

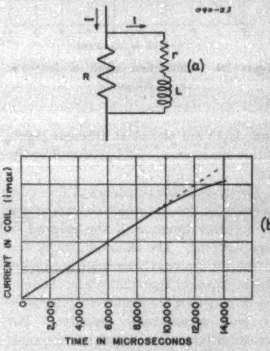

Figure 23. Response of magnetic surge integrator to square-front surge current

Magnetic Surge Integrator

The magnetic surge integrator shown in figure 22 is a relatively simple and inexpensive device for recording the total charge or the integral of the current in a lightning surge. It consists essentially as shown in figure 23*a* of a noninductive shunt which carries the main surge current, across which an inductor is connected.

Neglecting the resistance of the coil the current in it at any instant is equal to the integral of the main surge current and if the surge is nonoscillatory the final maximum value of this coil current is the total integral of the main surge current.

The magnetic field which magnetizes the links is a function of the coil current. Thus from a measurement of the remanent magnetism in the links a record of the total charge in the surge is obtained. To cover a wide range of sensitivity two magnetic links are placed at different points within the magnetic field produced by the coil.

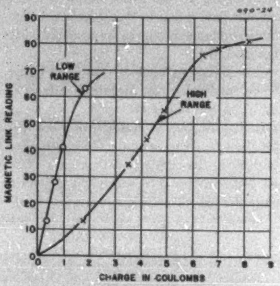

Figure 24. Calibration curve of magnetic surge integrator

The effect of the resistance of the coil is to limit the time for which the response is an accurate measure of the integral of surge current. The extent to which this is true for the constants used in this device is shown in figure 23*b* where the relation is given for the response of the surge to unit square-value impulse. For periods of time up to 10,000 microseconds the response of the coil is essentially linear. This device will therefore accurately integrate unidirectional surges which do not last longer than 10,000 microseconds. In figure 24 are given the calibration curves for one of these instruments having a shunt resistance of 0.05 ohm, designed to be used in transmission and distribution circuits. It is seen that for this value of resistance, charges from 0.1 to 8.0 coulombs can be measured.

In figure 25 are shown curves of three general types of surge currents which might be encountered. On the same curves are given current-response curves of the magnetic surge recorder. Since the magnetic links will give a record of the maximum current in the coils as long as the current is of one polarity it is seen that in the case of figure 25*a* a record of the total integral is obtained. In the case of figure 25*b* the integral of the initial predominant component only will be obtained. In the case of figure 25*c* the record obtained cannot be interpreted and is useless. The use of two surge-crest-ammeter links serves not only to measure the crest magnitude of the main surge current but also to detect change in polarity. It is thus thought that by the use of the combination of surge-crest-ammeter links and the magnetic surge integrator valuable data can be obtained on the nature of lightning currents.

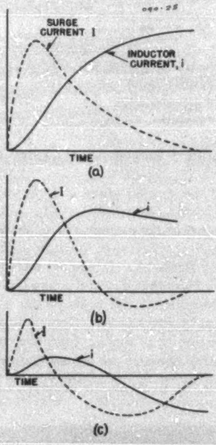

Figure 25. Response of magnetic surge integrator to different wave forms

The principal application of this device lies in the determination of lightning-arrester discharge currents, wherein the charge is likely to be less than eight coulombs. For direct strokes of the "continuing" type the charge associated therewith may be greatly in excess of the range of this particular instrument, not only in charge measurement but also in duration of the current.

Corona Discharge on Rubber-Insulated Cables

Discussion and authors' closure of paper 39-108 by E. B. Paine and H. A. Brown, presented at the AIEE Middle Eastern District meeting, Springfield, Mass., May 3–5, 1939, and published in AIEE TRANSACTIONS, 1940, pages 709–14.

G. M. L. Sommerman (American Steel and Wire Company, Worcester, Mass.): The writer's discussion of the interesting paper by Professors Paine and Brown is concerned chiefly with the graphs on the right side of figure 2. These graphs depict ozone formation and corona current as functions of the voltage applied to rubber-insulated cables on flat metal test plates for two conditions: (1) the corona produced between the cable and the curved ends of the test plate is included in the results; (2) only the corona produced along the test plate where the insulation is in firm contact with the test plate is included in the results.

For condition (1) ozone formation begins at a voltage which is the same as that at which corona current begins (less than three kilovolts). For condition (2) ozone formation does not begin until the applied voltage is nearly five kilovolts. This voltage is the same as that given in table I for the visible corona forming voltage for this cable (*P*).

This raises the following questions: (1) For cable in firm contact with a metal electrode, is ozone formed only when visible corona is observed? (2) Is visible corona observable in the space between the cable insulation and the curved ends of the test plate when the applied voltage is slightly above the "corona starting voltage" but less than the "visible corona starting voltage" given in table I? (3) If the corona in the space between the cable insulation and the curved ends of the test plate were eliminated by filling this space with solid insulation such as wax, would corona current be measurable at voltages less than that necessary to produce visible corona? These questions apply, of course, only to cables for which no "internal corona" is possible, that is, smooth unbraided cables in which the insulation adheres to the conductor.

While it is true that in practice the cables are not in firm contact with the conduit at all points, it would be desirable to have the answers to the above questions as they are of fundamental importance in the study of ozone formation and corona cutting of insulation.

In previous reports of the work carried out at the University of Illinois (reference 1 in the paper, page 37 and the following), data were presented showing the deterioration caused by corona on rubber-insulated cables. The writer suggests that it would be valuable to extend these studies to cases where the cables are surrounded by an inert gas, such as nitrogen, instead of air. The experimental setup portrayed in figure 1 of the present paper would lend itself admirably to such studies. These tests, in conjunction with tests made in air, would show the importance of pure corona cutting as compared with that of ozone as causes of deterioration of rubber insulation. This question is of interest in connection with the deterioration which might occur in cables in which the rubber does not firmly adhere to the conductor, because, as the authors have found, air does not readily permeate the spaces between the conductor and the rubber.

Wm. A. Del Mar (Phelps Dodge Copper Products Corporation, Yonkers, N. Y.): It is of interest to compare the conclusions of the authors with Insulated Power Cable Engineers Association standards.

"The commercial two-kilovolt cables with ozone-resisting rubber insulation both with braid and without braid and its saturant are in general, properly rated as to voltage from the corona starting point of view. The five-kilovolt cables are close to the nominal rating."

IPCEA requires no shielding for voltages up to 6,000 volts.

"The 12- and 14-kv cables which were tested appear to be overrated since corona discharge occurs below the normal operating voltage."

IPCEA requires shielding on braided cables for 6,001 volts and over.

The authors' tests confirm the IPCEA standard with respect to the two groups of ratings considered.

A further confirmation of the correctness of their findings is that corona trouble is experienced in some but not all 5,000-volt lines. The authors' tests therefore confirm practical experience in that respect.

I am interested to note that the authors give no data on internal corona. E. J. Merrell of our laboratory has found that an oscilloscope wave of the charging current reveals whether ionization is internal or external or both. If the high-frequency harmonics appear on the peak of one half wave the corona is internal, if on the other, it is external, and if both half waves show high frequency harmonics, there are both internal and external corona. It is easy to find which half wave corresponds with a particular kind of corona by substituting a sample of known corona characteristics. Figure 1 of this discussion shows a typical oscillogram of rather mild unilateral corona discharge. The high-frequency harmonics sometimes appear as distinct surges which may have an amplitude several times that of the fundamental wave, and sometimes as mere fuzziness of the fundamental wave. The former were found when ionization occurred at a metallic surface such as conductor or shield and the latter when no metal or other high emissivity electrode was present.

The oscilloscope test therefore possesses certain advantages over that used by the authors in enabling an analysis of the location and type of ionization to be performed.

We have found that when external corona becomes sufficiently violent it gives rise to internal corona at voltages which will not form internal corona if there is no external corona. This is shown by both the above described wave peculiarities and by the fact that cables with external corona often fail by internal ozone-cutting at voltages which are quite harmless if the external corona is suppressed by shielding. This is due, probably, to the greater potential drop over the internal air films, at the higher harmonic wave frequencies.

It is unfortunate that the authors do not give the specific inductive capacity of all their insulating compounds. With this information, it would have been possible to check the several theoretical formulas which have been developed, connecting ionization point with specific inductive capacity and the geometry of the cable.

The authors make a point that ionization occurs in many cables at a voltage below their normal operating voltage. This sounds alarming but is not really so, as ionization tends to die out and requires a higher voltage to re-establish it. This phenomenon occurs in paper and varnished-cambric insulation as well as rubber. Furthermore, a mild corona such as shown by a fuzzy wave of charging current is absolutely harmless. The authors' method undoubtedly reveals this fuzzy wave as ionization current. It is not until definite vertical lines show on the wave that ionization begins to be destructive.

E. B. Paine and **H. A. Brown:** Replying to the points raised by Doctor Sommerman: (1) this question cannot be definitely answered by the authors at present. Before an answer can be given it would be necessary to eliminate completely the corona at the curving away portions of the test piece outside the glass enclosing tube. The insertion of wax or paraffin probably could not be relied upon to eliminate all possible chance for the existence of minute air spaces

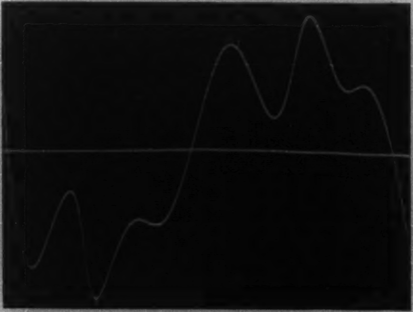

Figure 1

at the critical separation of insulation surface and metal test plate. However, a properly designed oil cup or trough could be cemented to the enclosing tube end cover plates, so that the curving away region could be kept under oil. The authors found that if a metal trough is substituted for the test plate and the test piece submerged in oil, all detectable corona discharge was completely suppressed, even though it was previously accompanied by full visibility. (2) In this investigation "visible corona starting voltage" was actually the point at which the corona became visible along the entire length of the test piece, including the sections of firm contact, as mentioned in the paper. On a number of test pieces definitely audible discharges, giving a small meter reading, were obtained. (3) We have discussed this under point (1); we feel that oil would be better than wax for this purpose.

Regarding the comments by Mr. Del Mar, the authors have previously made tests for internal corona, that is, for ionization discharges which may exist either between the conductor surface and the rubber covering, or in porous spaces which may occur in the insulation material. This was done by immersing the test piece in a salt-water bath, providing suitable pot heads at the points where the test piece entered the water. The authors wonder if the oscilloscope setup used by Mr. Del Mar provides a detector of *high sensitivity*. In the test equipment used by the authors a potential of 3×10^{-6} volts applied to the input of the preliminary amplifier produce a readable deflection of the output meter. In some cases the disturbances due to the corona discharge are minute as compared with the 60-cycle charging current at the starting point of detectable corona, the ratio being less than one to 1,000. Even with the high sensitivity mentioned the output level is sometimes so low at the starting point of corona discharge that the output meter shows no appreciable deflection, the discharges are merely heard in a high-sensitivity headset.

Characteristics of Restricted Ionization and Its Relation to Voids in Insulating Materials

Discussion and authors' closure of paper 39-109 by C. L. Dawes and P. H. Humphries, presented at the AIEE North Eastern District meeting, Springfield, Mass., May 3–5, 1939, and published in AIEE TRANSACTIONS, 1940, pages 701–08.

J. D. Cobine (Harvard Graduate School of Engineering, Cambridge, Mass.): The authors have presented a comprehensive study of the performance of a composite dielectric, under high electrostatic stress, such as may exist, for example, in a cable or the slot insulation in an alternator. The consistency of the experimental results is evidence of the precision with which the over-all characteristics of insulation may be determined by the Dawes-Hoover bridge. In view of the uncertainties always involved in studies of a-c gas discharges, the material presented agrees remarkably well with the results of d-c investigations.

Since one electrode of the air gap is of metal and the other is of glass, the experimental arrangement simulates the conditions for an air film between solid insulation and either the conductor or the sheath of the cable or any void in which conducting material forms one electrode. This arrangement would be expected to exhibit a polarity effect in the current wave. There appears to be no essential difference in the positive and negative half-cycles of current in figure 5. It would be interesting to learn if this is true for all conditions of voltage, current, gap, and pressure. It would seem valuable for the authors to investigate the characteristics of an air gap where both electrodes are of the same insulating material, so as to simulate the conditions where voids occur *within* insulation.

Although the gaps used are greater in thickness than the air films existing in cables, the experimental results can be referred to the shorter gaps if all the requirements of the similarity law are fulfilled. It is evident that the experimental arrangement, of carefully guarded plane parallel electrodes, is ideal from this standpoint. However, extreme caution must be exercised in determining the actual voltage across the air gap when a discharge exists for part of the cycle. The presence of a gas discharge results in space-charge distortion which does not completely disappear immediately after the discharge is extinguished. The gas discharge itself acts as a sort of valve in charging the solid dielectric. When the metal is cathode, electrons collect on the surface of the insulation and remain there during the nonconducting period, if the very small leakage current is neglected. This surface charge on the insulation establishes a high electric field across the gap while the applied voltage is decreasing, and the gap breaks down in the reverse direction while the applied voltage is relatively low, as is shown by the oscillogram. The electron charge is then replaced by a positive-ion surface charge and the process continues. Under such conditions the division of the applied voltage between the two series members of the composite dielectric would be expected to depart from the values determined solely by the capacitance of the two members. An examination of figure 9 reveals that the values plotted, that is, maximum gap voltage (determined by capacitances) divided by the gap length, do not quite satisfy Paschen's law, which states that the spark breakdown voltage is a *function* of the product of gap length and gas pressure. It is reasonable to believe that this discrepancy is due to the distorting effects of space and surface charges. Future work by the authors will undoubtedly be directed toward an experimental investigation of the actual voltage across the air gap and a determination of the effects of space and surface charges.

L. W. Marks (General Electric Company, Pittsfield, Mass.): The authors of this paper are working on a problem which should be of great interest to manufacturers of electrical insulation but which, unfortunately, has been the subject of far too little investigation. They indicate that their work is to be continued and this should prove of real value to a more complete understanding of the mechanism of ionization in narrow, restricted gaps.

I would like to ask the authors if the characteristics of the discharge would be altered if the ionized space were entirely enclosed as in a void in a cable. A continuous stream of air is said to pass through the apparatus shown in figure 4, and it seems possible that this may alter the ionized gas or sweep away the space charge. Would it not be necessary to make measurements in a completely enclosed space in order to obtain conditions more nearly comparable with those occurring in the gas pockets of cable or other insulation?

I have found from radio noise measurements on gas pockets in organic fabricated insulation samples blistered for test purposes by excessive heat and vacuum, that when the completely enclosed space is ionized, the effects of this ionization may exist for minutes, and in some cases even hours, after the voltage has been removed. Residual ionization was evidenced by a much lower critical gradient following the initial ionization. Moreover, if the void was vented mechanically, the critical gradient was increased to its original value.

Measurements at radio frequencies completely eliminated the 60-cycle component, and in most cases gave a sudden and distinct starting value, indicating the occurrence of cumulative ionization. Once ionization was precipitated, it was possible to reduce the voltage to as low as one-eighth the original starting value before secondary ionization ceased. It appeared that space charge played a prominent role in this action and may have become bound on the insulating surfaces of the void after the removal of the initiating voltage.

As shown by the authors, the critical gradient-gap length curve rises at small gap spacings in accordance with the law of Townsend, Peek, and others. In my radio-frequency measurements, the smallest gas-pocket thickness was eight mils or 0.0203 centimeter. The critical starting gradient for ionization was found experimentally to be 92.5 kv crest per centimeter. Substituting in equation 1, page 5 of the paper, we obtain

$$G = 30 + \frac{1.35}{0.0203} = 95.4 \text{ kv crest per centimeter}$$

which is in close agreement with experiment. On the other hand, substitution in equation 3 results in the unreasonably high value of 273 kv per centimeter and indicates that this equation does not hold in the region of small gap lengths below the range studied in this paper.

G. C. Nonken (General Electric Company, Pittsfield, Mass.): The authors are to be commended on their methods of test and the manner in which they have presented their findings on this complex phenomena of restricted ionization. They chose to restrict their measurements to the 60-cycle or fundamental-frequency characteristics of the corona or ionization. The ionization current is, however, made up of a series of random pulses which contain very high frequencies. The authors' oscillogram of corona current, figure 5, indicates the presence of high-frequency current.

The writer has conducted some tests on restricted corona in a 0.05-inch-thick air gap in series with a 0.2-inch-thick glass plate. The electrode against the glass plate was conducting material painted on the glass. The electrode next to the air gap was a 10-centimeter-diameter flat brass disk. These tests were made in dry air at atmospheric pressure.

Figure 1 of this discussion shows oscillograms taken of the corona current with a cathode-ray oscillograph. This oscillograph with attached amplifier is capable of giving true reproduction of frequencies up to 90,000 cycles, although the photography was not capable of reproducing such high-frequency traces. The preionization charging current was balanced out and does not appear in the oscillogram. The writer's experience does not check the authors' figure 5 as to the phase of the corona current with respect to the voltage. It has been observed that the corona current in voids always is in phase or leads the crest of the voltage. It would appear from past experience that the current and voltage in figure 5 are 180 degrees out of phase with their true phase relation.

Figure 1. Corona current in a 0.05-inch air gap in series with a 0.2-inch-thick glass plate

(*A*)—Current at 4.5 kv root mean square, 60 cycles

(*B*)—Current at 6.75 kv root mean square, 60 cycles

(*C*)—Current at 9 kv root mean square, 60 cycles

High-frequency measurements were made on the corona current of the above test piece with 60-cycle voltage applied. The tests were made with a tuned high-frequency meter across a resistance in series with the sample. The results showed that the corona current contains frequencies from at least as high as 20 megacycles down to the audio frequencies.

For the particular exterior power circuit used, the magnitude of the high-frequency current was greatest at 1.5 megacycles and diminished to about half the maximum value at 20 megacycles and at 0.16 megacycles. As the total voltage across the test piece raised from ten per cent above the corona starting voltage to twice that value, the high-frequency component of the corona current increased eight to ten times. The 60-cycle component of the corona current is nearly proportional to the first power total voltage 60-cycle voltage across the sample.

The writer believes, that although the authors have shown the 60-cycle component of the ionization current follows definite simple curves when plotted against different variables, the restricted ionization is more definitely a high-frequency phenomena. High-frequency measurements would add much to the study which the authors have so ably conducted at power frequencies.

G. M. L. Sommerman (American Steel and Wire Company, Worcester, Mass.): The paper by Professors Dawes and Humphries is a valuable contribution to the knowledge of ionization in its relation to voids in dielectrics.

In figure 6 of the paper, data are presented showing the voltage gradients across the air space as a function of the current density in the air space. Above a critical gradient G_0, the current increases more and more rapidly, and the gradient passes through a maximum G_m and then decreases with further increase in current. The authors liken this behavior to that reported by Engel and Steenbeck. For uniform fields and atmospheric pressure, however, it would seem that the ionizing current should be extremely small until the gradient reaches the breakdown strength of the air space, at which point the whole air space should suddenly discharge, resulting in a sudden increase in current corresponding to the electrostatic energy stored in the air gap, $^1/_2CV^2$. This would occur four times in each cycle of the applied wave resulting in a current increase of $4fCV$.

Actually with the experimental setup used by the authors, the field is not entirely uniform because the space between the guard and active low voltage electrodes ($^3/_{32}$ inch) is large compared with the thickness of the air space (0.08 to 0.4 centimeter), and stress at the edges of the low-voltage electrode is greater than the average stress. When the stress at the electrode edges reaches the ionizing value, local discharges begin, and the current would be expected to increase only gradually with further increase in stress. Thus, this might explain the shape of the voltage-current curves obtained, and could even account for the variations in G_m-G_0 with variations in spacing and pressure noted by the authors.

The data given by S. Whitehead (reference 13 in the paper) most nearly corresponding to the range of gap lengths investigated by the authors would seem to be that given in diagram III, page 43. For this, the expression for sparking voltage is

$$G=31.2+1.6/S$$

This is greater than that given by the authors in equations 15 to 17 although less than that indicated by equation 14 for the shortest gap. Incidentally, the writer would like to know if he is correct in assuming that equations 10 to 17 were derived on the basis that the coefficients of the last terms are obtained from G_m-G_0, in accordance with the suggestion made by the authors earlier in the paper.

C. L. Dawes: Both Doctor Cobine and Mr. Marks bring out the fact that these experiments were conducted for a gap bounded by an insulating surface and a conducting electrode, and that the results might be different if both boundaries of the gap consisted of insulating surfaces, such as ordinarily occurs within insulation. The authors agree that with both boundaries of the gap consisting of insulating surfaces the results might be somewhat different and also that conditions within insulation are more nearly simulated. However, the results given in this paper are merely the beginning of an extended research and it seemed rational to commence with the more simple arrangement. Also, it was felt that with one conducting electrode, conditions would more nearly simulate the conditions of breakdown tests between flat parallel electrodes, particularly in the ionization and glow discharge regions, figure 2 of the paper. The close agreement of our results with the breakdown values of Townsend and others indicates, we believe, that we have simulated such conditions quite closely.

Further investigation is still being conducted and it is planned to extend the research to the measurement of gaps of very short lengths and to gaps which are bounded on both sides by insulating surfaces. Both of these investigations are suggested by Doctor Cobine and Mr. Marks as well as by several of the reviewers. Also, Mr. Marks asks if the characteristics would be altered if the ionized space were entirely enclosed as in a void in a cable. We have not conducted experiments with insulation on both sides of the gap, but we have conducted preliminary tests with the metal electrodes and glass in which the gap was sealed so that the products of ionization could not escape. We found that the characteristics of the gap not only varied with time but that tests did not repeat themselves very well. There has not been time to carry this particular investigation further but it is planned to do so in the near future.

Also, for the investigation of very short gaps small electrodes capable of precise adjustment of the air gap, and a bridge designed specifically to measure the characteristics of such short gaps are now under construction.

Doctor Cobine mentions the valve effect of the electrons and the positive ions which collect on the insulating surface and remain over into the next cycle. There is no doubt that this effect exists, as is shown by the dissymetrical current waves shown in figure 2 of this discussion. For example, we have applied high-voltage direct current to such a gap and at the instant of application of voltage the gap is momentarily ionized, which usually may be seen by a flash of corona. This is due to the fact that with instantaneous application of voltage to the system, the voltages across the glass and gap are distributed inversely as their capacitances, and the gradient across the gap is sufficiently great to produce ionization. However, the free charge on the glass surface is immediately attracted to the metal electrode because the sign of the charge on the electrode is opposite that on the free charge. The charges on opposite sides of the gap then become of the same sign and the gradient is reduced to a value far below the ionization gradient. This condition persists for two or three minutes during which time the bound charge on the glass leaks to the electrode to which the glass is attached. This gradually raises the gradient across the gap until ionization again occurs momentarily and the cycle repeats itself. This shows that charge does remain on the insulating surface. With alternating current, however, this charge is removed as soon as the potential of opposite sign on the metal electrode becomes sufficiently great to attract the charge to itself. There is, however, some slight rectifying action as Doctor Cobine suggests. This is illustrated by figure 2, which shows an oscillogram in which the positive and the negative current waves are different in shape. The authors realize that space charges do have some effect on the gradient within the gap and state this fact in the paper. This undoubtedly has some effect on the breakdown gradient, for our breakdown values show some departure from Paschen's Law when the product of pressure and gap length are considered, as pointed out by Doctor Cobine. This effect cannot, however, be large because of the close correlation of our maximum gradients with breakdown values that have been obtained by others.

Figure 2

Volts, 11,600 root mean square; 45 cycles; gap, 1.59 millimeters

Upper trace—voltage; lower trace—current

Doctor Cobine points out that the gap breaks down at a relatively low voltage as shown by the oscillogram and this is due to the residual charge which remains on the surface of the glass in the manner just described for direct current. When the voltage reverses, the sign of this residual charge is such as to raise the gradient across the gap, causing ionization to begin at a lowered value of impressed voltage. The residual charge remains until the potential on the metal electrode is sufficiently great to attract it across the gap. It is difficult to evaluate this effect but again it cannot be large since the values of maximum gradient obtained by us are in such close accord with experimental breakdown values.

Mr. Nonken is correct in pointing out that the voltage wave in figure 5 of the paper is 180 degrees out of phase. An oscillograph vibrator was inadvertently reversed and the error was not noticed until too late to make correction. Mr. Nonken's investigations of the very high-frequency components of the corona current, made under conditions quite similar to ours, are very interesting and add to the knowledge of ionization phenomena. We have taken a large number of oscillograms of the corona current under different conditions and with any substantial ionization they showed frequencies from the fundamental up to the limit of the vibrator response as may be seen from figure 2. Accordingly, we realized that the frequencies must extend well up into the radio-frequency range. We did not know, however, that the maximum high-frequency current occurred at such a high value as 1.5 megacycles. We agree with Mr. Nonken that much could be learned in the high-frequency range, but measurements under the pulsating conditions of the high-frequency current will not be easy. In fact, these 60-cycle measurements are not simple. Also, the power-frequency voltage across the gap can be sinusoidal such as a 60-cycle wave and the harmonic frequencies in the current contribute no power with respect to this voltage. This, again, would make difficult the measurement of high-frequency power.

Doctor Sommerman, in his discussion, suggests that with uniform gaps the ionizing current is small between the gradients G_0 and G_m, figure 6, and when the gradient reaches G_m there is a sudden increase in current due to the electrostatic energy stored in the air-gap, ${}^1/{}_2CV^2$. Our results show that the ionization current is small but appreciable between the gradients G_m and G_0 but its rate of increase is increasing rapidly due to the increasing rate of ionization. We have investigated the literature and discussed with physicists the nature of the phenomena occurring in this region and there appears to be no general agreement. A number of proposed theories is given in the paper. If the voltage across the gap is maintained constant, that is, if the gap is connected across an "infinite bus" the energy stored in the capacitance of the gap ${}^1/{}_2CV^2$ would have no effect, for like the capacitance, the "infinite bus" can deliver an infinite current, but it can sustain this current for any time whatsoever, which the capacitance cannot do.

Under the conditions of these experiments, the energy that can be delivered when discharge occurs is limited by the series impedance of the gap. It is probably true that with rapid increase of current at breakdown with no series impedance, the current-voltage characteristic will not be identical to the characteristic when the current flow is limited and held at definite values as in these experiments.

The space between the guard and ring as used by us could probably be reduced. The edges of the plate and guard were slightly rounded and no local discharges at these edges have been noted. The variation of breakdown with electrode spacing which Doctor Sommerman attributes to this space, is a well-established fact and therefore the authors do not attribute the variation of G_m with spacing to this space between the plate and guard.

The coefficients of the last terms in equations 10 to 17 were obtained from a considerable amount of data and curves, all of which could not be included in the paper because of space limitations. The value of G_0 corresponds to the point where the current-voltage gradient curve departs from the straight-line relation. However, a more sensitive method for obtaining this point is to take the value of gradient in the calculations, at which an energy component of voltage first appears. Doctor Sommerman is correct in pointing out that diagram III, page 43 in Whitehead is more in accordance with our gaps than diagram II. The gradient equation which he gives is more nearly in accordance with our equations 14 to 17 than our equation 3.

The Rectifier Calculus

Discussion and author's closure of paper 39-101 by W. Melvin Goodhue, presented at the AIEE North Eastern District meeting, Springfield, Mass., May 3–5, 1939, and published in AIEE TRANSACTIONS, 1940, pages 687–91.

F. O. Stebbins (General Electric Company, Schenectady, N. Y.): The rectifier calculus as described in this paper makes available to the designing engineer a greatly simplified method for computing many of the characteristics of mercury-arc rectifiers such as output direct voltage, regulation, etc. We have checked some of the formulas developed in this paper and find them to be entirely correct for balanced supply-system voltages. Also they present a considerable saving in time and effort over conventional mathematics. In addition these formulas are no more complicated when the supply-system voltages are unbalanced whereas the solution of unbalanced rectifier circuits with conventional mathematics is somewhat laborious.

We note that the author does not describe any simplification in the method used for calculating rectifier wave shapes and power factor and would like to know if he has attempted to develop his mathematics to include these characteristics.

The author points out that the rectifier calculus has not been completely developed for all the different possible rectifier applications, and also that it can be used in other fields such as for example differential and transcendental equations.

C. C. Herskind (General Electric Company, Schenectady, N. Y.): The operational method proposed by Mr. Goodhue in his paper "The Rectifier Calculus" provides a new tool for calculating rectifier characteristics and behavior. While the methods used at present for making calculations on rectifier circuits are usually quite simple and adequate, the increasing growth of rectifier applications will undoubtedly bring complex problems where the operational method will prove useful.

The calculations commonly made on all rectifiers cover voltage regulation, power factor, efficiency, and wave form. These calculations usually involve a very simple formula derived from an analysis of the physical action in the rectifier and its circuit. Inasmuch as such an analysis of the physical action is quite valuable in studying rectifier behavior, the operational method will probably prove useful only in cases which are so complex that the physical action cannot be readily analyzed.

In order that a rectifier circuit be suitable for commercial application, it must have the proper characteristics not only over the normal load range but also over the full range from absolute zero load to dead short circuit. In the determination of rectifier behavior out of the normal range, unique characteristics, such as, rise in voltage at light load, pulsating current on noninductive load, prestarting due to excessive overlap, unbalance due to mutual reactance efforts and so forth, are frequently observed.

Perhaps the operational method may be a useful tool in handling some of these problems. I would like to ask Mr. Goodhue if he has applied his operational method to any of these problems.

A. Schmidt, Jr. (General Electric Company, Schenectady, N. Y.): Mr. Goodhue has given us a novel treatment of repeated transient problems yielding a useful form of solution, particularly for unbalanced conditions. The treatment of the effect of commutating reactance especially has been simplified. The assumptions which have been made to apply the solutions of full-wave cases to half-wave circuits should not affect the validity of the results in the linear range. It will be interesting to see the method extended to cover the nonlinear range of rectifier regulation, the calculation of peak currents during arc-back and like problems.

While the present physical concepts and associated mathematics will continue to be used for many problems, it is quite possible that Mr. Goodhue's rectifier calculus will find considerable use in due time.

I. K. Dortort (Allis-Chalmers Manufacturing Company, Milwaukee, Wis.): Mr. Goodhue has brought to the attention of rectifier engineers a relationship which should prove very useful in the analysis of rectifier performance under various conditions of unbalance. The fact that this relation is very apparent once it has been seen adds considerably to the value of this contribution.

The entire "calculus" is built around an operator S, which, I believe, evaluates the rectified value of the voltage difference between successively firing anodes. It is difficult to differentiate between operators and shorthand notations. It might almost be stated that operators are shorthand symbols for involved operations, that lend themselves readily to mathematical manipulations and transformations. I would prefer to consider S in the category of convenient descriptive symbols.

It appears that considerable simplicity and usefulness is sacrificed in attempting to apply S analytically. The use of operators is really justified only where the mathematical treatment of the subject becomes so involved that the human mind has difficulty in visualizing the physical concept of the mathematics or cannot readily follow the various quantities through all the steps. Most engineers will agree, and probably mathematicians too, that operators, while producing results quickly and mechanically, tend to destroy the physical concept which is so important in avoiding errors.

I think the paper itself will bear me out in this. Compare the proof of the transformation theorem given in the appendix to the beautiful and simple explanation afforded by figure 2a. The area beneath the positive envelope of the unbalanced anode voltages, divided by time, is the average direct voltage of the rectifier. It is quite obvious that this area is equal to the area between the negative envelope of these voltages and neutral. The direct voltage in the case of a three-phase three-anode rectifier is therefore equal to one-half the total area between the positive and negative envelopes divided by time. Using the three-phase connection shown in figure 5, the direct voltage will, of course, be twice as great or equal to the total area between the two envelopes divided by time.

The cross-hatched areas show very clearly that the total area can be obtained by summing the areas between e_a and e_b between limits 6 and 3; the area between e_b and e_c between limits 2 and 5, and between e_c and e_a between limits 4 and 1. At each of these limits the voltage difference between two anodes becomes zero, and, as pointed out in the paper, the contribution of each of these areas to the direct voltage, in the case of pure sine waves, is equal to the peak voltage difference divided by π.

By drawing similar pictures for various types of waves and unbalance conditions, it becomes apparent at once that equation 4 does not hold true when there are even harmonics present; nor when some of the anode voltages are so low that no part of their voltage wave is contained in the direct-voltage wave; or when the direct-voltage wave drops to zero for a finite interval of time.

If a graphic proof of the theorem is not sufficient, a rigorous analytic proof is available which is more readily followed than the one given in the appendix of the paper. The direct voltage can be expressed in the conventional manner as follows:

$$V_{DC}=\frac{1}{2\pi}\left[\int_{\theta_{p1}}^{\theta_{12}} e_1 d\omega t+\int_{\theta_{12}}^{\theta_{23}} e_2 d\omega t+ \int_{\theta_{23}}^{\theta_{34}} e_3 d\omega t \ldots .+\int_{\theta_{p1,p}}^{\theta_{p1}} e_p d\omega t\right] \quad (1)$$

in which the e's are the phase-to-neutral voltages, θ_{12}, θ_{23}, etc. are the points of intersection of e_1 and e_2, e_2 and e_3, and so on. The limitations listed above must be written into this equation for any specific case. (See figure 1 of this discussion.) This equation can be readily transformed by the transposition of the limits of integration to

$$V_{DC}=\frac{1}{2}\cdot\frac{1}{2\pi}\left[\int_{\theta_{p1+\pi}}^{\theta_{p1}}(e_1-e_p)d\omega t+ \int_{\theta_{12}+\pi}^{\theta_{12}}(e_2-e_1)d\omega t+\ldots .+\int_{\theta_{p-1,+\pi}}^{\theta_{p1}}(e_p-e_{p-1})d\omega t\right. \quad (2)$$

or

$$V_{DC}=\frac{1}{2}\cdot\frac{1}{2\pi}\sum_{n=0}^{n=p}\int_0^{\pi} e_{n,n-1} d\omega t \quad (3)$$

in which index $n-1=0$ refers to phase p and $e_{n,n-1}$ is the difference of successive phase voltages referred to their intersections for zero time. If any of the limitations are violated, additional terms will appear in equations 2 and 3, and cannot be overlooked.

It appears, then, that S is shorthand for each term of the above equations; in the author's paper it is used at various times to designate a curve, an area, and an average ordinate.

The application of equation 4 to the derivation of reactance drop does not follow

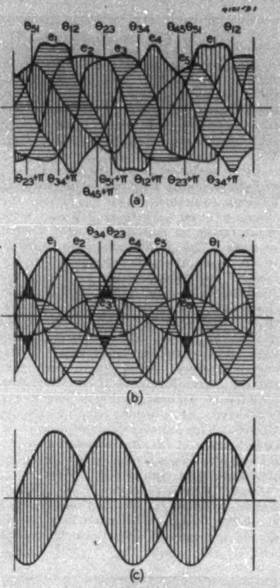

Figure 1

logically from the definition of S or from equation 4. In equation 6 the sum of the commutating reactances is multiplied by a direct current. There is nothing in what has gone before to justify such a procedure, and the explanation given in (6a) is merely the application of the older method of computing the area lost through overlap, applied to each individual overlapping period.

In this respect, it should be noted that if equation 6 holds true, the reactances must be the commutating reactance per phase and not from phase to phase. If the reactances are measured phase to phase, the right-hand side of the equation must be divided by 2. The rigorous derivation is as follows:

Reactance drop $d=$

$$\frac{1}{T}\left[\int_0^{\mu p1} L_{01}\frac{di_{p1}}{dt}dt+\int_0^{\mu 12} L_{02}\frac{di_{12}}{dt}dt+\ldots .\right] \quad (4)$$

If I is smooth,

$$d=\frac{I}{T}[L_{01}+L_{02}+L_{03}+\ldots .]$$

or

$$d=\frac{I}{2T}[L_{01}+L_{02}+L_{02}+L_{03}+L_{03}+\ldots]$$

$$=\frac{I}{2T}[L_{12}+L_{23}+L_{34}+\ldots .] \quad (5)$$

If the e's are sinusoidal,

$$d=\frac{1}{2}\cdot\frac{I}{2\pi}[X_{12}+X_{23}+X_{34}+\ldots .] \quad (6)$$

S cannot be applied as the reactance drop does not meet the requisites implied in the transformation theorem, although the final equations 5 and 6 resemble equation 4 of the paper. (See figure 2 of this discussion.)

In the expression for grid control, equation 7, the author states, and verifies in figure 3*b*, that when the release of the anode is delayed by grid control or other means, the voltage between adjacent anodes will still be integrated over a full 180 degrees, even though this integration will now include a negative part of the curve. This is a contradiction of what appears to be the only logical definition of *S* as an operator. We have here another case where the correct result is obtained because the answer was known beforehand. Figure 3 of this discussion shows the trick that must be resorted to to obtain the correct answer. There is certainly nothing in the definition of *S* or in the general theorem to justify this step.

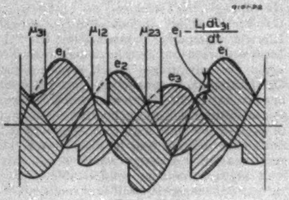

Figure 2

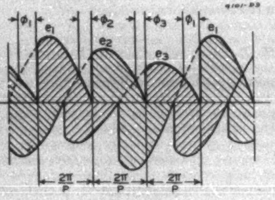

Figure 3

As in the case of overlap, the negative voltages and envelope must be assumed to be modified by grid control in the same manner as the direct-voltage wave. In the case of sinusoidal voltages this gives the same result as shifting both limits by an amount ϕ, but is more in keeping with the concept of *S* as the rectified anode-to-anode voltage.

Another point must be taken into account when calculating the effect of grid control under unbalanced conditions. Whether the phase angle or the magnitude of the phase voltages are unbalanced, or both, the intersections of the phase voltages will be unevenly displaced. Practically no grid-control systems in use today will have the releasing point of the anode displaced by the same amount. In other words, it will be necessary in each case to determine for each anode the actual amount of delay that will prevail under unbalanced conditions, and to calculate the drop in direct voltage for each anode individually.

It will be noticed that all the equations developed so far apply only to systems having all cathodes or all anodes tied together and having only one transformer neutral. When the system is split up by the use of interphase transformers, each group of phases obeys the above equations as if it were a complete rectifier system in itself. In other words, the number of phases, phase displacements, and output current are taken for that part of the system alone. Phase voltages are measured to the neutral of that group and not to the negative terminal of the rectifier unit.

Looking at it this way eliminates the necessity of visualizing the operator *S* as averaging the voltages of two or more different systems, which is another function not contemplated in the original definition of *S*. Furthermore, the voltages of the various groups will in all practical cases be equal to each other, and therefore need not be averaged. If these voltages are not equal, the load will be divided in accordance with the regulation of each individual group, and the correct answer is not obtained by a simple averaging of the output no load voltages. In such cases also it would be necessary in each individual case to determine whether or not the interphase transformers remain operative under such conditions of unbalance.

In a multiphase system such as shown in figure 5 of the paper, it will be seen that the rectifiers are divided into two groups, one group having all cathodes tied together, and the other having all anodes tied together. The first group will have a positive voltage with respect to neutral, and the second group an equal but negative voltage. Each group can therefore be treated separately, and the results added to give the total output voltage of the two groups which are effectively connected in series. This bears out the previous statement that for this connection the output voltage is the total area between the negative and positive envelopes of the phase voltages divided by time.

There are a few more minor points I would like to bring out. The statement is made that equation 8 is linear in p. Since this equation, however, involves terms such as $(e_a - e_b)$, which itself is a sine function of p, this statement is not strictly correct. As a matter of fact, it does not differ in this respect from the usual equation,

$$V = \frac{\sqrt{2}E \sin\frac{\pi}{p}}{\frac{\pi}{p}}$$

Since p is a fixed number for any given rectifier circuit, linearity or nonlinearity in p is of no practical importance.

The author's discussion of the difference between the calculus for rectifier circuits using interphase transformers with only half-wave rectification, as he states, and the calculus for star-connected or full-wave rectification, seems to me to be another example of how easy it is to be misled by an "operator". I cannot find any fundamental difference between the two rectifier circuits. Again we find that figure 2*a* gives the correct answer and that the output voltage of a rectifier with or without interphase transformers, and with odd or even phases, is measured by half the area contained between the positive and negative envelopes of the phase voltages of the individual groups. This fact seems to be entirely lost in the development of *S*.

In the author's explanation of equations 12, 13, and 14, it is stated that the double-wye output (meaning, I assume, output voltage) is $\sqrt{3}/2$ times the voltage of the fork-connected transformer, and that the voltage of the fork is 3/2 times the voltage of a single-phase rectifier. This assumes that the same phase voltage would be used in each case. If we assume the same direct voltage for each of the three connections, this statement is, of course, invalid. The author, however, goes further and states that the inverse voltage of the double-wye connection is $\sqrt{3}/2$ times that of the fork connection, and it may be implied that the inverse voltage of the fork connection is 3/2 times that of a single phase. Assuming equal direct-voltage outputs, no grid control and sufficient load to magnetize the interphase transformer, it will be seen that the inverse peak voltages of the double-wye and fork-connected rectifiers are equal, and the inverse peak voltage of the single-phase transformer is considerably higher than either of the other two.

The various numbered paragraphs in the author's conclusion presumably list the advantages of the new rectifier calculus over the older methods. Where unbalanced conditions exist, most of these advantages are real, at least as far as use is made of the differences between anode voltages instead of the phase-to-neutral voltages. However, where unbalance does not exist, but numerous harmonics are present (and this is becoming a very real problem), many of the advantages listed are imaginary. The notation certainly is simple, but the actual computation in most practical cases will still be found to require as much work as the conventional method.

W. M. Goodhue: F. O. Stebbins reports checking the formulas against known results for balanced systems and finding the formulas correct. He also reports labor saving observed in the new formulas, and asks if the rectifier calculus may be used to calculate wave shapes and power factor. Each S_y^1 term in the expansion theorem is a wave, for example a half-sine wave at light load when impedance drop is negligible. Because the S_y^1 wave is simple (180-degree interval) even for unbalanced rectifiers, its harmonics are known or very easy to obtain. The Σ sign in the transformation theorem indicates that the harmonics of a given frequency from different terms may be added, taking their phase angles into account. The result will be the output voltage expressed as harmonics; the d-c value previously obtained is a special case, that is the zero'th harmonic. This form of information would be suitable to telephone interference problems on the d-c side of the rectifier. For the a-c side, and for power factor, the subject, "alternating currents of polyphase rectifiers", given in the list of other application fields, is obviously involved. Developmental work in this field is not yet completed, but shows interesting possibilities. There are more factors involved such as harmonic cancellation. The author is indeed grateful to Mr. Stebbins for bringing out these interesting points.

C. C. Herskind reveals a characteristic of higher mathematical tools of showing great output when geared up to a really difficult problem. These problems will arise with continued industrial development. The author heartily agrees as to the importance of physical action, such as the rise and fall of anode current. Complex cases may be analyzed by the new mathematics, classified as to physical action, and the latter studied in a simple apparatus. Mr. Herskind asks if the new mathematics has been applied to problems beyond normal operating range of commercial rectifiers. Many of these problems are of transcendental (unknown angle) character, that is the fire and cutoff angles cannot be determined as elementary functions. The author has done some work, particularly with pulsating currents in the load; results indicate that such problems may be solved without cut-and-try methods. The subject is very complex, but promising.

A. Schmidt, Jr., agrees concerning the treatment of commutating reactance, and the application of the new mathematics to half-wave circuits. He suggests extending it to the nonlinear range of rectifier regulation. This may mean (1) treatment of nonlinear instantaneous arc resistance (instantaneous arc voltage drop plotted against instantaneous anode current not a straight line), (2) more than two anodes commutating, (3) peak current (hence boundary condition) unknown. Each of these subjects will be interesting to study relative to the new mathematics, though their study could undoubtedly fill a large book. The author is grateful for the suggestion. The problem of arc-back current calculation is complicated in addition by the variations possible in physical action, particularly voltage drops and inductance of the arc inside the rectifier; the previous problems should be tackled first.

I. K. Dortort goes into considerable detail in his discussion, and his recognition of the value of the theorem is appreciated. As he suggests, it is difficult to distinguish between operators and short-hand notation. This is a matter of personal opinion; some individuals have objected to recognizing the Heaviside operator d/dt, or even complex numbers such as $1+\sqrt{-1}$. But the usefulness of operators leads one to suspect that they "exist" as entities. More light on the new operator is given by considering other properties of rectifier circuits such as impedance, which may also be expressed by the operator. Considering a rectifier tube having but one anode, connected in series with load resistance R, electromotive-force source e, and having a constant tube drop E. The current i is given by:

$$iR=S^1(e-E)$$

Now solving for e:

$$e=E+\frac{R}{S^1}i$$

The instantaneous impedance may be defined as the voltage $(R/S^1)\ i$ divided by i, or R/S^1. The quantity R/S^1 evidently stands for an ideal rectifier tube connected in series with resistance R. Note particularly that R/S^1 is a derived quantity, not an arbitrary notation. Every operator, including the Heaviside operator, d/dt, begins with a notation, and ends with a system of derived quantities. The expansion theorem of the paper is another derived quantity. The impedance may be generalized by using any impedance z instead of resistance R, and extended by analyzing other circuit connections. The analytical treatment of the appendix, deplored by Mr. Dortort, was given only for those persons who insist on such things, and was placed in the appendix so that it could have been omitted if desired. Mr. Dortort must admit that the operator was responsible for the discovery of the theorem by the author. The integral method which Mr. Dortort suggests would hardly be applicable to the impedance calculations just given above, or the wave forms requested by Mr. Stebbins, since the wave forms are not integrals. Mr. Dortort is confusing the application to d-c calculation with the general theorem. His point on grid control is well taken, for only certain apparatus will preserve correct grid displacement under unbalanced conditions. For the general case it would be well to use a different cos α for each S_y^1 term in the expansion theorem, assuming only full-wave phase-angle conditions, which assumption is already made in the paper. The double-wye form, which Mr. Dortort wants to get rid of, is necessary to preserve the full-wave assumption. Written in simple half-wave form, the theorem would have to be restricted. Mr. Dortort's arithmetical calculations present merely a different form, as both the author and other discussers have checked the theorem. As to labor saving for balanced conditions, this depends on the form in which data are given; if the inverse or between-anode voltage is known, trigonometric functions such as $(p/\pi)\sin(\pi/p)$ may be avoided.

A New Measuring Instrument for Direct Current

Discussion and authors' closure of paper 39-92 by H. T. Faus and A. J. Corson, presented at the AIEE North Eastern District meeting, Springfield, Mass., May 3–5, 1939, and published in AIEE TRANSACTIONS, 1940, pages 683–6.

G. F. Gardner (nonmember; General Electric Company, Schenectady, N. Y.): Messrs. Corson and Faus have demonstrated again the advantages which accrue when the fundamental properties of a material are considered in laying out a new design. By abandoning the orthodox conception of appearance and size, they have started out along a fresh line of attack and the result has been a design which is not only well adapted for compact portable instruments, but one which will find ready adoption for incorporation in larger apparatus such as potentiometers and the like. Since space and weight, combined with good accuracy, are the outstanding problems in this larger type of instrument, their contribution will be appreciated by the designers of this type of equipment, who can thus make available to the user apparatus which is lighter and more compact without sacrifice of desirable characteristics.

This new design is remarkably stable in calibration as careful tests made under service conditions have shown.

H. T. Faus: Mr. Gardner has mentioned the importance of space and weight in connection with some instrument applications. This feature has not been emphasized in the paper, but a reduction in the weight and in the space occupied by the permanent-magnet system naturally follows the efficient use of a permanent-magnet material of high available magnetic energy. As an example, the substitution of a concentric Alnico magnet system for the conventional chrome-steel and soft-iron construction in a recording instrument saved 15 per cent in the total weight of the instrument and doubled the sensitivity. The entire saving was due to the change in the permanent-magnet system, no change being made in the moving system of the instrument.

Mingled Hydro and Steam Power Production in California—Past, Present, and Future

Discussion and author's closure of paper 39-119 by A. H. Markwart, presented at the AIEE combined summer and Pacific Coast convention, San Francisco, Calif., June 26–30, 1939, and published in AIEE TRANSACTIONS, 1940, pages 775–82.

E. E. George (Phoenix Engineering Corporation, New York, N. Y.): The history, condition, and prospects of power generation in California are presented in Mr. Markwart's paper in a very interesting, logical, and comprehensive manner. The importance of this subject to electrical engineers is self-evident. Similar studies of the other integrated areas might well be prepared for presentation to the Institute at future meetings. Many factors in the California situation are paralleled by those in the southeastern part of the United States except that the southeast is the victim of a more ruthless attitude on the part of governmental agencies. While development on the West Coast has been disturbed merely by a lack of orderly development, government policies in the southeast have tended toward the destruction of private ownership of generation, transmission, and distribution, instead of merely toward securing a preferred market for power generated under public ownership.

It is interesting to note that the marketing of Boulder Canyon power was based upon the idea of a delivered price equal to the local cost of substitute steam power, and that in the case of the Sacramento and San Joaquin River projects it was realized that co-ordination with steam power production was essential for minimum over-all cost, and that steam-plant construction on the part of the private power companies was encouraged.

Mr. Markwart refers to the change in policy following the Boulder Canyon project, in that later projects were launched without thorough investigation of markets and with no arrangement to liquidate any substantial part of the cost. This indifference of public authorities to economics has prevailed in Tennessee and neighboring territory since the inception of the TVA program in 1932.

Steam power production has never had any place in the plans of the Tennessee Valley Authority. The 56,000-kw steam plant near Muscle Shoals, accidentally acquired from the War Department, has never been operated to generate power for sale. Roundabout methods of compensating the city of Memphis or the private company in Memphis were worked out by TVA to avoid any necessity of operation of the Memphis steam plant by TVA. The proposed acquisition of the Tennessee Electric Power Company and its steam plants has brought up a problem of at least temporary operation of these plants to provide for the load and there is some disposition on the part of the friends of TVA to provide statutory approval by Congress for the operation of these steam plants. However, the TVA reports to Congress, their defense before the United States Supreme Court, and other official statements of their directors, indicate that they are relying solely on hydro production as the ultimate power supply for the area.

TVA has a present peak load and peak capacity of about 300,000 kw, including the Memphis load and the use of Memphis steam plant. The announced TVA program provides at least 450,000 kw of firm hydro power by 1943, but not including the firm steam-generating capacity proposed to be purchased from the Tennessee Electric Power Company. This figure does not include the Sheffield steam plant or any additional hydro units which have been included in the TVA ultimate program but which are not yet announced as to date of completion. Neither does the figure of 450,000 include any capacity at Gilbertsville, which might be completed before 1943. The peak capacity with any ordinary load factor would be at least 550,000 kw.

As on the West Coast, the entrance of the Government into the power business has greatly modified all the previously existing factors which would determine the trend of the industry. It has, therefore, been impossible for any utility in this region to make plans much in advance and little improvement in the situation will occur until the following factors take definite shape:

1. *Taxation Policy.* The taxation of private utilities amounts to 15 per cent or 20 per cent of gross income, or about 80 per cent of the wholesale cost of power using the wholesale rates realized by TVA during the past year. This is another way of saying that TVA would have to almost double their wholesale rates if the taxes previously paid by the private utilities were to be assessed against TVA. Their present 5 per cent wholesale tax paid to the states amounts to between 1 and $1^1/_2$ per cent of the retail revenue of their cities and co-operatives who handle the resale. But a small part of any tax on TVA power could be assessed against large power customers on account of competitive power costs, so that most of the increase would have to go against the domestic and commercial users.

2. *Co-ordination With Steam Power.* Government plans in the Southeast provide no part in the picture for steam generation. Overdevelopment of the rivers ahead of the market and use of storage reservoirs under dry-year rule curves for maximum power production are apparently counted upon to take care of the market without the economy that would result from mingling hydro and steam generation. Conflict between the operation of reservoirs for flood control and for maximum power production has been avoided by the fictitious assumption on the part of TVA that floods are impossible during the late spring, summer, and early fall months when the reservoirs are being filled, stored, and emptied. This conflicts with expert meteorological opinion and flood records in other areas.

3. *Territorial Limitations.* The implied distribution territory of the government projects in the Southeast has been outlined by the officials of these agencies and by congressmen friendly to them as covering about everything south of Pittsburgh and east of Little Rock. When the question of territorial limitation recently arose in Congress the chief power engineer of TVA stated that transmission limitations prevented hauling TVA power more than 25 or 50 miles, although the Norris-Wheeler line, which is 200 miles long, had been carrying 30,000 kw to Knoxville and East Tennessee and some power to the Aluminum Company for some time. Territorial protection is probably the most vital factor in determining future power production in the Southeast.

4. *Summary.* It is apparent that at the present time no safe prophecy can be made as to the future of either steam or hydro generation in the Southeast. It is therefore all the more interesting to note that conditions on the West Coast have crystallized to such an extent that engineers in that area can now agree on a fairly definite statement of the most probable projects during the next few years.

Mr. Markwart's paper brings out eloquently the disruption of planning that occurs when political objectives take the place of engineering and economic studies to which the power industry has always been accustomed.

Incidentally this paper contains an exceptionally clear discussion and explanation of the economies of mingled steam and hydro power production. It would be interesting if Mr. Markwart would discuss in a little more detail the effect of both daily and yearly load factors on operating procedure.

Although the objectionable features of governmental planning of power systems in the Southeast have been tempered by occasional technical excellence (as in the TVA hydraulic construction methods) these good features are more than offset by the increasing use of political pressure to counteract the loss of popular support. TVA, PWA, REA, states, counties, cities, co-operatives, and other organizations bound by common political ties and interlocking Federal appropriations make contracts with each other with an entire absence of the arms-length bargaining that the Securities and Exchange Commission is so insistent upon in its regulation of private companies.

In any discussion of government power policy before an engineering body, and particularly one in which reference is made to the taking over of certain private utility functions by the government, engineers will be greatly interested in the disposition of personnel as well as of plant facilities. The past and present policy of TVA is apparently to take over such personnel as are willing or are forced to accept governmental employment, and permit those who can become acclimated to work into the permanent government organization. For many field and miscellaneous employees this may work out satisfactorily but for the engineering and supervisory personnel who are familiar with some of the facts outlined above, the necessity of accepting a position with a government power agency to avoid complete unemployment is viewed as proof of the demoralization of private industry resulting from subsidized competition.

M. W. Edwards (California Railroad Commission, San Francisco): Mr. Markwart's paper ably presents a subject of great economic concern to all of us interested in power development. Furthermore, any planning that deals with the economic utilization of the natural resources of the State of California is of vital interest to every local citizen and taxpayer.

Due to the fact that this year we are facing a dry year (which so far is 40 per cent below normal in precipitation) our attention is forcibly directed to the question of what is a proper steam-hydro ratio. Also, the possibility of two dry years in succession must be visualized in setting this ratio. Steam power is cheap in California on account of the availability of natural gas and fuel oil. A good steam-hydro ratio in this state is necessary to carry over the dry seasons, and furthermore is economically sound.

The good management and farsightedness of the company is to be complimented on the present program of installing additional steam capacity in connection with process-steam production for certain oil refineries that will give low-cost additional energy.

The installation of additional capacity for the next few years in the form of steam will prove advantageous in the absorption of the state's Shasta power in the northern California market.

While power production in connection with the Central Valley project is a secondary consideration as far as being the reason for building Shasta Dam, still it is the principal means of paying for the cost of operation. In order that the project be nearly self-supporting and not prove too much burden on the taxpayer it will be necessary to sell the power for a higher price than the usual market value for this type of energy.

The economic value of Shasta power to the company is what it would cost to produce the same by some substitute means, either steam or hydro. However, on the other hand, if the duplication of transmission, subtransmission, and distribution lines, with their consequent long-run higher costs, is to be avoided a higher price will have to be offered for this power; or some other plan adopted whereby the state will share in the advantages of serving retail power. Public interest can best be served by some co-operative plan that will develop the Central Valley's water and power for the utmost benefit of the people and industry of the state as a whole at the lowest ultimate cost to the taxpayer.

L. A. Doggett (Pennsylvania State College, State College): I wish to make several comments on this paper. The first has to do with capital costs and running expenses of mingled hydro and steam power production. From a study of the statistics of some 55 electric utility companies in Moody's "Public Utilities," selected from the 1922 and 1934 editions, values of (total assets ÷ annual gross revenue) and [(operating expenses plus taxes plus depreciation)/annual gross revenue] were plotted versus (hydro kw/hydro kw plus steam kw installed). The medians of these points (figures 1 and 2) gave the following relationships:

$$\frac{\text{total assets}}{\text{annual gross revenue}}=4^1/_3+7\,\frac{\text{hydro kw}}{\text{hydro kw}+\text{steam kw}}$$

$$\frac{\text{operating expenses}+\text{taxes}+\text{depreciation}}{\text{annual gross revenue}}=0.7-0.2\,\frac{\text{hydro kw}}{\text{hydro kw}+\text{steam kw}}$$

For any given set of prices, load factor, locality, etc., formulas of this type may be fairly accurately derived. The above numerical values, however, should be considered as nothing more than crude averages. The formulas may nevertheless help to emphasize some of the general statements which the author has made on these matters.

The second point has to do with the general subject of conservation and aims at emphasizing the desirability of supplying energy by falling water rather than "by burning fuel". We see statements to the effect that our coal supply will last from three to four thousand years at our present rate of consumption. From the following simple analysis it is indicated that very small successive and regular increases in our annual consumption will produce surprising decreases in the life of our coal supply. Suppose that we have on hand a supply that at our present rate of consumption will last ten years and that we increase our consumption by 50 per cent successively each year; then

$$1-\frac{1}{10}-\frac{1.5^1}{10}-\frac{1.5^2}{10}-\frac{1.5^3}{10}-\text{etc.}=0$$

$$1=\frac{1}{10}+\frac{1.5^1}{10}+\frac{1.5^2}{10}+\frac{1.5^3}{10}+\text{ etc.}$$

$$1=\frac{1}{10}\,(1.5^1+1.5^2+1.5^3+\text{etc.})$$

which is a geometric series, summed as follows:

$$1=\frac{1}{10}\left(\frac{1-1.5^n}{1-1.5}\right)$$

In this simple illustrative case, where *n* equals 4.42 years, our 10-year supply has been reduced to a 4.42-year supply. The same reasoning applied to a 4,000-year supply and with a one per cent annual successive and regular increase gives

$$1=\frac{1}{4{,}000}\left(\frac{1-1.01^n}{1-1.01}\right)$$

whence *n* equals approximately 400 years.

Thus the practice of increasing our annual consumption by one per cent will bring exhaustion in 400 instead of 4,000 years. From the point of view of conservation our objective should be to use every drop of falling water and to build such steam plants as are necessary to accomplish this objective. On the whole California has attained this objective in a very commendable manner. Times have been when falling water was somewhat overdeveloped but sooner or later steam plants were built to match the hydro plants.

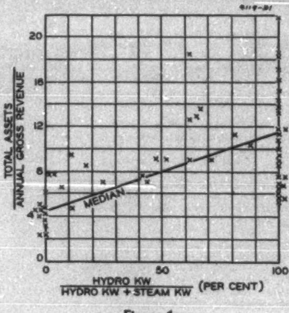

Figure 1

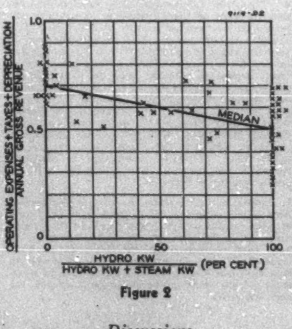

Figure 2

A. H. Markwart: The writer desires to express his appreciation of the written discussions contributed by E. E. George, Professor L. A. Doggett, and M. W. Edwards.

Mr. George has described the situation relating to power generation in the southeastern part of the United States and has called attention to the problems resulting from the entrance of the Federal government into the power business there. It is to be hoped that these problems will be solved with a minimum of economic disturbance to the taxpayers and the utilities now serving that area.

There are indications that the Government is adopting a milder attitude with the electric utility industry and there are evidences of co-operation with it. TVA has contracted to sell large blocks of power to the Arkansas Light and Power Company and to the Alabama Power Company and it is probable that the Bonneville administration will close a similar contract with the Portland General Electric Company. These contractual arrangements auger a modification of the policy on the part of the Government, which heretofore encouraged public ownership and in the Northwest actively supported formation of public districts. From a practical standpoint it appears obvious that the sale of substantial blocks of power in the near future must be done through the existing utilities. It is apparent that the Government now recognizes that the major outlet for its power projects lies in the established systems. This realistic solution of the problem of marketing power from government projects will result in substantial and immediate revenue.

Mr. George has suggested that the economics of mingled steam and hydro production might be discussed in more detail relative to the effect of both daily and yearly load factors on operating procedure. Insofar as the economics of mingled steam and hydro production in California is concerned, the writer has found it necessary to consider only monthly and annual load factors. Most California hydroelectric plants are provided with storage or with forebay facilities which permit daily and even weekly regulation of the water supplied to the plant so the installed capacity can be employed to its full extent when required to meet peak loads. A monthly study of available water supply is sufficient for such plants. Run-of-river plant capacity is small because none have been built for many years owing to the ineffectiveness of their capacity in low-water seasons. Such plants usually provide effective system capacity only to the extent permitted by continuous operation with the energy available in a critical dry month. The problem of providing the most economic new plant capacity in a regional system, aside from any consideration of standby, requires a study of the capacity and energy available in the existing run-of-river and peaking hydro plants, the capacity available in existing steam-electric plants, the cost of generating energy in existing steam-electric plants, and the cost of providing both capacity and energy by the alternate new plants under consideration. A study of the dry year is required to determine the effectiveness of the new capacity and a study of a period of years is required to determine the probable amount of energy which the new plant will provide. As stated above, a monthly study should be sufficient for this purpose if consideration is being given to a new peaking hydro plant or a steam-electric plant. However, if a large run-of-river hydro plant is under consideration, it may be necessary to study the daily load, particularly to determine the effectiveness of its capacity.

Professor Doggett, in addition to commenting on the desirability of developing hydro power in order to conserve our fuel resources, has presented some interesting formulas which can be employed to compare the financial operation of utilities which supply mingled hydro and steam power. The formulas show the effect of the hydro-steam ratio on the relation of assets to gross revenue and on the relation of operating expense to gross revenue. Professor Doggett states that for a given set of prices, load factor, locality, etc., formulas of the type shown may be accurately derived, but cautions that the constants shown in his formulas should be considered as nothing but crude averages. The writer confirms this idea because he has applied the formulas to the regional system supplying northern California and found a very close agreement (2 per cent) in the one case but a considerable discrepancy (25 per cent) in the other.

Mr. Edwards suggests that the possibility of two dry years in succession must be visualized in setting the hydro-steam ratio. For some years this possibility has been considered by the writer when determining the need for capacity to supply the northern California market, it being assumed that the combination of existing and proposed generating facilities should be capable of meeting the estimated load in two dry years like 1931 occurring in sequence.

Mr. Edwards also suggests that although the economic value of Shasta power to the company is what it would cost to produce the same by substitute means a higher price will have to be offered, to avoid duplication of transmission and distribution facilities, or some other plan adopted whereby the state will share in the advantages of serving retail power, because public interest can best be served by providing the benefits of the Central Valley Project at the lowest ultimate cost to the taxpayer.

It is not now known whether the Federal Government through the Reclamation Service, or the State of California through the Central Valley Authority, will contract the sale of the power of Central Valley Project. Should this be done by the Federal Government it is not improbable that the price at which Central Valley power is sold will be influenced by the price established by the Federal Government for power of other Federal projects. The rate structures thus far established by TVA and for other multipurpose projects are competitive, indicating that value has been considered, and with the new alternative wholesale rates for Bonneville power now proposed and under consideration, they follow the pattern developed by a two-part rate as suggested for Central Valley. What the policy of the State might be in the event it disposes of the power is unknown. However reports issued by the State from time to time and utterances by State officials indicate that calculated revenues of the project have been based on a price for power as determined by cost of power from alternate sources. It is inconceivable, in the light of low-cost competitive power available at Federal projects in the North and in the south (Bonneville and Boulder) that the public interest in northern and central California could best be served by establishing a price for Central Valley power above its value.

In the interest of water-supply development, the price for power should be as high as can be justified by the cost of power from competitive sources. This will not be injurious to the consumer because he would pay no more for power than were competitive sources developed, and furthermore, under regulation as it obtains in California, whatever is paid for power would be the cost allocated to power production in making up the power-rate structure, so there is no profit to the utility in purchased power. The only return to the utility would be on investment in distribution and transmission which the utility must make to deliver the purchased power to the consumer and this is but reasonable as determined by the regulatory body. Since the State makes no capital investment in this connection it is not clear why it should share in the advantages of serving retail power as suggested by Mr. Edwards.

Ionization Time of Thyratrons

Discussion of paper 39-116 by A. E. Harrison, presented at the AIEE combined summer and Pacific Coast convention, San Francisco, Calif., June 26–30, 1939, and published in AIEE TRANSACTIONS, 1940, pages 747–50.

V. C. Rideout (California Institute of Technology, Pasadena): Mr. Harrison's investigations show that the ionization times for various thyratrons, when plotted against the grid overvoltage give curves that are approximately equilateral hyperbolas. Because tubes of different construction, with different gases at pressures not accurately known, and with various values of plate voltage, have been used, it is difficult to say how ionization time is affected by tube design. If the results for the *FG*-81 and the *FG*-57 are compared, however, it may be seen (figures 5 and 8) that the argon-filled *FG*-81, which is similar in construction to the mercury vapor *FG*-57, has somewhat shorter ionization times.

In figure 1 accompanying this discussion, I have shown recent data for two tubes manufactured by Electrons, Inc. These tubes, the EL *C1B* and the EL *C6J*, are filled with xenon gas and are similar in construction. The *C1B*, which has somewhat smaller elements, and smaller interelectrode spacings, has shorter ionization times than the *C6J*. The 885 which has the smallest interelectrode spacings of all the tubes tested, had the shortest ionization times. It would seem that the higher gradients in such a tube cause ionization to more rapidly neutralize the space charge and create a plasma.

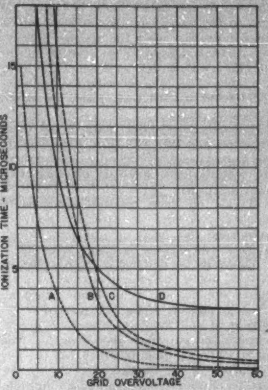

Figure 1. Ionization times as functions of grid overvoltage

A—EL *C1B* xenon-filled thyratron, 300 volts on anode

B—EL *C6J* xenon-filled thyratron, 600 volts on anode

C—EL *C6J* xenon-filled thyratron, 300 volts on anode

D—*OA4G* cold-cathode argon-filled, 300 volts on anode

Reynolds ("Studies With an Ionization Gauge," Neil B. Reynolds, *Physics*, volume 1, September 1931, pages 182–91) has shown that the probability of ionization for argon (ions per electron per centimeter path at one millimeter pressure) for a given electron velocity is about five times that for neon. This is probably the chief reason for the slower ionization times of the *KU*-610. The critical grid bias for this tube is positive, and it was biased positive about four volts under test. As there is a high resistance in the grid circuit of the test apparatus, there may be some slight error here. This was checked for the *OA4G*, a cold-cathode positive control tube, and the error was not found to be serious. The grid bias in this case was 67 volts positive. A curve showing ionization time characteristics of this tube has been included in figure 1 for comparison with Rockwood's data.

Fractional-Slot and Dead-Coil Windings

Discussion and authors' closure of paper 39-134 by Michel G. Malti and Fritz Herzog, presented at the AIEE combined summer and Pacific Coast convention, San Francisco, Calif., June 26–30, 1939, and published in AIEE TRANSACTIONS, 1940, pages 782–94.

P. L. Alger (General Electric Company, Schenectady, N. Y.): This subject of fractional-slot windings is one of perennial interest to designers. There is literally no end to the variety of the problems which arise in practice when the designer endeavors, on the one hand, to use existing punchings for a wide variety of machines, and, on the other hand, to continually meet new requirements of good wave form, low noise, minimum reactance, and other factors. The highly specialized character of these problems, together with their great variety, has caused designers generally to solve them by common-sense methods differing with each individual. Although little has been published on these practical solutions to winding problems, an extensive body of knowledge has been accumulated, which confirms and extends the authors' results.

Typically, the designer is given a number of slots, poles, phases, and circuits for a required winding, and he must first determine the best possible phase belt pattern or sequence of coil numbers, and then decide whether this pattern is good enough. Not infrequently, a winding which has the denominator of the fraction representing the number of slots per pole per phase a multiple of the phases, and is, therefore, unbalanced, can be arranged to make the unbalance so small that it is quite satisfactory. At other times, a winding which is perfectly balanced, and is arranged for the highest possible voltage production, as prescribed in the paper, is found to have an objectionably high reactance, or double-frequency vibration, which can be corrected by a different winding sequence.

Thus, for each combination of slots, poles, and phases, there is a particular winding sequence which is best for reactance, and another that is best for voltage, and a third that is best for noise or vibration. With fractional numbers of slots per pole per phase, such as $1^1/_2$ or $1^4/_5$, these three types of winding all coincide, but with such numbers as $2^3/_{11}$ they are normally all different, and the designer must decide what is the best sequence for his particular purpose.

From my experience, the best way to solve these problems is to visualize each coil voltage or current as the chord of a circle spanning an arc equal to the electrical angle between consecutive slots. The highest possible voltage will be obtained if the maximum angular spread between the coils connected in each single phase is a minimum; while phase voltage balance will be obtained if the pattern of each phase is the same with the correct phase displacement. For minimum vibration or noise, it is a question of grouping the coils in each phase separately most symmetrically around the entire periphery. For example, with $1^2/_5$ slots per pole per phase in a three-phase winding, the best sequence of phase belts in each phase considered by itself is 2, 1, 2, 1, 1, if minimum vibration is required; while the best sequence for voltage production is 2, 2, 1, 1, 1. I have not found any satisfactory way to visualize the grouping that gives the least possible reactance, but I have found the methods for calculating this reactance given by Gabriel Kron in chapter 12 of his recent book ("Tensor Analysis of Networks," John Wiley and Sons) very satisfactory.

Table I. Ratio of Three-Phase Reactances

Pitch Deficiency (Slots)	Slots Per Pole Per Phase			
	$1^1/_2$	$2^1/_2$	$3^1/_2$	$4^1/_2$
$^1/_2$	0.0457	0.0178	0.00811	0.00703
$1^1/_2$	0.0582	0.01735	0.00866	0.00594
$2^1/_2$		0.0225	0.00957	0.00554
$3^1/_2$				0.00665

While fractional-slot windings are normally used for synchronous machines with their large air gaps and relatively high total winding reactance, they are much more rarely used for induction motors because of the increased reactance frequently obtained with the relatively small air gaps used.

If the more general use of fractional-slot windings is desired, it will be very useful to determine the differential leakage reactances of all usual fractional windings and compare them with the corresponding values for perfectly regular windings. The values of per unit differential leakage reactance calculated by Mr. Kron's method for three-phase windings with $1^1/_2$, $2^1/_2$, $3^1/_2$, and $4^1/_2$ slots per pole per phase are given in table I of this discussion.

These may be compared with the values in table II of this discussion for regular windings, taken from table XI of my paper entitled "The Calculation of the Armature Reactance of Synchronous Machines", which appeared in AIEE TRANSACTIONS, volume 47, April 1928, pages 493–513.

Table II. Differential Leakage Reactance of Three-Phase Windings

Pitch Deficiency b	$s/3$ = Slots Per Pole Per Phase			
	1	2	3	4
0	0.0966	0.0284	0.0140	0.0089
1	0.0966	0.0235	0.0115	0.0074
2	0.0966	0.0284	0.0111	0.0063
3		0.0284	0.0140	0.0069
4			0.0143	0.0089

If plotted in curve form, the fractional-slot windings given are found to have only a little higher reactance than the regular windings, but when other fractions than multiples of $^1/_2$ are considered, differential leakage reactances several times as high as for regular windings frequently occur.

M. G. Malti and **F. Herzog:** Alger mentions in his discussion the possibility of slightly unbalanced windings. This falls outside the scope of our paper because we deal only with balanced windings. Again Alger notes that different winding sequences may be used to correct for high reactance, noise, etc. This can be readily accomplished by referring to tables II to V of our paper. In our terminology Alger's suggestion of new patterns would simply mean adding any multiples of bn/m to the numbers listed in these tables. Particular attention should be given to tables V*a* and V*b*. In these tables the same multiples of bn/m should be added in corresponding positions of these tables. Physically this means interchanging coils among phases while maintaining a balanced winding with no regard to maximum voltage. Our paper, therefore, is inclusive enough and flexible enough to allow the change of winding pattern while, at the same time, assuring the designer that the final pattern he selects will give a balanced winding.

As an illustration we shall take Alger's example of $1^2/_5$ slots per pole per phase. This winding belongs to type *B*. Using table III we have for phase 1, assuming 42 slots:

k	1	2	3	4	5	6	7
kb	17	34	9	26	1	18	35
$kb+n/2$	38−	13−	30−	5−	22−	39−	14−

This is a 2, 2, 1, 1, 1 winding as Alger asserts. But by adding $bn/m = 238$ to the slots in column 6 we have:

k	1	2	3	4	5	6	7
kb	17	34	9	26	1	4	35
$kb+n/2$	38−	13−	30−	5−	22−	25−	14−

This is the winding 2, 1, 2, 1, 1 which Alger seeks.

The remainder of Alger's discussion relates to calculating reactance which, naturally, falls outside the scope of our paper and is, in our opinion, irrelevant.

12-Kv Metal-Enclosed Bus and Switch Structure, Station C, Oakland, Pacific Gas and Electric Company

Discussion and authors' closure of paper 39-127 by F. S. Benson and H. E. Strang, presented at the AIEE combined summer and Pacific Coast convention, San Francisco, Calif., June 26–30, 1939, and published in AIEE TRANSACTIONS, 1940, pages 751–5.

A. Fulton (General Electric Company, San Francisco, Calif.): The authors of this paper have described many design and constructional details of this 12-kv metal-enclosed switchgear installation. Additional emphasis may properly be placed on the safety features which are inherent in this particular type of gear.

While the oil circuit breakers are of a design which has been proved by many years of satisfactory service, yet they meet the most modern requirements for low oil volume. The total oil required per triple-pole breaker is only 14 gallons, divided among six seamless steel vessels. The pair of these vessels per phase is completely enclosed and segregated from other phase units by steel barriers. Possible fire hazard thus approaches the irreducible minimum for any oil-circuit-breaker installation.

This factory-assembled metal-enclosed switchgear embodies another safety feature not commonly found in older types of construction. Accurately lined up steel work simplifies the problem of providing a sturdy and foolproof interlock between oil-circuit-breaker cell doors, and gang-operated disconnecting switches. Thus it is impossible for an operator to come in contact with any live parts in the circuit breaker compartment. Before obtaining access to the breaker cells, he must first open the disconnecting switches, as this operation automatically removes a solid bar lock from the cell doors.

The more conventional type of interlock between the disconnecting switches and circuit breakers is also provided, insuring against operation of the switches except when the breaker is in the open position. Gang operation of the six switches per breaker is easily accomplished through a worm-gear mechanism. A grounded steel barrier between the operator of the mechanism crank, and the switches, provides a still further safety feature.

As long as the job of controlling the production and distribution of electrical energy is entrusted to the functioning of human beings, we may expect occasional cases of erratic and unexplainable performance. The examples of this limitation, which have come to our attention, most frequently involve the operation of the wrong disconnecting switches. At times these result in nothing more serious than tripping out one machine or bus section, but too frequently they cause serious personal injury and considerable damage to nearby electrical equipment.

A recent investigation of several cases disclosed the fact that, in a majority of instances, the person involved was suffering from a temporary emotional disturbance, which apparently interfered with the mental processes accompanying even calm routine action to which he was accustomed. This is a condition which is definitely beyond the control of any employer, and from experience has been shown to affect even the higher-grade workers who are expected to think for themselves. It, therefore, appears obvious that a reduction in troubles of this kind can be expected only to the degree to which mechanical safeguards are provided to assist the human mind when necessary in making correct decisions.

J. P. Jollyman (Pacific Gas and Electric Company, San Francisco, Calif.): The authors have described a bus and switch structure which has been very carefully designed. Detaching the metal enclosures and the electrical conduits from the building structure has many advantages.

The necessity for a double 12-kv bus with two oil circuit breakers in each position arises from the functions which this station must perform. In seasons of average rainfall, the load in the East Bay area is fed principally from the hydroelectric transmission system with station *C* acting as a standby. Turbines are kept in operation at minimum kilowatt output, but with considerable reactive output to correct the power factor of the regional load. During dry seasons, the steam plant will be called on to carry a base load at very high load factors.

Station *C* is connected to two 110-kv stepdown substations with 12-kv cables of considerable length and to a third, station *X*, with a 110-kv cable as described by the authors. To secure the maximum output of the steam plant, power must be fed out through the three transmission substations. To control the flow over the three routes, the 12-kv bus at station *C* may have to be divided with certain loads and transmission connections on each section. It did not seem possible to secure the needed flexibility of operation with any other switching arrangement.

Load-ratio control was applied to 110/12-kv bank at station *C* so that the power factor might be controlled on the 110-kv cable. The flow of power over the cable may vary from full load into station *C* to full load out. A considerable range in transformer ratio will be required to meet this condition.

D. C. Prince (General Electric Company, Philadelphia, Pa.): This paper seems to indicate a trend of the times with implications rather broader than the mere subject matter of the paper. Prefabricated houses have come in for much debate and would probably be general by this time if it were not for preference for individuality in our separate homes.

In power plants we are striving for efficiency in functional design rather than individuality. Also, there is no immediate prospect of power houses in rows, whereas the interior arrangements should be harmonious for the best effect.

Therefore, the power switchboard and control plant generally lends itself to a prefabricated factory-built functional design. This paper may prove to be a sign post pointing the direction in which all sorts of structures will develop.

M. H. Hobbs (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): The paper presented by Messrs. Benson and Strang is very interesting, and is a further indication of the increasing use of metal-enclosed switchgear for larger and more important stations. The equipment design worked out, in general, seems well suited to the application and the station layout, and the paper shows how the station design work was simplified by the use of factory-assembled switchgear.

One of the features emphasized is the running of control conduit exposed, the impression being given that this was a new development, although this may not have been intended. This practice was followed as long as 15 years ago by the Northern States Power Company in their Minneapolis steam station, and other companies have used it since that time. Recent examples are in the substations for the Bay Bridge electrification in San Francisco.

It would appear that some compromise with the most preferred practice was required to accommodate the type of circuit breaker used. It has been considered necessary, in important stations, to isolate the main bus from other parts of the circuit to localize a fault at any point. The arrangement shown places feeder circuits, potheads, potential transformers, and reactors in quite close proximity to the busses. In addition, the operation and interlocking of disconnecting switches appears to have been somewhat complicated by the location selected for these switches.

It would seem that a preferred arrangement for this important station would have placed the different parts of the structure on three floors, with the main busses at the top, the breaker with its disconnecting switches on the middle floor, and the outgoing feeders with reactors, potential transformers, and grounding devices on the lower floor. The authors' comments are requested upon this suggested arrangement.

Modern oil circuit breakers are very efficient, and are ordinarily safe and dependable. However, from a fire-hazard standpoint, too much stress should not be placed upon simply the reduction in oil content for a particular design. This is only one feature, which may be obtained at a sacrifice in other points, such as, for instance, complete immersion of contacts in oil, dead-tank construction, elimination of stuffing boxes, and operation of contacts in such a way that gravity tends to open them.

A recent rather serious case of trouble involved approximately three gallons of oil, and similar instances have occurred in the past. Complete elimination of oil rather than a simple reduction in amount would seem to be the more desirable aim.

It is believed the increase in permissible temperature rise is entirely logical, although the proposed standard of the Institute limits the rise of air temperature within the compartments to 15 degrees above the outside ambient, rather than the 25 degrees permitted on the equipment described.

The importance of reduction in weight for metal-enclosed switchgear mentioned in the paper, as compared with concrete cell structures, is a feature which is sometimes overlooked and merits attention. It may have a very real influence upon the simplification of station design and upon the construction cost of the building.

The operating company should be complimented upon its broad planning with regard to its installation schedule. The completion of building construction prior to commencing electrical work permits both to be handled most efficiently, and enables the greatest advantage to be taken of the use of factory-assembled switchgear.

F. S. Benson and **H. E. Strang:** A. Fulton's discussion properly stresses the low-oil-content design of the circuit breakers used, and also the mechanical interlocks so as to prevent station personnel from operating disconnecting switches under load.

J. P. Jollyman gives reasons for the double-bus construction which was used to better control power flow from the steam plant bus to the transmission system.

We agree with D. C. Prince that the switchgear described in the paper indicates a trend of the times with implications that are broader than the subject material presented. Such uniform design of cell construction produced a structure of low cost and permitted its erection in record time.

M. H. Hobbs raised certain questions which will be answered in sequence.

Referring to the exposed runs of conduit, perhaps not enough information was given by the authors to emphasize the fact that the building itself was erected as a loft-type building with only openings in floors and walls to accommodate passage of these runs of conduit from one section of the building to another. It was this design that greatly facilitated building construction. The building contractor did not need to worry about conduit runs, facilities, etc.

Mr. Hobbs states that preferred arrangement for such an important station would have placed the different parts of the structure on three floors. This was one of the proposed designs, the costs of which were very carefully worked out, and a decision was reached that a two-story building could be used. It is believed that by using this type of metal-enclosed switchgear and bus cell, no operating hazard is incurred by placing the bus on the same floor and in the same room with certain other related equipment, such as reactors, current and potential transformer cells, and that the extra expense of a three-story building, together with the extra cost of the switchgear built for three stories instead of two was not justified. Therefore, the oil-circuit-breaker cells were placed on the top floor, the bus structure with reactors, disconnecting switches, current and potential transformers, and potheads was placed on the floor beneath or the first floor. It was also decided that with the steel cell construction with phases adequately isolated by barriers, all openings between various phase compartments were reduced to mere cracks or were screened so that if a fault occurred and gas did migrate from one phase to another, or from one cell to another, it would be completely deionized and should, therefore, not tend to produce a short circuit in cells adjacent to the one where the original fault occurred.

It was not mentioned in the paper that this bus structure is protected by a bus differential system which we believe will adequately protect the bus from severe burning due to short-circuit currents. The design of the structure is such that faults occurring in one phase should be limited to line-to-ground faults and not contact adjacent phases or adjacent cells.

With reference to the comments regarding the presence of any oil (regardless of small quantity) presenting disadvantage as compared with the total elimination of oil, the following factors were of primary importance in the selection of circuit breakers and other circuit components for this important location: The excellent and thoroughly proved operating characteristics of modern oil circuit breakers combined with the small amount of American operating experience with air circuit breakers for such an important location, undoubtedly, was a major influence in arriving at a decision to stay with oil circuit breakers for this location. However, it was recognized that there are underlying advantages in restricting the insulation path (as far as possible) to class *B* material, such as porcelain. The fact that oil was eliminated entirely as an insulating medium was regarded as a strong point of advantage. The quantity of oil is limited to a total of 14 gallons per one 1,000,000-kva breaker and this small quantity is split up among six seamless steel forged tanks per breaker. This compares to 165 gallons of insulating oil divided among three fabricated tanks in conventional dead-tank breaker designs, further reducing the fire hazard or insulation breakdown which might cause an oil fire.

At the time the bus structure was designed, the proposed standard regarding the rise of air temperature within the compartments above the outside ambient had not been agreed upon and the decision was reached by us that 25 degrees centigrade rise would not involve any hardship on the equipment installed in the cells. It is to be noted that later equipment has been designed to follow the new standards, that is, an average temperature inside the enclosure 15 degrees centigrade higher than the ambient temperature outside the enclosure.

This steel-cell structure weighs much less than a corresponding concrete-cell structure. This effects a material saving in cost of building. The equipment was installed with a minimum of time and erected without any changes being made in the field, as all component parts were so marked and shipped that the erection was only a matter of assembling these parts in proper sequence.

Electrical Equipment of the Union Pacific Steam-Electric Locomotive

Discussion and authors' closure of paper 39-139 by M. R. Hanna and J. F. Tritle, presented at the AIEE combined summer and Pacific Coast convention, San Francisco, Calif., June 26–30, 1939, and published in AIEE TRANSACTIONS, 1940, pages 756–64.

L. K. Sillcox (The New York Air Brake Company, Watertown, N. Y.): The writer has read with great interest this general description of the control and power circuits of perhaps as novel a steam-powered locomotive as the world has yet seen. Although resistance and regenerative braking are not new, the particular arrangement and control of the resistance brake on the driving axles warrants the highest commendations. In the past these means have been used generally to develop effective retardation only in the lower speed ranges. In this locomotive, however, some degree of resistance braking is made available over the whole speed range up to 120 miles per hour.

Just how effective is this type of brake? The impression may be gained by the reader of the paper that the resistance braking is adequate under all conditions to match air-brake performance and capacity of any type of train being hauled. Such is not the case.

This locomotive is designed primarily for hauling passenger trains, of both the conventional type and the "streamliners". In streamliner car equipment, the train air brakes, making use of a special electro-pneumatic straight air system, are much more powerful than are those fitted on cars of the more conventional order. The difference is automatically regulated on the locomotive by the difference in maximum air pressure admitted to the brake cylinders and in accordance with the air brake control system being used. In figure 13 of the paper, the authors show the maximum braking effort that can be developed by the resistance brake. The total output of 3,600 kw from the traction motors acting as generators is available only when the high-speed air-brake control system is being used and then only when it is calling for the maximum brake application that can be made. It will be noted that at 100 miles per hour the maximum braking effort is roughly 19,000 pounds. This is not all of the braking force, since low-powered air brakes are co-operating on the guiding axles, but the latter add no more than 6,000 pounds. The total of 25,000 pounds will produce a retardation of very slightly over one mile per hour per second. Even if it were possible to have the maximum of 35,000 pounds braking effort shown in figure 13 effective on the drivers for every second of a stop from any speed, the total retarding force on the locomotive would not produce a retardation in excess of two miles per hour per second.

In the high speed (streamliner) class of service, the braking effort on the cars is adequate to stop them from 100 miles per hour at an average retardation of over three miles per hour per second. The Bureau of Safety of the Interstate Commerce Commission has established 3,600 feet from 100 miles per hour as a satisfactory distance in which passenger trains should be able to stop under emergency conditions. To meet this requirement, the railroads are faced with the problem of developing three miles per hour per second retardation on their trains, including locomotives. It appears that the maximum braking effort developed by the resistance brake would give this locomotive an average retardation of less than half that required by this specification, and a great deal less than that of the train behind it.

As pointed out by the authors, the locomotive is also equipped with air brakes. The automatic control of the resistance brake comes from the air-brake system, and the latter applies brake shoes to the wheels in a normal manner in the absence of effective resistance braking. The design of the air brake is such that when it alone is used the retardation produced in the locomotive is truly but slightly less than that in the cars it is hauling, and is so proportioned that when it is coupled to one of the streamliners the train may be stopped from 100 miles per hour within 3,600 feet.

In all fairness, it must be pointed out that the lack of effectiveness of the resistance brake is only comparative. In absolute terms it is a very good brake indeed for a certain use, that of controlling the speed of the train. For grade work it has tremendous advantages as pointed out by the authors. As a brake for effective stopping under emergency conditions, however, it does not compare with and should not be considered as a substitute for the more powerful air brake also available on the same locomotive.

F. C. Lindvall (California Institute of Technology, Pasadena): The locomotive which is the subject of the paper involves a number of novel features, any one of which merits considerable discussion. One element however, may not command in the minds of electrical engineers the position of importance which it merits and that is the dynamic braking of the locomotive. Few engineers, particularly those who reside in territory involving no mountain grades of any consequence realize the acute problem which a long downgrade presents in the operation of modern railroad equipment. For example, situations occur in which a train must negotiate an average two per cent down grade at a speed of 35 or 40 miles per hour for a distance of 20 miles. (For a modern lightweight passenger car, this condition is equivalent to about 20 horsepower per wheel going directly into heat. The locomotive, with higher wheel loads, suffers even more acutely.) Under ordinary operating conditions, a locomotive with only air brakes actually does less than its proper share of braking and the wheels and brake shoes of the entire train at the end of such a grade are extremely hot. In one of the new Diesel-electric locomotives provision is made for water sprays to be directed at the tread of the wheels in order to afford some relief from such overheating. Stated very briefly and inadequately the high-speed train of so-called lightweight type has presented extremely serious braking problems, so serious in fact, that wheel destruction and brake shoe maintenance is a serious operating expense.

Dynamic braking is a very practical solution to this problem because under normal operating schedules speed upgrade is substantially the same as that downgrade due to curve restrictions and, as a result, the horsepower in braking required of the motors is less than that for traction by the amount of the train resistance factor. The problem, then, is one of heat dissipation, in other words, disposal of the energy taken out of the train in descending the grade. The condensing system in the steam-electric locomotive is adequate for the losses incurred in upgrade operation and, because of the inherent thermodynamic efficiency of the locomotive, is more than adequate for the power dissipation required in dynamic braking. The interesting feature of this new locomotive development is the rheostat which puts the train energy into the cooling system. A similar thing is, of course, possible in the radiator system of the Diesel-electric locomotive, but as yet dynamic braking has not been offered in that type of power plant. The designers of the steam-electric locomotive are therefore to be congratulated in having presented a solution to a problem which has been most annoying to western railroads operating a high-speed service.

J. V. B. Duer (Pennsylvania Railroad Company, Philadelphia): The paper prepared by Messrs. Hanna and Tritle outlines in a concise and complete way the electrical equipment necessary fully to control a steam-electric locomotive of entirely new design with the detail parts so co-ordinated as to provide a complete working unit.

The Union Pacific and the General Electric Company, as well as their engineers, are to be commended for their vision and courage in developing this unit, which is definitely of a pioneer type. Full automatic control of the steam boiler with its allied power units is provided. In addition, the multiple control of locomotive units includes a feature not previously accomplished; that is, the multiple control of steam power plants. The operating requirements of the locomotive have been worked out in a way which is particularly noteworthy. Fuel and air are automatically proportioned for best combustion and the electrical control apparatus permits using full output of the power plant, when required, without overloading. The braking system permits hard and continuous braking with entire flexibility of manipulation by the ingeniously combined action of electric and pneumatic brakes.

The detail to which the electrical equipment has been developed is apparent in the provision for extra ventilation above that normally needed by the main motors, to permit carrying protracted overload when required by the service.

This locomotive provides a type of motive power entirely different from any previously available and represents a definite forward step in that it combines the advantages of steam with those of electrical equipment in a single unit.

C. P. Kahler (Union Pacific Railroad Company, Omaha, Nebr.): The authors of this paper deserve to be complimented on the complete description which they have presented of the electric equipment on the new steam-electric locomotive of the Union Pacific. Also, on the manner in which they have shown the importance of the electrical equipment in tying together and making possible the operation of the steam locomotive.

While a good deal of the equipment and apparatus used is not new, the authors of this paper have clearly shown many new ways in which tried out equipment has been assembled in this locomotive.

As outlined by the authors, this locomotive was designed to handle:

1. Streamline trains with the many electrical services necessary
2. Conventional passenger trains with coaches, observation cars and Pullman cars, and
3. Freight trains

This would necessarily make the electrical apparatus on this locomotive very much more complicated than would be the case if it had been designed for any one of these services.

One of the outstanding features of this paper is the description of the electric brakes which is the first application of its kind that I have heard of. The manner in which the electrical energy generated when braking is converted into heat and a good portion saved by transferring to the steam circuits is certainly unique. Also, the reduction in brake shoe and wheel wear which results is also outstanding.

The test runs made with this locomotive have been very encouraging. They have also demonstrated that considerable simplification of the electrical apparatus can probably be made and that the trend of the development of this locomotive will be in the direction of simplification.

M. R. Hanna and **J. F. Tritle:** The authors appreciate the favorable reception accorded their paper on "The Electrical Equipment of the Union Pacific Steam-Electric Locomotive" and particularly wish to thank those submitting written discussions. The paper describes the electrical details of a pioneer development which we hope will serve as a milestone in the forward march of modern transportation vehicles.

Mr. Duer calls attention to the numerous automatic features of this locomotive which permit combining the advantages of steam with those of electrical equipment and the provisions for multiple-unit operation of two or more locomotives with their steam-boiler and power-plant control. He mentions the electric braking system capable of hard and continuous braking which is especially valuable in maintaining fast schedules descending long mountain grades. The super blowing of the traction motors also included in Mr. Duer's discussion is intended for use in transcontinental service, permitting trains to be handled without pushers up mountain grades where the demand would be considerably in excess of the normal continuous tractive effort rating of the motors. This is obviously better economy than to burden the locomotive with much greater motor capacity which would be fully utilized for not more than two or three hours in a transcontinental trip.

Mr. Kahler mentions the various service conditions under which the locomotive is designed to operate, and emphasizes the desirability of simplifying the electrical and mechanical equipment. Experience obtained under actual operating conditions and further studies have already enabled the designers to improve the accessibility of the apparatus and reduce the number of devices. We agree with Mr. Kahler that future developments should be in the direction of simplification.

Professor Lindvall emphasizes the importance of the dynamic braking feature in descending mountain grades. This feature is particularly applicable to the steam-electric locomotive and is obtained by minor additions to the equipment required for motoring. A novel design of braking resistor permits a continuous transfer of braking energy as heat into the main condenser by means of water diverted from the boiler. This is permissible since during the braking cycle only a small percentage of normal steam flow is required from the boiler.

Mr. Sillcox discusses the unique way in which the dynamic brake is blended with the air brake and the excellent results obtained when the two systems are properly co-ordinated. The dynamic brake was not intended to be used as a substitute for the air brake, but as an auxiliary to it. It is especially useful for slowdowns and for holding the train on grades. For emergency stops the air brakes must be applied on the cars as well as on the locomotive in order to meet the requirements of the Bureau of Safety of the Interstate Commerce Commission. Within the limits of motor and generator capacity the dynamic brake is very effective at all locomotive speeds. It can be applied instantaneously and there is no danger of sliding or overheating the wheels. When used in conjunction with the air brakes it appears to give the ideal combination for locomotives in high-speed service.

Tests on Oil-Impregnated Paper—IV

Discussion and author's closure of paper 39-113 by Hubert H. Race, presented at the AIEE combined summer and Pacific Coast convention, San Francisco, Calif., June 26–30, 1939, and published in AIEE TRANSACTIONS, 1940, pages 721–9.

Herman Halperin (Commonwealth Edison Company, Chicago, Ill.): Doctor Race's findings on the mechanism of tracking in high-voltage cable insulation agree with our findings in single-conductor solid-type 66-kv cable ("Studies of Stability of Cable Insulation," Halperin and Betzer, AIEE TRANSACTIONS, volume 55, 1936, pages

1074–82). We found, however, that tracking can start also at the sheath. While in our tests tracking was apparently started by gaseous ionization, free gas was not present in Doctor Race's samples and breakdown occurred at high stresses in the free oil space. Observations in Chicago on joints and on cable with expanded sheath showed that oil layers of considerable thickness may break down under lower stresses than thin oil films. The thickness of the oil film is, therefore, an important factor to consider.

One of the outstanding points of interest is the finding that copper and lead diffused throughout the insulation in spite of the fact that great care was taken to eliminate oxygen throughout the tests. It is, therefore, difficult to see how soaps could have formed, as acids, which could attack the metals to form soaps, require oxygen for their formation. These results, therefore, indicate that either the diffused metals were not in the form of soaps or that there was some other source of oxygen present in the samples.

In view of this absence of oxygen the amounts of metals in Doctor Race's samples were very large, namely, up to 9,700 parts per million of copper and 29,700 ppm of lead in dry paper. On the other hand, on badly deteriorated oil-filled cable removed from service the maximum amount of copper was 1,100 parts per million in dry paper in one sample and 2,660 parts per million in impregnated paper in another sample. The maximum amount of lead found was 40 parts per million of impregnated paper.

It was our understanding that the striations found sometimes in cable on the tape next to the conductor are caused by reaction of oxidation products in the oil with copper. In view of the absence of oxygen in Doctor Race's samples, what does the author consider to be the nature of the deposit appearing as striations?

The finding that most of the copper is in the oil-free paper rather than in the free oil agrees with our observations in cable tests.

We understand from table I that in all cases samples with washed paper had long lives and that none of the samples with washed paper developed general ionization.

We noted with interest the wide variations in specific inductive capacity of impregnated paper, namely from 2.00 to 4.92 according to table I. What is the cause of the unusually low value of 2.00?

The author states that layers of paper showing carbonization had high power factors. We found that if the carbonized paths are avoided in making the measurements, the power factors of the remainder of the paper are quite normal for aged samples. It seemed to us then that the increases in power factor of the insulation adjacent to the carbonized path resulted from chemical changes in the impregnating oil.

R. J. Wiseman (The Okonite Company, Passaic, N. J.): Our staff has read this paper with great interest and has noted some important facts that are worth keeping in mind whenever we study the breakdown of cables. We think it was ingenious of Doctor Race to take a metal rod and cut it to reproduce in grooves the corrugations which exist when we made up a concentric stranded conductor. He eliminated a very important variable—the flexibility of the stranded conductor, yet obtained the concentration of electric stress of a stranded conductor where the paper contacts the top of the threads. We have enjoyed reading the section on maximum electrical gradient. We are in accord with the views expressed, but we feel he could go a little further in his explanation as to why the brown markings were not at the point of contact of the paper and top of the thread. We believe that the variation in the dielectric strength of the oil in the film of varying thickness between the paper and the electrode are the controlling factor in the breakdown. Referring to figure 5, the dielectric strength of the oil film between flux line *A* and the point of contact of the electrode and the paper, as shown in figure 1 of this discussion at *B*, is higher than at *A*, due to the thin-film characteristic and the breakdown voltage will be higher than that at flux line *A*, even though the actual distance to the outer electrode is less than along flux line at *A*. To the right of line *A*, the oil films are larger between the inner electrode and the paper, and therefore, the dielectric strength per mil of the oil film is less. However, the length of flux lines to the outer paper electrode is greater and the voltage necessary to cause breakdown will be greater. In other words, failure will occur along line *A* because it takes the least voltage to cause breakdown. The thickness of oil film at *A* may only be five or ten mils and it is possible that it will have a dielectric strength of 1,400–1,800 kv (peak) per centimeter as Doctor Race suggests. It is fortunate for us that it requires such a high voltage to cause failure. Otherwise our cables would have to have smooth-surfaced conductors. We know this is so for dry paper insulation as we have reproduced the brown tooth markings on some high-gas-pressure dry-insulation experimental cables and they were offset slightly from the point of contact of the paper and conductor. As we operate our impregnated paper cables at much lower stresses than Doctor Race finds will produce this marking which is the beginning of failure, we do not need to be too greatly concerned about the importance of using stranded conductors, provided, of course, that oil is present around the strands. If not, then we approach the case of the dry insulation condition referred to above, and the breakdown voltage will be low.

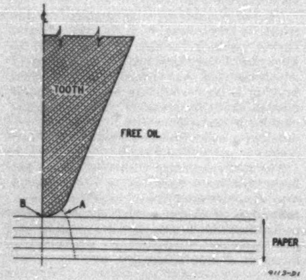

Figure 1

Our study of the radial power factor for the various specimens and tabulated in table I shows that many of the samples showed not only high power factor values at the electrodes but also at intermediate points. In figure 2 of this discussion we have plotted the radial-power-factor curve for specimen 305 to illustrate this. We, too, have observed this from studies we have made and have not been able to explain it. The upturns at the copper and lead electrodes have been explained as due to metallic soap or metallic ions. This will not explain the hump in the intermediate layers because the amount of copper and lead is very low. We hope that Doctor Race will be able to offer an explanation.

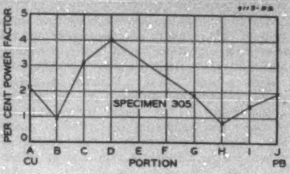

Figure 2

We are very much surprised at the comparatively large amount of copper and lead found on the paper at the lead and copper electrodes respectively for some cable samples. Doctor Race refers to this situation at the bottom of page 3 of his paper and believes it due to diffusion through the specimen because of temperature cycles and the electric field. It is puzzling to us, if there is diffusion, why the center does not show higher metal content. It would seem as if it is due to the high electric stress causing the rapid movement of the metallic ions. (May be initial stage of sputtering of electrodes. See Callender reports.)

Doctor Race's studies confirm Doctor Robinson's theory of breakdown, namely, that failure starts at the point of maximum stress. As the specimens were thoroughly filled with a degasified oil, any reference to the effect of gas voids cannot be made unless the gas is produced by the breakdown of the oil due to high electric stress. This study shows the value of using oil of such viscosity that it will thoroughly fill all the space between the paper and the conductor and also we should provide means for keeping the oil in place. The so-called oil-filled cable accomplishes this. It can also be obtained in solid cables by using oils of about one-fifth the viscosity we now use and let the oil flow through the spaces in the strands of the conductor.

H. H. Race: Near the end of the first paragraph of R. J. Wiseman's discussion he refers to stress "marking which is the beginning of failure. . ." I should like to make a slightly different interpretation of the evidence. Stress markings on oil-impregnated paper are found whenever extremely high gradients have existed for some time. However, they do not appear to be heavier at or near a failure point than elsewhere. In fact, failures may occur to an unmarked region (see also my discussion of Doctor Whitehead's paper on "The Dielectric Strength and the Life of Impregnated Paper", AIEE Transactions, volume 59, 1940, pages 1087–8). Also they have been found in test specimens which have not failed. Therefore, while the stress marks are unquestionably evidences of some chemical changes resulting from high electrical gradients, they are not necessarily indications of the beginning of ionization breakdown.

In the second paragraph, Doctor Wiseman asks for an explanation of the high power factor in the center of specimen 305. Table II shows that the materials responsible for the high power factor were largely but not entirely benzene soluble. Whether these materials were deterioration products of the oil or the paper or both we do not know. On the other hand, the accuracy of these measurements is not too good, probably because of irregularities in electrode contact so that the differences may not be significant except for general trends indicated by a number of samples. My guess is, however, that in addition to metal soaps there are other deterioration products of both the oil and the paper which contribute to dielectric losses. Such deterioration products might have resulted from the incipient ionization which, according to figure 3, penetrated through the first five layers of this specimen.

I agree with the comments in the third paragraph of Doctor Wiseman's discussion and further suggest that some additional chemical reaction, such as catalysis at the metal electrodes, must be postulated in order to account for the concentration of the metal compounds in the layers adjacent to the electrodes.

In his last sentence, Doctor Wiseman implies that the advantages of the oil-filled cable system can be obtained in "solid type" cables simply by using low-viscosity impregnants. I feel sure that he did not mean this since during changes in load, ionization cannot be prevented at rated voltage unless a positive liquid pressure of approximately one atmosphere is maintained at all points in the cable at all times. This requires reservoirs, oil channels, and stop joints and is the "oil-filled" system.

Although not mentioned in the paper we have had specimens whose inner electrodes were smooth instead of threaded cylinders and have observed failures starting from the outside, as noted by Halperin. The important point is that such failures appear to start from an electrode at a point of highest gradient caused by some irregularity such as a sharp point or edge on the surface of the conductor.

Paragraphs 2–5 of Halperin's discussion raise very interesting questions as to the chemical reactions resulting in the observed metal concentrations in the layers of paper adjacent to both electrodes. Mr. Van Brunt of our laboratory has made several attempts at identifying the dark-brown striations in these specimens. The microphotograph of the inner layer of specimen 250, shown in figure 3 of this discussion, shows that the colored material is concentrated in the interstices between the paper fibers and as films encasing the individual fibers. Under the microscope these appeared to be composed of discrete particles. The deposits are definitely *not carbon*, nor sulfides. The material seems much less reactive chemically than ordinary metal soaps. It may be a mixture or compound of metals with hydrocarbon polymers in varying degrees of polymerization.

In the absence of both free oxygen and oxidized oil but in the presence of very high electrical gradients and possibly incipient corona, it appears that chemical reactions are occurring which are very different from those which take place in the absence of the electrical field and with which the chemist is familiar. As pure conjecture I would suggest residual water as a source of oxygen or acidic decomposition products of cellulose or direct combination of metals and hydrocarbons as in catalysis.

I attribute the long life of the washed specimens simply to the shrinking of the paper around the sharp edges of the threaded electrode and the resulting elimination of the free oil space in the highest stress field so that the corona starting voltage was raised above the operating voltage.

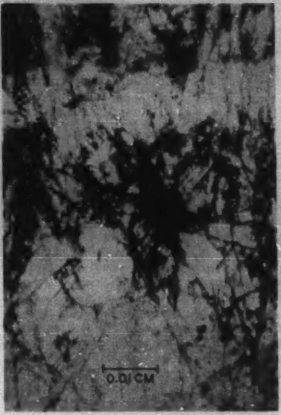

Figure 3. Microphotograph of portion of inside of inner layer of paper from specimen 250 showing concentration of dark-brown deposits in the interstices between and on the surfaces of the paper fibers in regions of highest stress at the edges of the area of contact between the paper and the inner conductor

In his seventh paragraph Mr. Halperin questions the meaning of the large variations in dielectric constant measured in a strip cell. I think these are simply poor measurements caused by wrinkles or irregularities in the paper which were not smoothed out by the moderate weight on the upper electrode, and therefore that they have little significance except to show the order of magnitude of possible errors.

Referring to Halperin's last paragraph, we could find little evidence that oil which could be centrifuged out of the paper was deteriorated. Table I shows the acid number of such portions to be uniformly low and in many specimens the power factor of the centrifuged oil was as low as new oil. Some of those showing high values contained free carbon resulting from incipient failures and carbonized paths in adjacent sections of paper.

The Dielectric Strength and Life of Impregnated-Paper Insulation—I—The Influence of the Density of the Paper

Discussion and author's closure of paper 39-111 by J. B. Whitehead, presented at the AIEE combined summer and Pacific Coast convention, San Francisco, Calif., June 26–30, 1939, and published in AIEE TRANSACTIONS, 1940, pages 715–20.

Wm. A. Del Mar (Phelps Dodge Copper Products Corporation, Yonkers, N. Y.): The effects observed by Doctor Whitehead all relate to cable fully impregnated with thin oil, as in oil-filled cable and I therefore confine my remarks to cable of that type, in contradistinction to the so-called "solid type."

The use of high-density paper in such cables is primarily for the purpose of increasing the dielectric strength against severe steep-front transient voltages of short duration and there appears to be ample evidence of its value for this purpose. A gain of 15 to 20 per cent in cable dielectric strength, by this means, appears to be entirely practicable.

While, therefore, Doctor Whitehead's study is a valuable contribution to our knowledge of the physics of cable under stress it relates only to a condition which never occurs in service, namely sinusoidal voltages of two to three times normal operating voltage for periods of 50 to 100 hours.

The significance of this study is, therefore, not in its bearing on present cable design but in adding another link to our chain of knowledge in relation to the mechanism of breakdown of impregnated-paper insulation.

R. J. Wiseman (The Okonite Company, Passaic, N. J.): As usual, Doctor Whitehead has written a very clear paper on the researches which he has been carrying out for many years on the dielectric, paper and oil in combination. We, in Insulated Paper Cable Engineers Association have followed this particular research during its progress and have had the opportunity from time to time of offering suggestions and explanations from the application side. It is a surprise to us to note a decreasing dielectric strength when the weight density increases. We have tried to explain it further than the stress in the oil gap as described by Doctor Whitehead. Our views are associated with our experiences in the testing of solid-type cables before and after we had begun to use high-density papers. We have noted higher breakdown voltages when using high-air-resistance paper, although not as much as one would expect if we took the short-time dielectric strength of a sheet of paper and calculated the theoretical breakdown. Doctor Whitehead used a very thin oil and much higher stresses than we test our cables at, so it seems as if there is a time-stress element that has a big influence on what results. Our company's feeling is that we have obtained some valuable fundamental knowledge of a combination of oil and paper that will require careful study in its application.

Our company, when considering the variation in the physical characteristics of paper, has not felt that we should consider the weight density as the important variable, but the air resistance per mil, or else the space factor, which in turn is related to the amount of oil that can be absorbed by the paper. Mr. Gooding replotted for me figures 1, 2, and 3, using per cent of oil by volume in place of the specific gravity of the paper. These are shown in figures 1 to 4, inclusive, of this discussion. Figure 1*A* shows the maximum breakdown stress against per cent oil volume. Papers *A*, *B*, and *D* fall fairly well on a straight line. Paper *C* shows a low stress for the corresponding oil volume. The breakdown values appear to correlate better with the specific gravity as shown by Doctor Whitehead's figure 1. In figure 1*B* breakdown stress is plotted against air resistance per mil and all points except *E* lie on a smooth curve.

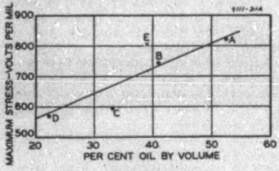

Figure 1A

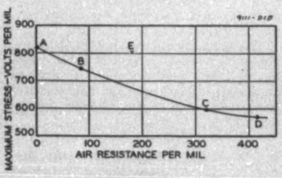

Figure 1B

Figure 2 shows the relationship of power factor and oil volume. It is possible to draw a straight line, and papers *C* and *D* line up better than if the specific gravity is used. Figure 3 shows the watt loss against oil volume, and here also a straight line can be drawn with papers *C* and *D* lining up better with the other papers than when specific gravity is used. Figure 4 shows the conductivity plotted against oil volume and we again get a straight line, but paper *A* seems to be out of line. The last three curves indicate that there is a direct relationship between volume of oil and the various electrical loss characteristics. Granting this is so, Doctor Whitehead is justified in considering the electric stress on the oil in the gaps as the controlling factor in determining the expected voltage breakdown. I think the agreement between the different papers on the oil electric stress, as given in paragraph 4 under "Discussion of Results", is good. Perhaps some of this variation may be due to a distortion of the electrostatic field in the gaps due to the narrowness of the gaps, and therefore, taking the ratio of the dielectric constants is not exactly correct, but is a very good first approximation, sufficiently close to believe that breakdown is a function of the electric stress in the oil gap. An improvement could be made if we knew more about the dielectric strength of oil in narrow gaps and thin films.

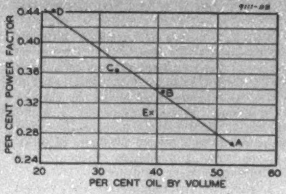

Figure 2

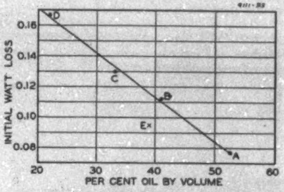

Figure 3

Paper *E*, which Doctor Whitehead used five years ago on another research, lines up fairly well with the other papers, yet its physical properties are quite different. Doctor Whitehead refers to the effect of age on this paper. We are inclined to believe it is due to fiber structure. If we refer to table I on the properties of paper and figure 4 on oil content, we note that it lies between *A* and *B* for gravity, between *B* and *C* for Gurley air resistance, and oil by volume, and just above *B* for oil by weight. It seems desirable, if possible, to find out if this paper was made the same way as papers *A* to *D* and if the same kind of pulp were used. Perhaps the lining up of the paper fibers may be different or more calendering was performed on paper *E*.

We wish to congratulate Doctor Whitehead on another valuable contribution to his previous papers on the electrical properties of oil and paper in combination.

W. T. Peirce and **G. M. L. Sommerman** (American Steel and Wire Company, Worcester, Mass.): Doctor Whitehead has made a signal contribution to the knowledge of the electrical properties of oil-saturated paper insulation. We would like to add our word of caution against the interpretation of these results as applied to solid-type cable insulation.

In the first place the life tests started at an average stress of 400 volts per mil and ran up to 700 volts per mil. Such stresses produce test conditions within the dielectric never encountered in ordinary use and therefore are *more* than accelerated tests.

The tests were made in an open bath using a very light oil which is thus able to move freely and without building up pressure under the mechanical forces set up by spots of ionization.

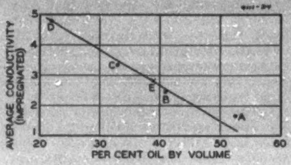

Figure 4

In tests made in an oil bath the property of paper to resist the migration of the heavier saturants ordinarily used in solid-type cables is not realized. This migration of oil is an important feature in the deterioration of actual solid-type cable and the somewhat greater resistance of high-density paper to such migration has not been evaluated by these tests.

The whole body of insulation tested was one grade of paper of relatively small thickness compared with cable insulation. Therefore, no effect of stress grading due to the different specific inductive capacity of the different grades of paper was realized. The effect of grading in some cases is to reduce the value of maximum stress which Doctor Whitehead has found to be so important, and to lead to a more uniform stress distribution throughout the dielectric.

The thyratron interrupter employed by Professor Whitehead and his associates in their cable-life tests makes it possible to obtain considerable information on the origin and mechanism of electrical breakdown of insulation. Thus Whitehead finds that most of the failures begin in the spaces between successive turns of paper tape. H. H. Race has also used the thyratron interrupter in cable life tests, and in table I of his recent paper, "Tests on Oil-Impregnated Paper—IV" (*Transactions pages 721–9*) data are presented on the starting point of, and the number of layers involved in, incipient electrical failures. We should like Professor Whitehead to give similar quantitative information, including the number of incipient failures which began in layer 1, the number which began in layer 2, etc.

The values for per cent oil content by volume given in table I apparently have been obtained by multiplying the per cent oil content by weight by the specific gravity of the paper and dividing by the specific gravity of the oil (0.90). From this it follows that the values given for per cent oil content by weight are in terms of the weight of the dry paper, and are not in terms of the weight of the impregnated paper.

It is, of course, well known that the dielectric constant of impregnated paper increases with increasing density of the paper. Values of dielectric constant which we have measured, however, are about 15 per cent lower than those experimentally determined by Whitehead, and are in good agreement with the average of Whitehead's computed values (for series-parallel distribution of oil and cellulose).

The increase in d-c conductivity of the impregnated specimens with increasing paper density is attributed by Whitehead to increases in supply of conducting ions from two sources: (1) soluble electrolytic impurities in the paper; (2) residual moisture retained by the paper. The first source is the predominating one for reasonably well dried paper, and the magnitude of it may be reduced by additional washing of the paper either during or after paper manufacture. More generally, therefore, the conductivity of impregnated paper depends on the degree of washing of the paper as well as on the density of the paper. As an illustration of this, the d-c conductivity of very well washed high-density paper is lower than that of regular-washed average-density paper. Such variations in conductivity, however, probably are not responsible for variations in breakdown strength and life, within the low range of conductivities covered in Whitehead's studies.

The power factor of impregnated paper at temperatures below 50 degrees centigrade depends almost entirely on the density of the paper and little if any on the degree of washing of the paper; it does not, therefore, vary with the d-c conductivity in all cases. At temperatures above 70 degrees centigrade however, the power factor does vary with the conductivity. Thus, the complete power factor-temperature curves of impregnated papers of different densities often cross each other in the neighborhood of 60 degrees centigrade.

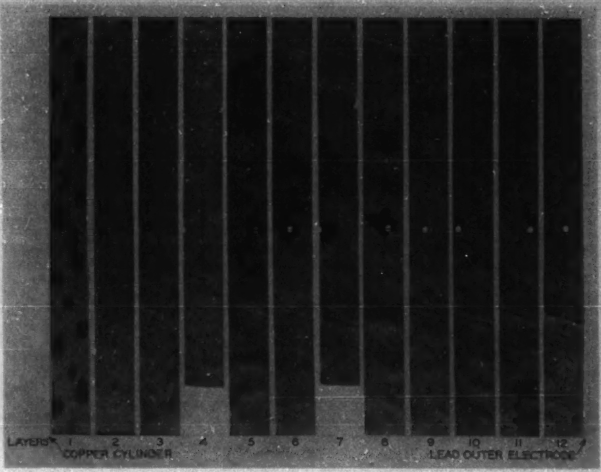

Figure 6. Cell 518, inside surfaces of all tapes in area of puncture

H. H. Race (General Electric Company, Schenectady, N. Y.): I am particularly interested in this paper for two reasons. First, this work, although different in several respects, is related to experiments we have been conducting for several years, as reported at the last four summer conventions; and second, I have been privileged to serve as chairman of the AIEE committee representing the sponsors of the project and have therefore followed its development in detail. I am sure that all members of the sponsoring committee will echo the thought that this project has been carried through in a very excellent manner.

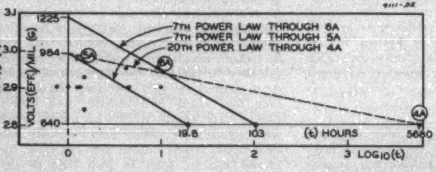

Figure 5. Plot showing that application of seventh-power law to high-voltage life-test data is misleading

We have conducted one experiment in an attempt to correlate my long-time life test at constant voltage with Doctor Whitehead's short-time voltage step-up tests. He sent us three specimens made early in this project and we made a glass cell with a sylphon reservoir so that a specimen could be assembled, evacuated, impregnated, and tested in the same manner as my smaller specimens have been tested. We have obtained a life run on only one specimen because it lasted 236.6 days or 5,680 hours at 30 kv (effective). Since the specimen was made with 12 layers of 0.004-inch (nominal) paper and had a measured thickness of insulation when dissected of 0.047 inch, this corresponds to an average gradient of 640 volts (effective) per mil or 356 kv peak per centimeter.

Several specimens identical to the one I tested were made and tested by Doctor Whitehead during the preliminary stages of his investigation and I am taking the liberty of listing them in table I of this discussion, since none of the specimens reported in Doctor Whitehead's paper is exactly comparable to the specimen I tested.

It has been suggested that we attempt to correlate these data by means of the "seventh power law" proposed by F. M. Farmer ("Tests of Paper-Insulated High-Tension Cables", AIEE JOURNAL, volume 45, May 1926, page 457). This relation may be stated $(t_x/t_l) = (G_l/G_x)^7$ where (G_l) is the gradient at which the specimen will fail in one hour (t_l) and (t_x) is the time in hours which the specimen should live at the gradient (G_x). From table I, I have plotted in figure 5 of this discussion the number of hours to failure of each specimen on its last voltage step. According to the seventh-power law specimen 5*A* should have lasted one hour at 984 volts per mil or 19.8 hours at 640 volts per mil. Actually the specimen had previously withstood 24 hours at 900 volts per mil. Now if this last point were taken as a datum through which to draw a seventh-power line the specimen should have failed in one hour at a gradient of 1,430 volts per mil and in 260 hours at 640 volts per mil. Actually the specimen failed in 1.25 hours at 950 volts per mil, whereas a companion specimen on my test lasted 5,680 hours at 640 volts per mil even though my test is more severe in that the specimens are subjected to daily heating and cooling cycles with a maximum temperature of 100 degrees centigrade. Even with the limited data available this analysis indicates that it may be extremely misleading to attempt to apply an empirical rule to conditions where a proportionately small change in voltage gradient may radically change the mechanism of failure and resultant life. W. S. Clark (AIEE JOURNAL, volume 45, November 1926, page 1158) pointed out in a discussion of Farmer's paper that for oil-filled cable "the exponent, instead of being 7, should be something in the neighborhood

of 19". Note in figure 5 the line drawn through point 4*A* with an exponent of 20. I think that the absence or presence of ionization is one of these critical phenomena and that corona-starting-point measurements may be even more important than short-time extreme-voltage breakdown tests.

In connection with my paper in which I show that chemical deterioration (like cancer) may be the cause of death at a ripe old age if the patient is immune from ionization (like pneumonia), the appearance of the tapes removed from Doctor Whitehead's specimen is of interest (see figures 6 and 7 of this discussion). The inside of the first layer shows large areas of stress marking around each hole in the inner conductor although the puncture did not occur at such a spot in agreement with Doctor Whitehead's observation that the punctures showed no preference for such spots. The outer surfaces of the outer layers showed considerable darkening, indicating metal reaction products.

The results of our work agree in so many aspects with those reported by Doctor Whitehead that I can only take the space necessary to point out where we disagree.

1. Doctor Whitehead states that failure sometimes starts in oil channels "in the center of the insulation wall". True, the damage is sometimes more apparent here, as explained in my paper and sometimes a magnifying glass is necessary in order to find the small hole which constitutes the conducting path back to one electrode. However, close examination of hundreds of our specimens, many of which had multiple partial failures, has never revealed a single carbonized path which did not start at one electrode. I hope Doctor Whitehead has kept the paper from all his specimens so that he can check back on this point.

2. Doctor Whitehead states that calculated gradients of 1,500 volts (effective) per mil or 835 kv peak per centimeter are too high to be considered as breakdown gradients in oil. However, my paper on insulating liquids shows hundreds of measurements of this order and higher. It seems to me that our data make unnecessary the rather forced explanation that the dielectric constant of the oil is increased 50 per cent by ionic conduction and space charges. To be sure, ionic conductivity is enormously increased at high gradients but the energy concentration is still extremely small compared to that occurring in a spark discharge and I believe the latter is necessary before carbonization of paper can start.

3. The dielectric constants reported by Doctor Whitehead are considerably higher than those obtained in commercial cable made from papers of similar density. For comparison, table II of this discussion shows data taken in the factory on full lengths of commercial cable and on ten-foot samples made up for test purposes. I believe the reasons for these differences are that Doctor Whitehead's specimens are wound with smaller butt spaces and since the total insulation wall is relatively thin and the inner conductor is a rigid cylinder, the paper can be wound much more tightly than on commercial cable. Cable with thick insulation wall has to be built with adequate butt spaces and with decreasing tension at increasing radii in order to pass the severe bending and wrinkling requirements. Therefore the volumetric proportion of paper fiber to oil would be greater in Doctor Whitehead's specimens than in commercial cable with a correspondingly greater apparent dielectric constant.

R. W. Atkinson (General Cable Corporation, Perth Amboy, N. J.): Doctor Whitehead's results indicate that for his samples long life is associated with *low* paper density. Tests on cables, however, have indicated that long life in cables is associated with *high* paper density.

The correctness of Doctor Whitehead's conclusions for his samples is not open to question and his theory explaining his results appears adequate and reasonable. Similarly, we believe that the conclusions with respect to cables rest on an equally sound foundation.

The foundation on which cable practice rests is mainly the result of direct comparative tests made on cables insulated with paper of different densities, that is to say, the result of tests with the same variable as that used by Doctor Whitehead. Before presenting such data, however, it will be useful to give a statistical picture.

We have analyzed data taken from extensive reports of the Electrical Testing Laboratories, showing the results of specification tests by all cable manufacturers over the period from 1926 to 1931 (both inclusive). Specifically, data have been taken for so-called life tests under the Association of Edison Illuminating Companies specifications in which failure normally took place in from 12 to 24 hours. The data selected are limited to single-conductor cables because fewer extraneous conditions, such as terminal failures, are here involved.

The average dielectric strength, for each year, of all single-conductor cables covered in these reports is shown in figure 8 of this discussion. From 1926 to 1928 there is a one-third increase in dielectric strength. The year 1926 marks the beginning of important commercial introduction of wood paper. By the end of 1928 wood paper had practically supplanted manila paper. Wood paper, as initially introduced, had materially greater density than did manila, and during this period of time the density for both manila and wood pulp was continually increasing. It will be noted that there is a peak in the curve for the year 1929, with the values dropping off again for 1930 and 1931 to values only slightly higher than for 1928. Detailed analysis indicates that the high value for 1929 was due to unique causes making the data for that year not comparable with the data for other years.

That the large increase in dielectric strength has coincided with a large increase in paper density does not necessarily mean that there is a causal relationship between them. However, when coupled with the fact that manufacturers were under marked pressure to increase the strength of cables as measured by this test and the further fact that each, individually, had opportunity to evaluate results on cables made with steadily increasing paper density, the evidence is strong indeed that the effect obtained was at least in part due to this cause.

Over a period of many years extending to

Table II. Dielectric-Constant Data for Commercial Cable

	Number of Lengths	Diameter of Conductor (Inches)	Diameter Over Paper (Inches)	Density of Paper	Dielectric Constant		
					Maximum	Minimum	Average

		0.814	1.376	0.9 –1.0			3.58
		0.814	1.376	1.18			3.83

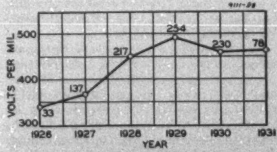

Figure 8. Average dielectric strength of single-conductor cables by years, as shown by the 1931 report of cable inspection of Electrical Testing Laboratories

The number at each point is the number of tests averaged the present time, and including a period of intense activity around 1928, much information involving *direct comparison* between lower and higher density paper has been obtained by cable manufacturers. Obviously, only a small part of these data can be given here, but it should be borne in mind that the trend of all the data on cables, extending to the present time, is entirely consistent with the typical tests here mentioned.

During 1928 we carried on in two laboratories (Perth Amboy and Pittsburgh) an extended program, including both short-time tests and tests extending to hundreds of hours duration. Paper of five-mil and eight-mil thickness, both manila and wood pulp, was used, the density range corresponding with the lower end and middle of Doctor Whitehead's. In the tests at Perth Amboy, the full thickness of insulation (9/32 inch) of the lead-covered cable was tested. At Pittsburgh the sheath and outer layers of tape were removed down to a remaining thickness of 6/32 inch and a foil outer electrode applied.

The results of the short-time breakdown tests from both laboratories are shown in figure 9 of this discussion. The dielectric strength is plotted against the air resistance (reciprocal of porosity), rather than the density of the paper. In general, increasing air resistance is accompanied by increasing density, although our tests have shown a closer correlation of dielectric strength with air resistance than with density. It will be noted that the dielectric strength increases with air resistance, rapidly for low values, and slowly for high values.

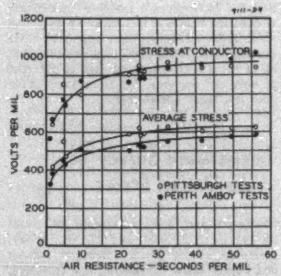

Figure 9. Breakdown stress of cables as a function of the air resistance of the paper used in the dielectric

All tests are evaluated to five minutes on the assumption of a seventh-power voltage-time relation ($E^7 = KT$)

Long-time tests at 45 kv (160 volts per mil, average stress, 275 volts per mil at the conductor) are shown in figure 10 of this discussion. Here there is even a more marked effect of air resistance, particularly in the lower range.

Tests were also made with graded insulation, using denser paper near the conductor than in the outer layers. The results of these tests are in general agreement with those just indicated. Other comparisons have been made, both long-time and short-time, covering a density range corresponding to the upper half of the range in Doctor Whitehead's tests. In these tests there is also a general tendency for longer life to be accompanied by higher density, although the actual difference in life between papers within this range is small. Similar results have been obtained on load-cycle aging tests made to represent accelerated service conditions. In none of these has there been a relationship between density and strength like that found by Doctor Whitehead.

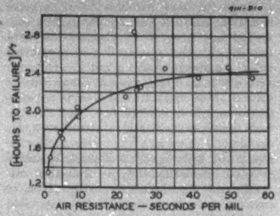

Figure 10. Seventh root of hours' life of cables at 45 kv (160 volts per mil, average stress, 275 volts per mil at the conductor) as a function of the air resistance used in the dielectric

It should be recognized that the importance of Doctor Whitehead's results is all the greater because of the apparent disagreement between his results and those just given. Moreover, it is not to be concluded that because the apparent disagreement is so great and so fundamental there can be no conciliation.

From the physical comparison of Doctor Whitehead's samples with cables it is not obvious why the density-dielectric strength relation should be so different. However, there are important physical differences and some of these must be responsible for the difference in performance. The specific dielectric strength of Doctor Whitehead's specimens is very high compared with that obtained in cables and this high relative strength is one measure of the importance of the actual difference between the physical character of his specimens and of cables. It is not at all unreasonable that the main difference between the effect of paper density in his specimens and in cables is due to developing in cables a much lesser proportion of the theoretical strength with paper of low density than with paper of high density.

Some of the differences between Doctor Whitehead's samples and cables are the following:

(*a*). Doctor Whitehead's conductor is a substantially smooth cylinder as contrasted with the stranded conductor of cables.

(*b*). The insulation on his samples did not need to be designed so as to permit bending. This gave greater latitude as regards paper application (tightness of wrapping, amount of valley space between adjacent turns) than is permissible in cables. (Aside from the rigidity of the conductor, I believe the insulation on his specimens would not permit the bending that cables are required to stand.)

(*c*). The dielectric constants reported by Doctor Whitehead for his samples are of the order of 10 to 20 per cent higher than are obtainable on cables made with equal density of applied insulation.

(*d*). Associated with most tests on *cables* there has been a certain amount of corona on test leads, whereas Doctor Whitehead has carefully avoided corona. It should be noted, however, that one somewhat limited experimental study of the effect of corona in cable tests has shown no difference in results due to corona.

(*e*). The fact that there is a longitudinal variation in even the most carefully made specimens gives some advantage to very short specimens such as Doctor Whitehead's. That this may not be unimportant is illustrated by the discarding even in Doctor Whitehead's data of the results from some specimens found subnormal on the tests.

It will be noted that, while obviously many of these differences help to explain the high strength of Doctor Whitehead's samples in comparison with cables, none of them seems an obvious explanation for the reversal in relative strength of high and low density paper.

Another relevant point may also here be mentioned. Commercial cables in this country fall, in general, into two classifications: "oil filled" and "solid type." Inasmuch as the saturant used in Doctor Whitehead's tests is similar to that used in oil-filled cables, his data are more directly applicable to that type. The tests and experience reported in this discussion are confined to "solid-type" cable, but commercial experience with "oil-filled" cables is not materially different from that with "solid type." Tests which Doctor Whitehead plans to make later, with a less fluid saturant, may perhaps show agreement with experience with "solid-type" cables.

While Doctor Whitehead's results are not directly applicable to cable design, their practical importance must not be underestimated. His results will be of great value even though there should be no further contribution than the fundamental data and analysis which have been given; and since fundamental information such as his usually goes on to practical applications not originally suspected, such a result may reasonably be anticipated from Doctor Whitehead's work.

D. M. Simmons (General Cable Corporation, New York, N. Y.): Mr. Atkinson has discussed Doctor Whitehead's paper largely with respect to "solid-type" cable. My discussion will be with respect to oil-filled cable. For several reasons, consideration of Doctor Whitehead's data in connection with oil-filled cable must be on quite a different basis than for "solid type."

First may be considered the requirement of service. In the case of solid-type cables, the limitation of voltage rating for a given thickness of insulation is essentially the long-time voltage strength of the cable. Normally, the strength for transient voltages is entirely adequate to take care of any transients which may occur. In the case of oil-filled cables, in general less than one-half the solid-type thickness of insulation is used for any given voltage and it is clear from tests, laboratory and field, that even considerably lesser thickness may be adequate so far as concerns the long-time strength. However, the transient strength of a given thickness of cable insulation is no greater for oil-filled than for solid-type insulation. Thus, while the margin for withstanding *normal 60-cyle voltage* is greater for oil-filled cables than for solid type, the margin for withstanding *transient voltages* is much smaller. While operating experience has clearly shown that with present insulation thicknesses of oil-filled cables there is ample margin for both operating and transient voltages, the difference in relative factor of safety seems to warrant placing emphasis on transient dielectric strength. For these reasons, any procedure tending to increase the transient voltage strength of oil-filled cables seems to be in order.

For the determination of the transient and of the long-time 60-cycle voltage strength of oil-filled insulation, we made up and tested, some years ago, two cables similar in all respects except as to the density of paper. Cable A was made with paper of approximately the highest density used by Doctor Whitehead, while cable B was made with paper of a density intermediate between Doctor Whitehead's two least dense samples. Both were saturated with "oil-filled cable oil." In the surge voltage tests, cable A gave a dielectric strength about 25 per cent higher than cable B. In the 60-cycle tests, made at a voltage such that failure occurred after several hundred hours, the results for both cables were practically identical. Thus, while the "long-time" 60-cycle strength in these tests on oil-filled cable was substantially independent of paper density, the transient voltage strength was definitely higher for the paper of higher density.

Another reason, important though nonelectrical, emphasizes the desirability of using dense insulation with oil-filled cables. It will be recalled that in Doctor Whitehead's tests the densest paper which he used contained, within a given volume, less than one-half as much oil as the least dense paper. The greater the oil volume, the greater will be the change in volume due to temperature changes and the greater the channel and reservoir capacity which must be provided. Thus, the denser the paper used, the smaller the oil channels and reservoirs would need to be.

Accordingly, in the case of oil-filled cable, technical and economic reasons give special and definite advantage to the dense paper without any corresponding disadvantage.

J. B. Whitehead: It is a pleasure to find that no one has questioned the accuracy of our conclusion that laboratory and accelerated life tests of impregnated-paper insulation of the oil-filled type indicate decrease of dielectric strength and of life with increasing density of the paper. The foregoing discussion has in fact taken the direction of an examination of this result as related to the design and the operation of present-day cables of standard types. Unfortunately our results are in apparent contradiction to the convictions of some of our most competent and experienced cable engineers, on the influence of increasing paper density, and also to existing practice in cable manufacture in which high-density paper is used with the aim to increase dielectric strength. Much of the discussion is the presentation of evidence and reasoning to the effect that our results should not be applied in cable design and that in cables, higher-density paper means higher and not lower dielectric strength and life.

Thus, we have before us a remarkable situation in which a series of carefully controlled laboratory tests planned and conducted with the co-operation of prominent cable engineers has given results exactly contrary to the present convictions of some of these engineers and of certain manufacturers. It is not the first time that we have found ourselves in a position of this character. We have frequently conducted laboratory investigations of single variables in cable insulation only to find that our results are discounted by cable engineers because of the large number of uncontrolled variables in cable insulation, and the belief that behavior due to one variable is not independent of that of the others.

It was not my intention in the paper nor is it my intention now to express an opinion as to the significance of our results for cable manufacture. The extremely able group of engineers who have discussed the paper are better qualified for this purpose and the discussion indicates clearly the reasons why most of them feel that our very clear-cut results should not be applied for modification of present-day methods of design. I shall therefore limit myself to commenting on only a few of the matters brought forward in the discussion.

Messrs. Atkinson, Del Mar, Sommerman, and Peirce have indicated clearly evidence and reasons why they feel that the results should not be applied to cables with solid-type insulation. No exception can be taken to these excellent surveys and moreover our experiments have been limited to insulation of the oil-filled type. Our experiments are continuing under conditions approaching very much more nearly the solid-type insulation and when this phase of the work is completed, it is possible that further light may be thrown on the question of paper density in solid-type insulation.

Messrs. Del Mar and Simmons have emphasized the importance of high-density paper in increasing the impulse strength of oil-filled insulation. The results they report are well known and cannot be questioned. It may be pointed out, however, that under impulse voltages the division of stress between paper and oil channels is the same as at low frequencies, that incipient discharges in the oil are possible, gas formation being suppressed by the sealing action of the oil, and that under a sufficient number of high-voltage impulses, a progressive attack of the paper structure by minute discharges is still possible.

Our results, it seems to me, apply particularly to the long-time stability and life of oil-filled insulation. Mr. Del Mar apparently attaches no importance to this question. Mr. Simmons, however, recognizes it as an important question although relatively unimportant as compared with the impulse strength. While the duration of our life tests was relatively short, there was plenty of evidence that the time element entered at any value of stress and that therefore progressive instability was present. Although our range of stresses was relatively high, there can be no doubt that even within the ranges of stresses of practice, there are always present a certain number of points of exceedingly high stress between paper fiber and oil from which initial discharges take place and progressive deterioration sets in. Our results, therefore, seem to me to apply definitely to the matter of the long-time stability and in some measure also to the repeated impulses on an oil-filled insulation. So far as I know, no data have been recorded on these questions except the single isolated example reported by Mr. Simmons. I do not see how it is possible to avoid the conclusion that so far as long time behavior is concerned the use of high-density paper works against long life. It is a pleasure to note that Messrs. Atkinson and Wiseman feel that careful consideration must be given to our results in balancing the various important elements in future cable design.

Several speakers have commented on the high values of dielectric constant and I am glad to report that we have found an explanation of something more than one-half of our excess values. The results as reported were based on values of charging current in the ground connection of the measuring electrode of our sample. More recent measurements based on the capacitance in the Schering bridge have shown that the former values are too high and that our correct values which have now been checked in various ways at both 60 and 1,000 cycles are only 6 or 7 per cent higher, instead of 15 per cent, than the values found by various manufacturers. The error in the ground-current measurement was due to a peaked form of the current wave, apparently due in its turn to a slight third harmonic in the apparently smooth generator wave. In my paper, I have given a possible explanation of our high values of dielectric constant and some of the discussers have suggested other explanations. It is obviously possible that all of these may enter and that an increase of only six per cent for their joint effect does not seem unreasonable.

Temperature Survey of the United States

Discussion and authors' closure of paper 39-141 by J. J. Smith and H. W. Tenney, presented at the AIEE combined summer and Pacific Coast convention, San Francisco, Calif., June 26–30, 1939, and published in AIEE TRANSACTIONS, 1940, pages 769–75.

P. L. Alger (General Electric Company, Schenectady, N. Y.): This question of limiting values of ambient temperature in which normal apparatus life may be expected under rated load operation has been discussed at length in recent International Electrotechnical Commission committee meetings. As a result, the IEC has proposed a dual value of ambient temperature of reference; a maximum or limiting value of 40 degrees centigrade being associated with a limiting value of 35 degrees centigrade averaged over any 24-hour period. The 35-degree-centigrade value was selected largely as a result of an investigation of limiting summer temperatures in Italy conducted by B. Cerretelli, who has kindly given me access to his data.

The cities of Milan, Naples, and Palermo were selected as representative of the extreme climatic conditions under which power apparatus is used in Italy, and a three-year record was made of the outdoor temperatures experienced. It was found that a 32-degree-centigrade average over a 24-hour period was normally associated with a 40-degree-centigrade maximum temperature. Since it was desired to adopt a value representative of the maximum value of daily average temperature, and because the maximum and average temperatures indoors usually differ less than the outdoor values, it was decided to assign the value of 35 degrees centigrade as the limiting 24-hour average temperature of reference for international rules.

It is interesting to note that the summer temperature conditions in Palermo are about identical with those in Chicago, as reported in this paper:

	Palermo	Chicago
Average summer temperature	23 deg C	23 deg C
Average daily variation	10 deg C	9 deg C
Maximum temperature recorded	40.5 deg C	39.5 deg C
Average number of days exceeding 32.2 deg C	13	12

Differences in usual operating loads as compared to rating, in continuity of loading, and in life expectancy, representative of the practices in different countries, must be considered in any international comparison of the standards of rating and the operating recommendations. It is to be hoped, however, that the data presented in this paper and its discussion will be helpful in bringing about a closer alignment of IEC and American practices in apparatus rating and operation.

A. Naeter (Oklahoma Agricultural and Mechanical College, Stillwater): The "Temperature Survey of the United States" is a real contribution to the literature available to the electrical engineer. Its authors are to be congratulated upon making available to the profession the various conclusions that may be drawn from the publications of the United States Weather Bureau.

Just a few years ago it was my privilege to supervise a research project involving the design of less expensive rural electric lines than were being built at the time. In one phase of the study determinations were made of the maximum probable temperatures that could occur, under the probability theory, during the life of the distribution circuit. All temperature records of the United States Weather Bureau in Oklahoma City were used to determine the probable maximum temperature in a 20-year period, the assumed composite life of such a power line. This computed temperature was used to determine the maximum sag, during summer months, and thus provide the required minimum clearance at the same time. Yet it was recognized that the maximum temperature of a 100-year, or even a 1,000-year period could come within that 20-year life. As a matter of fact, during an extreme heat spell two or three years ago, but after the completion of the research project, the heat produced temperatures that would not occur more often, than once in several hundred years. This risk must be recognized and considered in financing projects.

The same study gave data on the probable minimum temperatures that could be experienced during the same time, as well as data on wind and ice loading, etc. It showed, for example, that while the maximum temperatures in August were higher than those in July, the minimum temperatures were lower, thus producing a wider spread, as a possibility, for August than for July.

According to Smith and Tenney "the maximum temperature to be expected once in ten years is three degrees Fahrenheit below the maximum recorded to date". The probability approach to this value is a much safer one than placing dependence on maximum recorded data in that the study, of the conditions in a series, brings into the problem the frequency of lesser conditions, which indicate to a much greater degree of accuracy the probable frequency of future happenings.

In terms of the results of the probability study for Oklahoma City the maximum temperature to be expected once in ten years is five degrees Fahrenheit above the probable annual maximum. There is no fixed maximum to which this ten-year maximum could be referred, because the probable maximum for a 1,000-year period is certainly higher than that for a 100-year period. The difference in reference points is fundamental.

The authors report that a study of the maximum temperature recorded at all points in the country shows that 104 degrees Fahrenheit is an average of these maxima. In the probability study made for Oklahoma City the probable maximum temperature occurring annually is 102 degrees Fahrenheit while the median and the mean are 101.5 and 101.4, respectively. When the median approaches the mean in value, it is commonly an indication that the series of observations follow closely the laws of probability. It is clear that the value secured from the probability studies for Oklahoma City is in close agreement with the national average value indicated by the authors' paper.

Details of the probability studies on temperature are shown on pages 26–40 of Publication No. 20, Rural Line Design Investigations, Bernard E. Lowe, published by the Engineering Experiment Station of the Oklahoma Agricultural and Mechanical College in Stillwater.

R. E. Hellmund (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): The authors have given in their paper some very valuable information on temperature conditions created by nature and have supplied thereby an excellent background for further considerations. From the data given it is quite evident that for large areas of the country there is a comfortable margin of several degrees between the ambient temperature set by the weather and the customary 40 degrees commonly used for many years as a basis for machine ratings. In a great many cases, in fact probably for the larger part of installed machinery and apparatus evaluated in kva capacity, there are factors which bring the ambient temperature appreciably above that supplied by nature in a shaded open-air location.

Most machinery is installed in enclosed areas. Electrical apparatus in itself always generates heat, thus raising the temperature within the enclosure above that outside in spite of reasonable provision for ventilation. With generating equipment, except that in hydraulic stations, there is furthermore the heat generated by heat engines, such as steam turbines, Diesel engines, etc., which contributes materially to an increased ambient temperature. Not only the generators but most of the auxiliary rotating apparatus as well as the converting apparatus in power stations and substations is exposed to it. Even with arrangements for forced circulation of outside air it is often difficult to avoid re-entry of some of the heated air into the system. This is true not only of stationary installations of machinery but also of traction equipment; especially when some or all of the cooling air is taken from the cab of a locomotive, the temperature of the cab is usually above that of the air outside. Again, in many industries using electric motors and apparatus, there are in addition to this electrical apparatus many heat-generating processes within the same building which result in elevated ambients. Many indoor motors, such as those used in the oil industry, are located in small enclosures exposed to considerable sun radiation; similar conditions apply to small switch housings, etc. In outdoor installations of apparatus the heat absorbed from sun radiation may be a factor of practical importance. These and other conditions are not merely of occasional occurrence but are more or less typical, each in its particular field of application, and, therefore, the margin furnished by nature does not warrant a feeling of added security but is really needed in many cases, if not the majority, in order to justify the 40-degree ambient temperature usually assumed. This is especially true with large apparatus and machines used in the central-station field, in some traction work, in many important industries, and also in marine applications.

On the other hand, it undoubtedly is true that the margin indicated in the paper actually is available in many installations of smaller motors, perhaps in an appreciable percentage of such motors (in number, not in horsepower). When these small motors are installed in rooms which are large in comparison with the motors, the indoor conditions will often be even more favorable than the natural outdoor temperature conditions. This is fortunate, because with small motors a certain margin is required for other purposes. For example, the power supply (voltage in particular) varies widely, and since the obvious economies of quantity production of small apparatus make the manufacture of motors for many slightly different voltages impractical, reasonable allowance must be made for this (see my discussion of "Determination of Temperature Rise of Induction Motors", by E. R. Summers, AIEE TRANSACTIONS, volume 58, 1939 (September section) page 474).

Although conditions vary a great deal, there seems to be considerable evidence that our existing rating structure is essentially sound for the majority of conditions met with in actual practice.

V. M. Montsinger (General Electric Company, Pittsfield, Mass.): Messrs. Smith and Tenney have presented some very valuable data on the weather conditions that can be used for many years to come.

Having been closely connected with the question of ambient temperatures under discussion for transformers during the past ten years, I am pleased to see that the data which the authors have presented justify the action taken by the AIEE transformer subcommittee and the ASA sectional committee on transformers in recognizing the fact that the daily average ambient throughout the country is about 30 degrees centigrade, coupled with a maximum ambient of 40 degrees centigrade. These facts have been used as a basis for the guides for operation of transformers by temperature, which are being issued as an appendix to the standards.

The values given in the sixth column, table I, show that the average number of days per year in which the temperature exceeds 90 degrees Fahrenheit (32.2 degrees centigrade) is approximately 25 days. The temperature, of course, does not exceed 90 degrees Fahrenheit during the 24-hour period. Assuming that it exceeds 32.2 degrees centigrade six hours each day, this means that the total time during the year is only 1.71 per cent. This indicates that a daily average ambient of 30 degrees centigrade as established in the transformer standards is a reasonable and conservative value in relation to actual conditions.

Several years ago it became quite apparent that, if certain electrical apparatus having 55-degree-centigrade temperature rise, and using class *A* insulation were operated continuously at full load, in a 40-degree-centigrade ambient, undue deterioration of the insulation would take place. This necessitated taking one of two steps; either reducing the temperature rise below 55 degrees centigrade for rating purposes, or setting up a lower reference ambient temperature in which the apparatus could be operated continuously at rated load with a reasonable life. It was decided to reduce the reference ambient to a value more nearly in agreement with actual conditions rather than reduce the temperature rise. Experience since that time has well justified this change.

Not only has the idea of establishing a daily average ambient, along with the maximum ambient, been accepted by the AIEE and ASA transformer committees, but the IEC has also established a maximum ambient of 40 degrees centigrade with a daily average ambient of 35 degrees centigrade.

In view of the progress being made in establishing both a daily average and daily maximum ambients here and in Europe, I am disappointed in the only conclusion reached in the paper, namely, that an ambient of 40 degrees centigrade selected for general rating purposes is a reasonable one. I am afraid that this conclusion may give the impression that it is safe to operate 55-degree-centigrade apparatus continuously in a 40-degree-centigrade ambient. I say this because the present standard ambient of 40 degrees centigrade for air, which was established in 1913, for rating purposes only, has been interpreted by many to mean that apparatus should be capable of carrying rated load continuously in a 40-degree-centigrade ambient.

While the data given in the paper can be used, if it is decided to establish both daily average and daily maximum ambients when revising AIEE Standards No. 1, I feel it would have been very desirable for the authors to have discussed this question in the paper.

J. J. Smith and H. W. Tenney: Mr. Montsinger has given a very interesting discussion on the basis of rating of apparatus. He has expressed his disappointment that the scope of this paper did not include this subject. The paper was intended only to furnish facts on atmospheric temperature conditions to the profession and to aid the AIEE standards committee in its work. This committee will undoubtedly consider such points as are introduced in the discussions of Messrs. Alger, Montsinger, and Hellmund. The brief reference in this paper to the 40-degree-centigrade ambient as a basis for rating, was merely made to indicate that the purpose of this paper was not one of advocating a change. There is apt to be confusion between the basis of rating apparatus and the basis of application. The temperature selected as a basis of rating is a benchmark for the purpose of comparison, whereas in the application of apparatus due consideration must be given to the conditions under which it is to be used.

The authors were glad to note Mr. Alger's reference to the international standardization situation. The efforts directed toward international standardization are, of course, important and must be given consideration in the evolution of standards in this country.

Professor Naeter has presented an illustration of the application of the information presented in this paper. In calculating the sag of a power line, the probable maximum temperature is a very important factor in establishing the minimum clearance. On the other hand, as far as insulation of electrical apparatus is concerned, if the maximum atmospheric temperature anticipated in a given period is exceeded infrequently no serious damage is done.

It was felt that the presentation of a summary of atmospheric conditions throughout the country for an extended period of time should prove useful in many ways. The scope of the paper was limited to just this and no attempt was made to analyze the uses to which it might be put and the methods used in its application.

Electronic Measurement of Surge-Crest Voltages

Discussion and authors' closure of paper 39-156 by J. M. Bryant and Morris Newman, presented at the AIEE Great Lakes District meeting, Minneapolis, Minn., September 27–29, 1939, and published in AIEE TRANSACTIONS, 1940, pages 807–11.

C. M. Foust: See discussion, page 1094.

E. J. Wade (General Electric Company Pittsfield, Mass.): Messrs. Bryant and Newman are to be congratulated on the excellent work which they have done in measuring short impulse voltages by means of electron tubes.

Now that the accuracy for steep waves has been demonstrated, the method should find wide acceptance, not only where the cathode-ray oscillograph is not available, but as an accessory to it particularly where a large number of similar measurements must be made.

The authors have shown that the circuit is capable of accurate results on waves which are so short that accurate results with the cathode-ray oscillograph are difficult or questionable. Under these conditions the use of the circuit will be attended by most of the difficulties encountered with cathode-ray oscillographs, such as oscillations induced on the circuit components and the errors of voltage dividers. However there is the danger in the use of the electronic trip circuit that the presence of fast oscillations may not be suspected whereas on oscillographic measurements the circuit must be modified to eliminate or reduce oscillations to an unobjectionable value.

This means that in the use of the electronic circuit the same technique must be adopted to avoid oscillations as is used in oscillograph work.

I would like to ask whether in the development of the electronic trip relay circuit an attempt was made to use the Eccles-Jordan circuit or its modifications, which require only a single power supply, which could be common to a multiplicity of stages. If equally short tripping times could be obtained this would permit a very material simplification on a ten-stage circuit as it would eliminate ten power supplies.

M. Newman: We quite agree with C. M. Foust in distinguishing between the functions of an electronic instrument which gives surge-crest values and of the cathode-ray oscillograph which records the entire phenomenon. It is to be emphasized that a direct-reading crest instrument of the type discussed does not replace but supplements the cathode-ray oscillograph by providing a convenient check on the oscillograph as well as giving considerable information more directly. Adjusting the operating range is no more difficult than in the case of the cathode-ray oscillograph; and, as E. J.

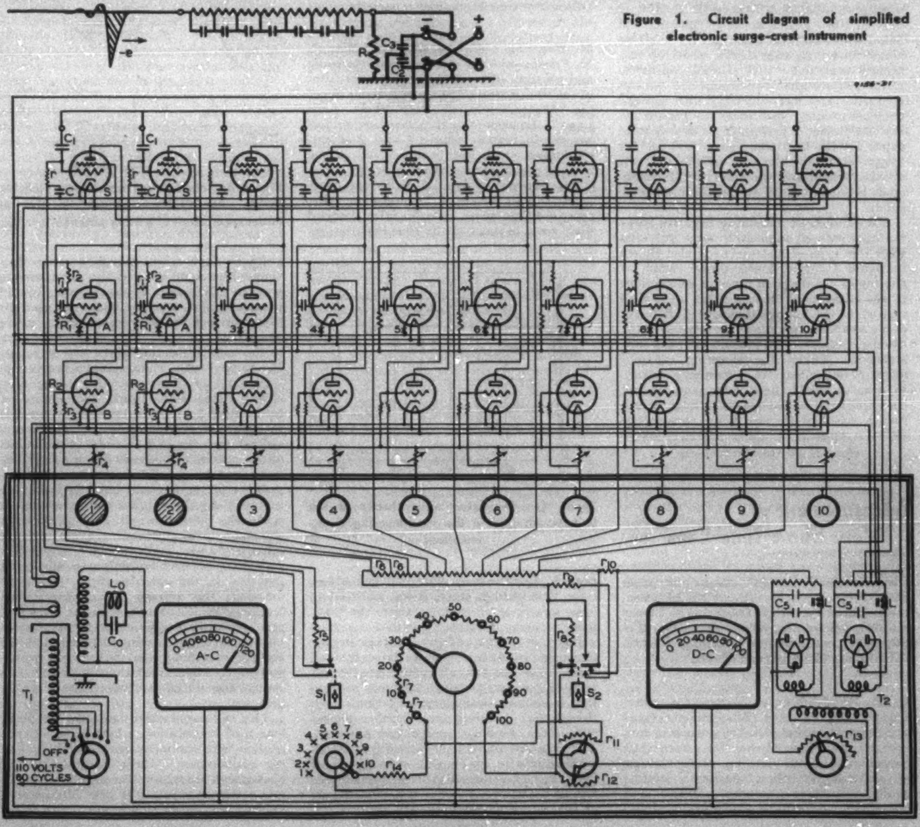

Figure 1. Circuit diagram of simplified electronic surge-crest instrument

Wade points out in his discussion, the problems of obtaining proper voltage division and freedom from superposed stray oscillations are the same as with the cathode-ray oscillograph.

Replying to Mr. Wade's question as to possibilities of using a common power supply to the various vacuum tubes, we present figure 1 of this discussion which shows a simplified instrument. In the original instrument described in the paper a maximum of versatility and flexibility was desired, and separate power supplies were incorporated so that each of the ten units could be used independently of any other. As it became apparent that we could find application for a number of such instruments in our research work, and as it was not so important to use the same instrument in a variety of ways, we combined the separate circuits, as shown in figure 1. Quite probably further simplification is possible. For instance, Doctor H. J. Reich in his book "Theory and Applications of Electron Tubes", pages 206–08, gives a "trigger circuit" modification using a single multigrid tube, and Doctor H. E. Hartig and M. W. Leslie at the University of Minnesota have worked out a very sensitive single-tube triggering device based on secondary emission. But general considerations indicate that combining the various operating functions necessary into a single tube may easily contribute to instability. We feel that it is preferable to use separate tubes for the bias comparison and for the trigger section; the cost of the tubes is relatively low, and the plate power supply drain is not increased by the use of separate tubes.

The method of measuring negative surge voltages, as well as positive surge voltages, with this type of instrument is also shown in figure 1. The double-throw switch at the top of the diagram reverses connections of the entire bank of measuring units with respect to the voltage divider. This introduces a capacitance across the low end of the divider, but it can be shown that for a low-resistance divider the shunting capacity effect is negligible. It is generally advantageous to shield the divider, and in that case the ratio of capacitances may be adjusted so that the shunting capacitance effect is completely compensated.

Measurement of Very Short Time Lags

Discussion and authors' closure of paper 39-157 by J. M. Bryant and M. Newman, presented at the AIEE Great Lakes District meeting, Minneapolis, Minn., September 27–29, 1939, and published in AIEE TRANSACTIONS, 1940, pages 812–16.

C. M. Foust (General Electric Company, Schenectady, N. Y.): That these authors are doing some real pioneering work in connection with instruments for short time measurements and time lag of breakdown is attested by these papers. Results achieved to date are important and it is hoped this work will be continued.

At present the electronic voltmeter arrangement appears to be most suitable to laboratory work where the surges to be measured can be brought to the apparatus and where some idea of amplitude is necessary to provide for preliminary setting of the electronic voltmeter. Of course in laboratory impulse work such a preliminary setting is generally possible and where shots can be readily repeated the electronic voltmeter certainly gives immediate information on crest values. This is often advantageous. The cathode-ray oscillograph while requiring film development and drying before analysis, and being, therefore, somewhat slower in this respect, still has the advantages of less preliminary adjustment for amplitude and a complete wave-shape record. As is usually the case, each type of instrument is fitted to particular fields of work.

In connection with the time lag data, figure 3 seems to indicate an overvoltage surge on the front of the applied wave. Is this present in the tests represented by figure 5 and if so do the authors believe it affects the time lag values reported?

M. Newman: We are very glad that C. M. Foust raised the question as to the cause and possible effect of the peak at the front of the timing wave T in figure 3 of our paper on "Measurement of Very Short Time Lags". In answering that question we feel we should present figures 1 and 2 of this discussion which had been left out of the original paper for the sake of brevity.

The curve a of figure 1 shows the theoretical output voltage of the surge generating unit and the curve b is the fully damped wave used in most of the time-lag tests reported. For the very short time lags of less than 10^{-8} second, where it was essential to have a very steep voltage wave, the wave form a was used on the basis that the overvoltages were high and the slight oscillatory overswing would introduce a relatively small error. For the lower overvoltages it was more important to have the surge voltage free from any oscillatory variations even though the damping introduced a slower rate of rise of voltage, and wave b was used.

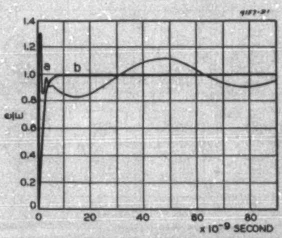

Figure 1. Calculated wave shapes of the voltages applied in the short-time-lag determinations

It was not possible to take fast enough oscillograms to check the wave fronts of figure 2. Therefore when it was desired to obtain oscillograms to illustrate the theory of the time-lag measurements we used an entirely different setup from that used in the short time lags of figure 5 of the paper. The example used was obtained in the case of a rod-gap breakdown on the front of a slowly rising voltage wave; and the timing wave T of figure 3 of the paper which Mr. Foust questioned is not the wave form applied to the gap, but is merely a timing wave initiated in synchronism with the time of application of voltage to the gap under test. The reason for and the method involved in producing that particular timing wave is indicated in figure 2 of this discussion. Diagram A represents the conditions in the case of the very short time lag tests reported in the paper, where the applied voltages were steep enough so that they themselves could be used also as the timing waves. Diagram B shows what would happen if the same method were used for slowly rising voltage wave forms—there would be discrepancies of Δt_1 and Δt_2 in the time of meeting of the two waves, as the applied surge-voltage values are varied. This kind of discrepancy in testing with slowly rising wave fronts was eliminated by devising a sort of automatically variable resistance $R(e)$ as shown in C. The timing voltage thus jumps to a value at which one of the gaps of $R(e)$ breaks down. This adds a resistor in parallel with the wave impedance of the line and tends to lower the voltage. As the applied voltage continues rising the voltage across $R(e)$ reaches the $R(e)$ gap breakdown value again and another resistance is "switched" in parallel. And so resistances are automatically being switched in through the gaps, tending to maintain the voltage at the breakdown level of the $R(e)$ series of gaps. The first gap breakdown occurs on the steepest wave portion so there is some time lag and the voltage overshoots the general gap breakdown level maintained thereafter, and thus causes the initial overswing that was in question.

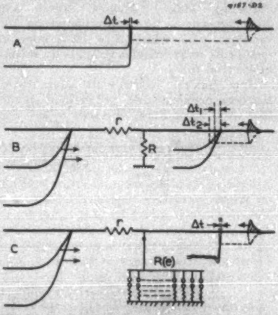

Figure 2. Method of obtaining a suitable timing surge synchronous with the time of initial application of a rising potential to a gap

This last explanation indicates the problem, and its solution, which arose in connection with the measurement of long time lag phenomena. These longer time lag phenomena are within the range of cathode-ray oscillography; still the "dual-wave" method is so much simpler and more direct that it lends itself to rapid quantitative results, and we are using that method over the entire range of time lags both short and long in a general study of gap characteristics. In the latter connection we wish to acknowledge gratefully the co-operation of the Works Progress Administration in assigning us S. H. Teresi who is assisting in making time-lag tests with this apparatus.

Importance of Gas in Electrodes for the Glow-to-Arc Transition

Discussion and authors' closure of paper 39-152 by F. A. Maxfield, H. R. Hegbar, and J. R. Eaton, presented at the AIEE Great Lakes District meeting, Minneapolis, Minn., September 27–29, 1939, and published in AIEE TRANSACTIONS, 1940, pages 816–21.

J. Slepian (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): The phenomenon studied by Doctor Maxfield and his associates is the most important one in the physics of mercury-arc rectifiers and electric gas-discharge tubes. In spite of its great importance, until now, it has not been at all understood, and no theory which I am able to accept has yet been presented. This is true in spite of the fact that the practical design of mercury-arc rectifiers and ignitrons is determined principally by the use of empirically found devices for reducing arcback frequency, and the development of very high-voltage mercury-vapor tubes is still not successful, because of too frequent arcbacks.

As I understand the theory put forth in this paper, the authors postulate (last paragraph in paper) that "in a mercury-vapor tube the electrodes are probably continuously absorbing and re-emitting a certain amount of gas. . . . this gas is not emitted uniformly over the electrode surface but instead is emitted in very small bursts." This statement I presume is to hold for an electrode in complete thermodynamic equilibrium with the surrounding vapor. Otherwise it would be necessary for the theory to explain how applying voltage to an electrode, otherwise in equilibrium, brings about the emission of gas in bursts. The data of figure 4, for example, cover the mere application of voltage to an electrode which has been allowed to rest in contact with vapor overnight, and under conditions where the glow current is far too small to have any disturbing effect.

But the second law of thermodynamics requires that the gas emitted from the electrode shall be in the same state as that absorbed. If the gas is emitted in small bursts, it must also be received and absorbed in exactly similar small bursts. Otherwise, it is easy to devise "perpetuum mobile" machines which will turn out work at the expense of heat at a single temperature.

Now it is well known that the vapor reaching the electrode to be absorbed does not arrive in an absolutely uniform and steady stream, but that in sufficiently small volumes there are fluctuations of considerable magnitude from the average density. To this extent the "gas burst" theory of the authors is justified. However, the mathematical formula is well known for calculating the frequency of occurrence of these fluctuations. When such magnitudes for volume and density, as the authors state are necessary for the occurrence of an arc cathode, are used in this formula, frequencies are obtained which are very, very much smaller than those obtained by the authors.

The discontinuous emission of nitrogen from mercury which the authors describe, is not a case of an electrode in thermodynamic equilibrium with the adjacent gas. The compounds of mercury with nitrogen are unstable and generally denoted as explosive.

Apart from the theory, the data presented by the authors is very valuable. One must be careful, however, in drawing too positive and definite conclusions. The data of figure 4 for example would seem to contradict the conclusion drawn from figure 5, that at low densities of glow current, the arcback frequency diminishes as the vapor pressure is increased. In the experiment of figure 5 the glow current was kept constant probably by varying the exciting arc current at the mercury pool, and this may have had something to do with the shape of the curve obtained.

A number of years ago, one of my assistants, J. E. White, also carried out experiments similar to those of the authors, and concluded that the arcback frequency had a pronounced maximum at a temperature somewhat under 500 degrees centigrade. However, there were such inconsistencies in his results upon repetitions that I doubted whether the effect really existed. One point that seemed to me important in his case was that the surface temperature of the sleeve near the electrode tested was affected by the anode temperature, and thus the vapor density might be altered near the anode, particularly if there were any small drops of mercury on the sleeve.

F. A. Maxfield: Doctor Slepian has raised the question that the theory proposed to explain the results obtained in these experiments is contrary to the second law of thermodynamics. We thought that we had made it quite clear, both in this paper and in the one that preceded it (see reference 1 at end of paper), that the gas is not necessarily held on or in the electrode in a state of thermodynamic equilibrium with the surrounding vapor, since a high degree of degassing is only obtained after prolonged positive-ion bombardment.

Although we did not pretend to say how the gas is actually held on the electrode surface we did propose several explanations, any one of which could explain the results obtained and any one of which was compatible with the gas-burst theory. One of these was that the gas is held on the surface in the form of unstable complex compounds which break down under the action of positive-ion bombardment. Simply as an illustration of the possibility of these complex compounds accounting for the gas bursts, we cited an experiment with a U tube containing two mercury electrodes and a small amount of nitrogen. In this tube the formation of these unstable complex compounds between the nitrogen and the mercury of the electrodes was very evident and a large part of the gas could be made to disappear or appear again at will. As another explanation, we also suggested that the gas is simply held on or within the electrode surface in an uncombined state. Here again thermodynamic equilibrium is not necessary because positive-ion bombardment of the electrode is necessary before any large amount of gas can be released and even then it may be emitted at discrete points rather than uniformly over the electrode surface. As evidence that this process of nonuniform emission is possible, I might cite the work of E. Bruche and H. Mahl[1] or of A. J. Ahearn and J. A. Becker[2] on thoriated filaments. Using an electron microscope these workers showed that thorium does not diffuse uniformly to the surface of the filament. On the contrary it appears in the form of small bursts from discrete points randomly distributed on the filament surface and then spreads out over the filament surface.

Regardless of how the gas is held on or in the electrode it is evident that application of heat alone only removes a small part of the gas. This is very strikingly brought out in figure 1 of this discussion (reproduced from the paper by Maxfield and Fredendall.) This figure shows that the transition probability decreased continually as long as the electrode was bombarded by positive ions. However, when positive-ion bombardment was stopped and the electrode simply heated no change in the transition rate occurred. The figure shows that during the first 120 test intervals while positive-ion bombardment was taking place the transition rate continually decreased. Heat treatment alone apparently had no effect for after 477 intervals of heating, reapplication of high voltage showed approximately the same transition frequency as at the end of the last period of positive-ion bombardment. The transition frequency then continued to decrease and the data when plotted as a continuation of the first test (the dotted portion of the curve) all lay on a smooth curve. It is quite evident from this that positive-ion bombardment is necessary for effective gas removal and that the gas bursts are not occurring under conditions of thermodynamic equilibrium.

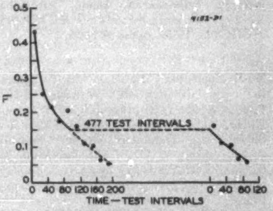

Figure 1. Effect of high-voltage treatment on gas removal from the cathode

Doctor Slepian also mentioned an apparent contradiction between figures 4 and 5 of the paper. It is difficult to compare figures 4 and 5 for the curves of figure 5 were obtained under conditions of constant positive-ion current, while figure 4 refers to a condition when no arcs were present in the tube. It is worth noting again that under this latter condition, tests with a well-treated electrode (curve 2 of figure 4) gave a transition probability of zero at all pressures used.

The effect of electrode temperature on the transition probability was completely reproducible at all times. There was no question of the transition being due to the evaporation of mercury drops from the electrode surface, for the same results were obtained when the temperature was reduced as when the temperature was raised. Although it is possible to explain this effect on the basis of the size and frequency of gas bursts it may simply be due to an exceptionally large gas emission at temperatures near 400 degrees centigrade. As a matter of fact, E. F. Lowry[3] in studying the rate of gas removal from oxide-coated filaments found a variation in emission of just this sort.

Dynamic Characteristics of a Single-Phase Induction Motor

Discussion of paper 39-160 by E. B. Kurtz, presented at the AIEE Great Lakes District meeting, Minneapolis, Minn., September 27–29, 1939, and published in AIEE TRANSACTIONS, 1940, pages 801–06.

W. R. Appleman (Marathon Electric Manufacturing Corporation, Wausau, Wis.): Papers of the type presented by Professor Kurtz, "The Dynamic Characteristics of a Single-Phase Induction Motor", indicate the increasing trend of the university to co-operate with industry by analyzing actual problems and giving the results to industry to use.

A number of the smaller manufacturers are not set up to run all of the tests which Professor Kurtz ran, nor do they feel that they can spend the time in such technical research. The university, therefore, fits very nicely into this scheme by performing this research and publishing its results.

There has been quite a bit of discussion for some years as to what constituted starting current. The motor manufacturers have always desired to measure locked amperes as it is a positive value readily measured by any of the standard types of ammeters. For a time there was quite a bit of discussion about measuring the swing of a well-damped ammeter to indicate the actual starting current of a motor. This, of course, varied very much with the type of ammeter used.

Figure 14 of the paper by Professor Kurtz indicates that the maximum true current drawn by the motor during the starting period occurs under locked condition. This chart shows a steady decrease in current with increase in speed.

If a series of such tests were run on all types of single-phase motors, then it could be shown definitely when the maximum starting current occurs, and whether this is under the locked condition. This would be a point of interest to both the manufacturers of motors and to the power companies. It would at least settle the question of what should be termed the starting current.

Analysis of Factors Which Influence the Application, Operation, and Design of Shunt-Capacitor Equipments Switched in Large Banks

Discussion and author's closure of paper 39-158 by J. W. Butler, presented at the AIEE Great Lakes District meeting, Minneapolis, Minn., September 27–29, 1939, and published in AIEE TRANSACTIONS, 1940, pages 795–800.

J. E. Hobson and W. H. Cuttino (nonmember; both of Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): Mr. Butler's paper is of considerable interest at the present time since there is a definite trend toward the installation of large capacitor banks often arranged for separate switching of sections automatically controlled by voltage, current, or power-factor variations. Although the number of large banks installed with automatic switching equipment within the last ten years has been very small compared to the total installations of capacitors, yet the activity in this field is expected to increase considerably due to the increasing number of capacitors being applied on distribution circuits. As a typical example, quite recently a 1,350-kva bank was installed on a distribution bus, 4 kv, to be automatically switched in and out of the circuit in sections of 450 kva, the switching being initiated by voltage changes on the bus. After a careful study of the switching currents which might be expected in this installation, a small amount of impedance was added to each bank to limit the transient equalizing currents.

The existence of high transient currents between an energized bank and a bank switched in parallel with it was brought to our attention several years ago when, in a particular installation, the circuit breakers were throwing oil and giving other evidence of distress when performing such duty. In this case the difficulty was eliminated by introducing into the circuit between parallel banks the small impedance afforded by a short section of iron pipe. That such transient equalizing currents may reach high magnitude has been demonstrated a number of times by laboratory tests. In one case of two 75-kva banks very closely associated a transient equalizing current of 20,000 amperes, at a frequency of 50,000 cycles per second, was measured. The inclusion of a very small amount of impedance between banks reduced this current materially.

When switching large capacitor banks in parallel, with low circuit impedance between banks, consideration must be given to the selection of suitable switching equipment which can satisfactorily handle the transient currents without excessive maintenance, or the transient currents must be reduced and modified by additional impedances, or a combination of the two methods of approach must be made. Our experience indicates that it is economical in many applications to limit the current by external impedance and use a lower rated switch than would otherwise be satisfactory. It is necessary to have information regarding the characteristics of the device to be used for switching, particularly its behavior when closing high-current, high-frequency circuits. This information can only be obtained from actual test data for the particular device. It is unfortunate that such data are not provided nor discussed in this paper, that actual test data on capacitor transients are not given, and that the conclusions are therefore rather inconclusive.

In connection with the mathematical analysis in sections 2*a* and 2*b* of appendix *A*, we should like to point out that it is very difficult to obtain from the laboratory or by calculation accurate data on the circuit constants, and therefore any calculations which can be made give only very approximate results. Also, in highly oscillatory circuits such as those discussed, the validity of such assumptions as neglecting resistance in the calculations for the effect of added inductance and neglecting inductance in the calculations for the effect of added resistance, is open to question. In comparing the relative results of added inductance and resistance the effects upon the duration of the transient and upon the recovery-voltage conditions in the circuit as well as on the reduction of current magnitude should be recognized and evaluated.

We believe the matter of circuit closing under such conditions is more complicated than has been indicated, and that Mr. Butler's analysis does not recognize all of the phenomena which may be present during the switching of parallel capacitor banks. From experience gained with a number of installations, we agree that circuit breakers applied to satisfy other requirements will usually successfully handle the currents when switching capacitor banks in parallel. There are exceptional cases, however, and the consideration of transient currents cannot be entirely ignored. Attention must be given to automatic equipments in which the impedances between adjacent banks are quite low and the switches are expected to operate frequently.

In addition to the general considerations mentioned in the paper, the phenomena of ferroresonance between shunt capacitor banks and transformers has been encountered in a few rare cases during line switching operations, the ferroresonant condition usually appears in the zero-sequence equivalent network. Very high currents and voltages at the transformer and capacitor banks may result, but the condition may be avoided by changing the sequence of switching, or by the addition of resistance to the circuit. The phenomena of ferroresonance is quite well explained in part 3, chapter 5, of "Les Reseaux de Transmission d'Energie" by Jean Fallou, a book published by Gauthier-Villars, Paris.

C. Concordia (General Electric Company, Schenectady, N. Y.): In the appendices of this paper it will be noted that the operational expressions arising from those circuits having no losses are evaluated at once without the necessity of using the conventional form of the operational expansion theorem. This is not because the intermediate steps have merely been left out of the paper, but because of the application of a modified form of the expansion theorem which makes them unnecessary. This modification or short cut is believed to be of sufficient general interest to warrant presentation in this discussion. In addition, certain general concepts are given which may be helpful in making the application of the expansion theorem a purely mechanical and more or less foolproof process. The discussion to follow has importance only as a labor-saving device for the use of engineers; it has no mathematical significance. Moreover, it does not apply directly when two or more p roots are equal.

1. A Modified Form of the Operational Expansion Theorem

The conventional form of Heaviside's expansion theorem specifies the dependent variable as the sum of a series of exponential functions of the independent variable. In many cases, however, the most convenient and logical expansion is in a series of sine or cosine functions. For example, the motions of a mechanical system without damping and the currents in an electric network without resistance are commonly of the latter, purely oscillatory form. Such cases may be recognized by inspection of the operational solution of the differential equations of motion since if the operational solution is

$$\left.\begin{aligned} y&=\frac{N(p)}{D(p)} \\ p&=\frac{d}{dx} \end{aligned}\right\} \qquad (1)$$

Then $D(p)$ contains only even powers of p and the roots of

$$D(p)=0$$

are pure imaginary in p or real and negative in p^2.

To find y *directly* as a sinusoidal function of x we may use the following expansion formula

$$y=\frac{N(o)}{D(o)}+\sum\left[\frac{N_e(p)\cos p_nx+\dfrac{1}{p_n}[pN_0(p)]\sin p_nx}{p^2\dfrac{d}{d(p^2)}[D(p)]}\right]_{p^2=-p_n^2}$$

$$(\text{or } p=+jp_n) \qquad (2)$$

where p_n are positive real numbers,

$$p^2=-p_n^2,\ p=\pm jp_n \qquad (3)$$

are the roots of $D(p)=0$, the summation is over the roots in p^2 (or over *only* the positive roots in p of $D(p)=0$, and $N_e(p)$ and $N_0(p)$ are respectively the even and odd components of $N(p)$, that is if

$$N(p)=a_0+a_1p+a_2p^2+\ldots \qquad (4)$$

then

$$N_e(p)=a_0+a_2p^2+a_4p^4+\ldots \qquad (5)$$

$$N_0(p)=a_1p+a_3p^3+a_5p^5+\ldots \qquad (6)$$

$$[pN_0(p)]=a_1p^2+a_3p^4+a_5p^6+\ldots \qquad (7)$$

This expansion formula (equation 2) may also be expressed in the form

$$y=\frac{N(o)}{D(o)}+2\sum\left[\frac{N_e(p)\cos p_nx+\dfrac{1}{p_n}[pN_0(p)]\sin p_nx}{p\dfrac{d}{dp}[D(p)]}\right]_{p^2=-p_n^2}$$

$$(\text{or } p=+jp_n) \qquad (8)$$

If the even and odd components of $N(p)$ cannot easily be separated by inspection, the formulas

$$N_e(p)=\frac{1}{2}[N(p)+N(-p)] \qquad (9)$$

$$N_0(p)=\frac{1}{2}[N(p)-N(-p)] \qquad (10)$$

may be used.

Note that in equations 2 and 8 the grouping of terms is such that only real numbers need be used at any stage of the numerical substitution.

Equations 2 and 8 are derived from the exponential form of the expansion theorem simply by noting that the roots of the denominator occur in conjugate imaginary pairs and combining the corresponding pairs of coefficients of e^{pt}. These pairs of coefficients are themselves conjugate complex quantities; the real part arising from the even component of the numerator and forming the cosine terms of (2), and the imaginary part arising from the odd component of the numerator and forming the sine terms of (2).

It may be remarked that it is never necessary to differentiate the denominator D, since it is always required to know its p^2 roots; to know, e.g., that

$$D(p)=A(p^2+p_1^2)(p^2+p_2^2)(\ldots) \qquad (11)$$

whence

$$\left[\frac{d}{d(p^2)}D(p)\right]_{p^2=-p_n^2}=\frac{D(p)}{(p^2+p_n^2)} \qquad (12)$$

This simply means that the factor $(p^2+p_n^2)$ is left out of $D(p)$.

2. "Direct" Evaluation of Operational Expressions

The operational expression (1) can usually be evaluated most directly and simply by noting in it those factors which are evidently exponential or sinusoidal terms. For example, if $D(p)$ is given by (1), y is given by

$$y=\frac{N(o)}{D(o)}+\sum\left\{\left[\frac{N_e(p)/p^2}{D(p)/(p^2+p_n^2)}\right]\cos p_nx+\left[\frac{N_0(p)/(pp_n)}{D(p)/(p^2+p_n^2)}\right]\sin p_nx\right\}_{p^2=-p_n^2} \qquad (13)$$

The cosine terms are thus obtained by factoring out all the quantities which are recognized as cosines

$$\frac{p^2}{p^2+p_1^2},\ \frac{p^2}{p^2+p_2^2},\ \text{etc.}$$

in turn from y, and the sine terms are similarly obtained by factoring out all the quantities

$$\frac{p_1p}{p^2+p_1^2},\ \frac{p_2p}{p^2+p_2^2},\ \text{etc.}$$

in turn.

The concept may of course be applied also to exponential solutions by factoring out in turn the quantities

$$\frac{p}{p+\alpha},\ \frac{p}{p+\beta},\ \text{etc.}$$

to obtain

$$\left[\frac{N(p)/p}{D(p)/(p+\alpha)}\right]_{p=-\alpha}e^{-\alpha t},\ \text{etc.}$$

In general

$$y=\frac{N(o)}{D(o)}+\sum\left[\frac{N(p)/p}{D(p)/(p+\alpha)}\right]_{p=-\alpha}e^{-\alpha t} \qquad (14)$$

J. W. Butler: Messrs. Hobson and Cuttino cite a few cases where transient equalizing currents have required special attention. The case cited of a breaker throwing oil may have been due to the fundamental characteristics of the breaker however, rather than the duty to which it was subjected. At any rate the ease with which it was cured, namely, the introduction of a short section of iron pipe, bears out the authors' contention covering the relative ease with which these conditions can be cured if the phenomenon is recognized and understood. I would, however, contribute the success of the expediency to the reactance rather than the resistance of the iron pipe, since a very little inductance introduces a very large reactance to these high-frequency equalizing currents. For instance, 0.3×10^{-6} henry at 50,000 cycles would limit the current at 2,300 volts to 20,000 amperes. Since a circuit only 12 inches long of 1/0 copper wire with 15-inch equivalent spacing has this much inductance, I doubt the accuracy of the above figures given for a certain installation of two 72-kva banks. It is pleasing and encouraging, however, that Messrs. Hobson and Cuttino "agree that circuit breakers applied to satisfy other requirements will usually successfully handle the current when switching capacitor banks in parallel," which is in substance the authors' number 1 conclusion. It is hoped that the analysis presented will facilitate the application and understanding of the few special cases that may arise.

Mr. Concordia has called attention to a very useful and ingenious labor-saving device for solving operational expressions, defining circuits having no losses. It is felt that engineers in general should become more familiar with the operational calculus since it presents such a powerful and straightforward method of attack in many types of problems.

The Application of Class B Insulation to Auxiliary-Type D-C Motors in Severe Duty Service

Discussion and author's closure of paper 39-169 by F. A. Compton, Jr., presented at the AIEE Middle Eastern District meeting, Scranton, Pa., October 11–13, 1939, and published in AIEE TRANSACTIONS, 1940, pages 828–34.

P. L. Alger (General Electric Company, Schenectady, N. Y.) and **R. E. Hellmund** (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): An important feature of this paper is the information given on the relative values of winding temperature-rise by the resistance and by the thermometer methods. Figure 5 indicates that, due to the time lag of the thermometer temperature, the ratio of the armature rise by thermometer to rise by resistance is only 0.60 for a half-hour test and 0.67 for one hour, as compared with 0.87 under a continuous load. These ratios are for a totally enclosed motor, and even lower ratios apply to open or forced-ventilated d-c machines.

Thus the practice of using a half-hour 75-degree-centigrade rise by thermometer specification to secure a reduced size of machine is only possible because of the great time lag of the thermometer rise, and by the same token the temperature actually obtained is an extremely uncertain quantity that varies widely with the precise location of the thermometer. The authors' suggestion that the resistance method be used instead is logical, but its acceptance requires agreement on very much higher hot-spot temperatures than 75 degrees centigrade for short-time or intermittent rated machines.

Before effecting the proposed change to the resistance method of temperature measurement, it is desirable to determine what the differential between the two methods of measurement is for typical machines of different types. The recent papers by E. R. Summers and C. P. Potter (published in the 1939 AIEE TRANSACTIONS, September section) indicate that in the case of open-type general-purpose induction motors the ratio of rise by thermometer to rise by resistance lies between 0.80 and 1.00 for the great majority of cases, averaging about 0.90. The winding temperature by resistance, however, averages only 0.95 to 1.0 times the maximum lamination temperature by thermometer, reflecting a relatively low copper loss as compared to iron loss on conservatively rated machines.

Comprehensive data on this subject are given in two articles by Jacottet[1] and Jacottet and Hillebrand,[2] who analyzed the temperature-rise values by the two methods on a large number of German machines, both alternating-current and direct-current. For d-c armatures, the average differential was 11 degrees centigrade at full load (roughly, 55-degree-centigrade rise by resistance), giving a ratio of thermometer to resistance temperature values of 0.80. Similarly, the ratio for d-c fields averaged about 0.90; for induction-machine stator windings 0.86; for turbine-generator stators 0.75; and for all machines tested 0.85. In the second article, armature-core temperatures by thermometer are compared with winding temperatures by resistance, the latter being found to be from 2 to 15 degrees centigrade, or an average of 8 degrees centigrade higher. This makes the ratio of winding temperature by resistance to maximum core temperature by thermometer roughly 1.15, as compared with the 0.95 to 1.0 value for the less highly rated American machines cited above.

Other evidence, on large d-c machines especially, indicates that there are many machines now operating which have a temperature rise of the winding of 55 degrees centigrade or more by resistance, even though they meet the normal rule of 40-degree-centigrade rise by thermometer.

From all these data, it appears reasonable that the winding temperature rise by resistance for standardization purposes should be obtained by dividing the present values of rise by thermometer by a factor of about 0.8, giving the following table of equivalent temperatures in degrees centigrade for continuous-rated machines:

40 by thermometer becomes 50 by resistance
50 by thermometer becomes 60 by resistance
65 by thermometer becomes 80 by resistance
75 by thermometer becomes 90 by resistance
80 by thermometer becomes 100 by resistance
100 by thermometer becomes 125 by resistance

These values seem to be suitable for standards applying to various types of machines in general. However, if in the standardization of an individual type of apparatus or winding by some standardizing body a change from the thermometer to the resistance method is decided upon, other values may be selected if a careful study and carefully conducted tests show this to be advisable.

1. Statistischer Vergleich von gemessenen Wicklungs- und Eisenerwärmungen elektrischer Maschinen, Von P. Jacottet. *Elektrotechnische Zeitschrift*, March 24, 1932, number 12.

2. Vergleich der Wicklungserwärmungen elektrischer Maschinen, ermittelt aus Widerstandszunahme und Thermometer Messung, Von P. Jacottet und F. Hildebrand. *Elektrotechnische Zeitschrift*, July 23, 1931, number 30.

F. A. Compton, Jr.: Messrs. Alger and Hellmund have derived from figure 5 ratios of thermometer rise to rise by resistance for armatures of totally enclosed d-c motors.

It should be noted that figure 5 shows results obtained from test on one particular size of motor and is not necessarily representative of the average of all ten sizes of motors tested. The average ratios of the ten frame sizes tested, and the ratios obtained by Messrs. Alger and Hellmund from figure 5 are as follows:

	Ratios of Thermometer Rise to Rise by Resistance on Armature Winding of Totally Enclosed Motors	
Time of Heat Run (Hours)	From Figure 5	Average of Ten Frame Sizes Tested
0.5	0.60	0.70
1	0.67	0.77
8	0.87	0.89

For field coils the average ratio of thermometer rise to resistance rise for eight-hour heat runs of all totally enclosed motors tested was 0.96. In all motors the field-coil temperatures were less than the armature temperatures, hence the greater ratio for field coils as compared to armature coils.

The results given by Messrs. Alger and Hellmund of tests reported by Messrs. Summers, Potter, Jacottet, and Hildebrand on other types of machines will prove helpful in deciding on resistance rises to replace the present thermometer rises for standardization purposes.

From the available data, Messrs. Alger and Hellmund have proposed that the winding temperature rise by resistance of continuous-rated machines for standardization purposes be obtained by dividing the present values of rise by thermometer by a factor of about 0.8. This factor will probably serve the purpose for standardization of various types of machines in general, but each type should be considered separately.

The following factors should be given consideration in arriving at a rise by resistance to replace the present thermometer rise standard for any given type of machine:

1. Class of insulation
2. Winding construction
3. Type of ventilation, if any
4. Application
5. Time rating
6. Ratio of thermometer rise to rise by resistance

Lightning Investigation on a 220-Kv System—III

Discussion and author's closure of paper 39-165 by Edgar Bell, presented at the AIEE Middle Eastern District meeting, Scranton, Pa., October 11–13, 1939, and published in AIEE TRANSACTIONS, 1940, pages 822–8.

C. M. Foust (General Electric Company, Schenectady, N. Y.): Mr. Bell has called attention to the fact that when incoming currents at the tower tip are added, the sum is usually greater than outgoing currents. These incoming currents flow in along the ground wires and up through the tower structure. The outgoing currents under consideration are usually those flowing up through the lightning rod. An explanation which seems reasonable to account for the differences has to do with multiple strokes. Multiple-discharge lightning strokes have been recorded many times by various investigators using both oscillographic and photographic methods and the general understanding now is that about 25 per cent of all cloud-to-ground strokes are of the multiple-discharge nature. While it has not been demonstrated experimentally, still it is reasonable to assume that each discharge of a multiple-discharge stroke is associated with the discharge of a particular cloud area. Particular cloud areas are located in different positions as regards the transmission line and the point of contact of the lightning stroke. Assuming that a first discharge gives overhead ground wire and ground currents flowing into the tip of the lightning rod from one direction, and that another discharge because of the different location of the cloud area participating gives overhead ground wire and ground currents flowing in from the opposite direction, it is obvious that the two in-flowing discharge currents will not be simultaneous. In such a case the magnetic links on the lightning rod will record only the maximum value of current which will not be the sum of the in-flowing currents.

It must also be recognized that a circumstance similar to this might also be present in the case of single-discharge strokes. The currents in the early portion of a discharge, because of different cloud-field positions, may be more associated with incoming currents from one direction than from the other. In fact that circumstance of exactly balanced distribution of induced earth charges around the point of contact of the stroke should be considered a very exceptional one. Maximum current values, therefore, flowing inward from both directions will not be simultaneous and an exact check between incoming and outgoing currents will not be obtained.

Mr. Bell has also called attention to occasional cases where outgoing currents are larger than incoming currents. The best explanation of this seems to be that magnetic link readings on some of the incoming wires have been reduced because of reversed currents. It is entirely reasonable, therefore, that different results will be obtained when comparing incoming and outgoing currents for particular strokes. However, the broad fact is that these differences are not great and that in many cases incoming and outgoing currents do agree well.

A. F. Bang (Pennsylvania Water and Power Company, Baltimore, Md.): Mr. Bell calls attention to the effectiveness of overhead ground wires and efficient tower-footing grounding as a preventive against lightning flashovers. I wish to underscore this statement by giving a few records taken from the transmission system of the Pennsylvania Water and Power Company. In 1911 this company operated about 80 circuit miles of 70-kv circuits; in 1939, 573 circuit miles, of voltages varying from 66 kv to 220 kv. In 1911, the first lightning season in the history of this company, the number of momentary outages due to lightning was 60 per 100 miles; in the past 1939 lightning season, 1.04 per 100 miles. This substantial improvement is essentially due to the installation of counterpoise on all but 3 per cent of the company's transmission circuits, together with heavy insulation and overhead ground wires. Since 1930 all the transmission lines built by this company have been equipped with carefully designed and tested counterpoises when built; during the same period practically all the older circuits have gradually been improved in the same way.

Edgar Bell: I concur with Mr. Bang in endorsing overhead ground wires and low tower-footing resistance for prevention of lightning faults on effectively insulated transmission lines.

Mr. Foust's discussion of some of the apparent inconsistencies in surge-crest-ammeter analysis is logical and may apply in some cases. Other explanations include fundamental accuracy of individual link measurements, accuracy of interpretation of two-link measurements, and the justification for algebraic summations as made.

An encouraging feature of the surge crest ammeter is that in many cases the various associated records hang together surprisingly well, in spite of the adverse factors encountered.

New Developments in Current-Transformer Design

Discussion and author's closure of paper 39-173 by G. Camilli, presented at the AIEE Middle Eastern District meeting, Scranton, Pa., October 11–13, 1939, and published in AIEE TRANSACTIONS, 1940, pages 835–42.

V. M. Montsinger (General Electric Company, Pittsfield, Mass.): Mr. Camilli is to be congratulated on his very important contribution to the art in designing current transformers with the arrangement of the insulation corresponding so nearly to the ideal as utilized in high-voltage cables. Two factors account for the tremendous reduction in size which the author has made in the cable-type design. These factors were not mentioned in the paper, and I believe it is well to point them out in this discussion.

To understand the situation it will be necessary to state the basic laws of the electrical breakdown of insulation, and of the division of voltage stresses when voltage is placed across two different kinds of insulations having different dielectric constants. These may be stated as follows:

1. For nonuniform dielectric fields the required thickness of insulation, including oil, solid, or solid and oil in series, varies approximately as the 1.5 power of the test voltage, whereas in uniform dielectric fields the thickness varies approximately as the first power of the test voltage.

   Stated the other way around, the dielectric strength of insulation varies as the two-thirds and first powers of its thickness, depending on whether the dielectric field is nonuniform or uniform, respectively.

2. The division of the dielectric stress of oil operating in series with solids is inversely proportional to their dielectric constants.

The author, like the cable engineer, has taken advantage of both of these laws in reducing the amount of insulation required in the cable type of design. That is, he has produced practically a uniform dielectric field in the insulation and has eliminated free oil ducts. To do this necessitated the use of an oil-impregnated insulation having a low power factor.

The significance of eliminating free oil ducts in series with solid insulation can be gained from the following assumed example:

If 100 kv is placed across one-half-inch solid and one-half-inch oil, the division of voltage will be 67 kv across the oil and 33 kv across the solid, because the ratio of their dielectric constants is approximately 1:2, that is 1 for oil and 2 for solid.

Since the dielectric strength of oil is somewhat less than that of solid insulation, this means that the oil breaks down long before the solid approaches its breakdown value. This means that part of the space—the solid—cannot be effectively utilized.

As mentioned before, since the author has employed electrodes comprising the smooth metal ring surrounding the high-voltage winding and the outside ground shield, giving approximately uniform dielectric fields, he can use thick tapings without being handicapped due to the fact that the dielectric strength varies approximately as the first power of the thickness of the insulation. A few calculations will show that if it requires the same insulation for uniform and nonuniform fields for 100 kv test, for a test of 650 kv the amount of insulation required, when the thickness of insulation varies as the test kilovolts raised to the 1.5 power, is 2.54 times that required when the insulation thickness varies as the test kilovolts raised to the first power. In other words, by eliminating sharp corners and edges, Mr. Camilli has made it possible to reduce his insulation to approximately 0.4 that required for a nonuniform dielectric field.

With reference to the reduction in size of the cascade design as compared to the old standard—the author mentions the fundamental reason why this is possible, namely, that when the dielectric strength of insulation varies as the thickness raised to some power less than unity, it is possible to reduce the amount of insulation by dividing it into steps.

The author states that for oil strike the thickness of insulation varies as the 1.6 power of the test voltage. The data which I have obtained, and also considerable published data, indicate that the power should be 1.5 instead of 1.6. If we assume that the power is 1.5, a few calculations again will show that even with a nonuniform field, by dividing the unit into six voltage steps it was possible to use approximately 0.4 the amount of insulation required for the same transformer built in only one voltage step. This, of course, is possible only when the winding is shielded to give approximately a uniform impulse-voltage distribution. That is, each unit must not be subjected to more than its share of the voltage.

Someone may ask: if it is possible to make such drastic reductions in the insulation of cable-type current transformers, would it not be possible to do the same thing for other transformers; that is, distribution and power transformers? The principal reason why it is not possible to do so is because other transformers have many times the copper loss to be dissipated from the windings. It is not practical to enclose the windings with thick insulations on account of heating requirements. Provision has to be made for the circulation of oil through the windings. As previously shown the introduction of free oil in series with solid requires for the same test kilovolts from two to three times the spacing required for solid alone.

There are, then, two reasons why it is not possible to design other transformers with insulation so closely approaching the ideal cable design. Up to the present time it has not been practical to make the dielectric field uniform, and to eliminate all free oil spaces between the high-voltage and low-voltage windings. Some day we may be able to do it.

A. Boyajian (General Electric Company, Pittsfield, Mass.): As cables are old, one may wonder why it was that the current transformer with cable-type insulation featured in this paper was not thought of many years ago. One reason may be that Mr. Camilli was not born earlier; a second reason, that the Spirakore construction of the magnetic circuit was not invented until very recently. To explain this: a high-accuracy current transformer requires a magnetic circuit with minimum possible exciting current. Referring to figure 4*a* of the paper, it will be seen that the Spirakore construction of the magnetic circuit is essential for this type of current transformer for the higher voltages. If the core in figure 4*a* were ring punchings, the high-voltage winding shown there could not have been wound around it and insulated as shown. If the high-voltage winding was first wound and completely insulated as shown, and then a core were assembled around it out of straight pieces, joints would be introduced into the magnetic circuit, and the accuracy of the current transformer would be correspondingly impaired. Figure 4*a* attempts to illustrate how a jointless magnetic circuit is placed around the fully insulated winding by the Spirakore principle. A single figure cannot adequately explain this principle: complete details of it will be found in reference 3 listed at the end of the paper.

Strange how each new invention leads to many others, and the art grows at an accelerated rate. What is impractical in one art today may become highly practical later by an invention in another art.

John H. Chiles, Jr. (Westinghouse Electric and Manufacturing Company, Sharon, Pa.): The author has presented a very interesting paper covering a wide variety of current-transformer designs. This paper indicates a rather exhaustive study ranging from the single-stage conventional design of excessive weight through two types of cascade designs and on to a type of single-stage paper-taped transformer. While these designs show a remarkable reduction in weight and oil volume, this reduction is not so striking when compared to other modern current transformers of conventional core-type design. For comparative purposes, the author's table I is reproduced below with the addition of the figures for a 230-kv conventional core-type design with a steel tank and condenser bushing.

	The Author's Designs		Modern Core-Type Design
	1929	1939	
Weight (pounds)	40,000	4,200	5,600
Total height	23 ft	13 ft 8 in.	18 ft
Gallons of oil	3,200	115	294

Comparable metering and overcurrent accuracy.

Figure 1 of this discussion shows the type of design referred to above. Figure 2 shows the core and coil construction of this unit. Figure 3 shows an interesting application of this core and coil design to a 161-kv porcelain-cased current transformer. This particular design shown in figure 1 is for 161 kv and is somewhat higher and heavier than necessary due to the use of a bushing with a long gas space so that it will be interchangeable with the bushings used on a power transformer. This design lends itself very readily to transportation and installation. It would appear that the units described by the author would be difficult to handle due to their small metal case and the high center of gravity above the case. The design described above has the further advantage of having the live parts well above ground, without the necessity of a supporting structure to accomplish this. Unlike the designs described by the author, the core and coils of the 230-kv design are readily adaptable to metering transformers and to double secondary construction. They are also readily changed in ratio by the purchase of new coils only, while in designs, figures 4 to 7, described by the author practically a complete unit is necessary.

The author's revision of the three-stage porcelain-spool cascade design to a two-stage paper-taped design is interesting. "However, in the wound-type current transformers for high-voltage service we have not found a willingness to accept errors of five per cent at 10 to 12 times normal current with a *Z* burden. There are perhaps many applications where such performance is entirely acceptable. However, these can generally be much more economically filled by the use of a ring-type current transformer." In the case of the 287-kv breaker, the question is raised as to whether two current transformers are used in order to make up to some extent for the poor overcurrent performance. If there is justification for two separate secondary circuits it would seem much simpler and more economical to apply a single current transformer with a double secondary. The steel-cased core-type design shown in figure 1 lends itself very readily to the application of a double secondary, that is, two separate secondary cores and windings with a common primary winding. This application is not readily possible in a cascade type of unit.

Cascade current transformers were built in Europe some years ago, but apparently were given up for a design similar to the paper-taped single-stage unit described by the author. Several years ago porcelain-spool cascade current transformers were introduced in this country. Apparently due to their poor overcurrent performance, these did not prove successful. We believe that cascade-current-transformer designs have little merit except for specific applications where poor overcurrent performance can be tolerated.

Apparently, a great deal of work has been applied to the designs described by the author in order to reduce the height and the amount of oil. It is difficult to see that much of this work is justified, for a conventional unit, as shown in figure 1, might be just as readily applied to the breaker. It is apparent from the author's figure 12 that the breaker is mounted well above ground such that a tank of reasonable height could be used in the structure. If the breaker is such that a reasonably small volume of oil constitutes a hazard, a compound-filled condenser bushing would eliminate any hazard from this source. Certainly years of experience have shown that high-voltage current transformers with which we are familiar are most reliable, so that the small volume of oil in the steel case need be of no particular concern. The oil in the steel tank of the unit in figure 1 would not be subject to release by rupture from external forces as might be the case with porcelain-cased designs.

Two interesting points were brought out by the author: the application of the well-known condenser-bushing principle to the lead of the current transformer, and application of the sealed-case construction. Approximately four years ago the company with which I am associated discarded the open-air breather on the high-voltage current, potential, and metering transformers.

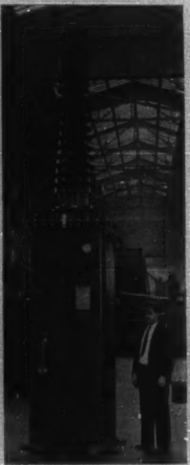

Figure 1(left). 161-kv core-type current transformer

Height $16^1/_2$ feet, weight 5,700 pounds, gallons of oil 370

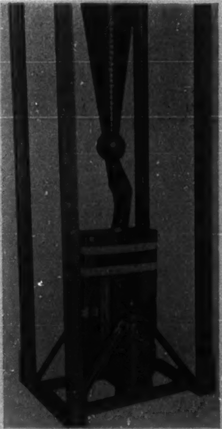

Figure 2. Core and coil construction of the 161-kv current transformer shown in figure 1

The customer was given the alternate of sealed cases, Inertaire equipment, or dehydrating breathers.

The author has stated that his paper-taped designs are worked at somewhat lower gradients than is conventional in cable design. The reason for this is readily apparent since the junction of the lead tube and the primary ring containing the coil makes a difficult taping operation. Apparently, a great deal of this taping is a hand operation requiring the greatest of care and supervision. One difficulty with a heavily taped design is that of dissipating the heat generated in the primary winding. The paper tape is a fairly poor conductor of heat. The heat in the coil leads is rather easily dissipated as its exposed surface is large compared to its watts loss. Doubtless actual coil temperatures have been measured as a resistance measurement would only give the average of the coil and lead temperature. Under short circuit up to the thermal rating of the unit if the winding reaches the usual 240 degrees centigrade temperature gas bubbles will doubtless be generated. In normal designs the clearances are materially greater than those used by the author, and steps are taken to provide cooling ducts so that any gases generated will be readily released and not trapped in the winding.

The application of wound cores to current transformers is not new, as such cores have been in active commercial use for at least eight to nine years. Likewise, the method of compensation described by the author was proposed by an associate of the writer about nine years ago and was placed into commercial use on wound-type cores at that time. This method has been found particularly useful in current transformers with a small number of ampere turns.

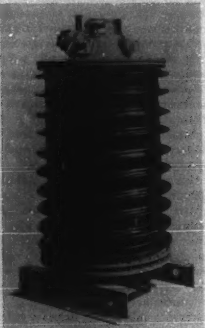

Figure 3. Porcelain-cased 161-kv current transformer applying the core and coil shown in figure 2

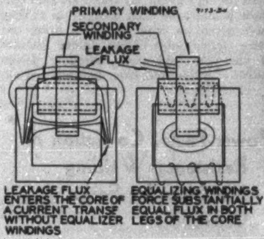
Height 6 feet 6 inches, weight 2,500 pounds, gallons of oil 90

Another method of compensation that has been found more effective for transformers with many ampere turns is the method which uses an equalizer winding on the core to prevent leakage flux from entering the core. Such a scheme is shown in figure 4 of this discussion. This scheme is readily adaptable to either a rectangular or ring type of core.[2] The effect of this scheme is somewhat different than that shown in the author's figure 22. This scheme not only compensates the ratio over the range of 5 per cent to 100 per cent current, but, because the leakage flux is excluded from the core, the overcurrent performance will be better than for the same transformer without any compensation.

It is difficult to see the economy of a wound core with a secondary coil wound by hand through the very restricted space between the core and the primary insulation. The problem can be solved easily with form-wound coils and a cruciform core of I-plate construction. The elimination of the leakage flux by equalizer windings more than makes up for the hypothetical value of a wound core without gaps.



PRIMARY WINDING

D. C. Prince (General Electric Company, Schenectady, N. Y.): The size and cost of a tank-type high-voltage circuit breaker are determined to a considerable extent by the need of bushings. If advantage were to be taken of low oil content or air types of circuit-breaker design, which have no bushings, an acceptable substitute for the bushing current transformer had to be found. On the basis of the larger transformer of figure 1 the Boulder Dam circuit breakers are impossible. On the basis of figure 12, they are still pretty expensive.

The new design of figure 14, is a valuable step in the right direction, while the success of such designs as figures 6 and 7*a* may, when sufficient experience has been obtained with them, bring about a final abandonment of tank-type designs in high-voltage circuit breakers.

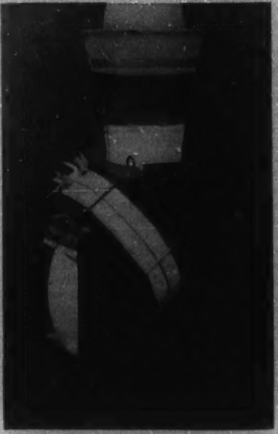

Figure 5. Internal view of the current transformer shown in figure 4b of the paper, showing two independent secondaries

G. Camilli: Mr. Chiles has drawn up a comparison between the latest conventional core-type design made by his company and the cable-type spiral-core design described in the author's paper. I hesitate to say much regarding this comparison in view of the fact that there seems to be some doubt about the correctness of Mr. Chiles' data in that the weight and amount of oil are greater for his 161-kv transformers than for the 230-kv transformers. However, a few comments will be offered assuming that the data are at least approximately correct.

While Mr. Chiles' data show that his present transformer marks a vast improvement over what was available in 1929, they also show that it is still 33 per cent heavier, 32 per cent higher, and requires 156 per cent more oil than the Spirakore design. Incidentally in the latter design we secured the advantages of a ring core with its low secondary impedance and the safety of a grounded shield between the high-voltage and low-voltage windings.

Although the Spirakore transformer is shorter than the conventional transformer if additional clearance to the live high-voltage terminals is required, it can be obtained at low cost by using a concrete pad or steel frame.

As a matter of fact, the compactness of the Spirakore design often permits mounting in the bus structure rather than on the ground and hence out of reach. Undoubtedly the transformer shown in Mr. Chiles' figure 3 would be similarly mounted.

Since these units have the highest standard accuracy classification of $^1/_4X$, $^1/_4Y$, and $^1/_4Z$ they are adequate for any metering purpose. The maximum voltage rating for which it is practicable to build combined metering equipments depends upon the size of the elements. Therefore, since the Spirakore transformer is smaller than the conventional design, the use of it in metering equipments will tend to raise this voltage rating limit.

Mr. Chiles claims that the type of design described in the paper is not adaptable to double-secondary construction. As a matter of fact, the cable-type Spirakore design is adaptable to any number of secondaries and the 230-kv unit described actually had two secondaries. This is shown in figure 5 of this discussion, which was omitted from the original paper for the sake of brevity.

The transformer of figure 4*b* indicates how easily the ratio of the Spirakore design may be changed. The top structure contains a number of external terminals by which six combinations of primary turns are readily secured. This construction obviates the necessity for changing primary coils.

It will be noted that a 5 per cent error at 10 to 12 times normal applies to cascade designs which were built for 287 kv only and that the 230-kv transformers are good up to 30 times normal. The usual ratio of the 287-kv current transformers is 600/5 and therefore 10 times normal is 6,000 amperes or about 3,000,000 kva. It is believed that interest in errors above this current is rather slight since the accuracy in the expected short-circuit current region is adequate for relaying.

The height of the insulating columns of the oil circuit breaker of figure 12 was dictated by the impulse strength requirements. Since it was possible to insert the entire current transformer within a column it seemed unnecessary to add a steel tank below. It also seemed unnecessary to develop bushings for current transformers capable of supporting the weight of a circuit breaker. It may be of interest to know that the porcelain is merely a weather shield and its rupture would not release the current-transformer oil.

Another point raised by Mr. Chiles is with reference to the heating of these transformers. By actual measurements using thermocouples, the temperature rise of the windings of these transformers is well below the AIEE limits.

As to the generation of gas bubbles, there is practically no possibility of this in the Spirakore design. The reason for this is very interesting. The high-voltage winding is enclosed in a metal shell connected to the winding. The coil is cooled by oil circulating within this shell. There is not voltage stress in this oil and, therefore, even if any bubbles were generated in it under short-circuit conditions, no harm would result. The cable-type paper wrapping which insulates the high-voltage form does not transmit any heat and therefore cannot be subjected to any bubble generation under any conceivable condition. It has been our experience that it is rather in the conventional type of design that bubble generation is a problem to the engineer, because in this design the same oil acts both as major insulation and as the heat carrier.

The use of two current transformers, one on each side of the circuit breakers, in the Boulder Dam installation was necessitated by the scheme of relaying and had nothing to do with their overcurrent accuracy which was entirely adequate for the purpose as is indicated by the fact that additional units have since been purchased. The scheme of relaying was described by D. C. Prince in his paper, "Circuit Breakers for the Boulder Dam Line," ELECTRICAL ENGINEERING (AIEE TRANSACTIONS), 1935.

Mr. Chiles mentions the fact that wound cores have been used in current transformers for eight or nine years. The reasons for changing to this construction were so obvious that we had no intention of taking any credit for introducing this feature. However we feel now that we must do this since Mr. Chiles infers that someone else was responsible for it. Furthermore, it was not until the advent of the Spirakore principle that wound cores could be used in anything but bushing-type current transformers. They cannot be applied to the transformers shown in figure 2 of my paper and figures 1 and 2 shown by Mr. Chiles.

It might be inferred from Mr. Chiles' comments that the Spirakore transformer could be improved by the use of equalizing windings. This, however, is not the case as the Spirakore construction is inherently free from the difficulties which necessitate such compensation and which are present in the conventional core-type transformer.

In closing I might say that I am glad that these points have been brought up as they have given an opportunity to bring out more clearly some of the unique features of the new cable-type Spirakore design which were omitted from the paper itself.

Power-Factor Correction of Resistance-Welding Machines by Series Capacitors

Discussion and author's closure of paper 40-11 by L. G. Levoy, Jr., presented at the AIEE winter convention, New York, N. Y., and published in AIEE TRANSACTIONS, 1940, pages 1002–09.

J. W. Butler (General Electric Company, Schenectady, N. Y.): The use of capacitors connected in series with the load, as well as in shunt with the load, is increasing in popularity at a notable rate. This is due in part to both the price reductions effected during the last few years through improved design and production methods, and an increased knowledge of the art of application. At first, shunt capacitors were generally used to improve power factor and series capacitors were used to improve voltage regulation. At present, it is not uncommon to see shunt capacitors switched for voltage regulating purposes; and now Mr. Levoy describes a fundamentally sound method of improving power factor with series capacitors. It is believed that the area between these two uses of the series and shunt capacitor represents a large potential field of application for the capacitor.

Fundamentally, a capacitor at rated load represents leading kilovolt-amperes on the system. Therefore, if it is desired to improve a certain lagging-power-factor load, leading kilovolt-amperes can be added to the circuit by capacitors connected either in series or in shunt. At rated load, a given amount of capacitor kilovolt-amperes will give the same power-factor improvement whether in series or in shunt. Practically, however, for a given load characteristic and voltage source, either method cannot be chosen at will because the effect on the load voltage is widely different for the two types of application. If one were to start from scratch and design a complete circuit from the voltage source to, and including, the load, we could often use either capacitor connection to accomplish a certain objective. Of course, a decision in the matter would be largely based on the economics of the situation being considered.

The design of a circuit and load to include capacitors is illustrated by a recent installation of a series capacitor rated approximately 2,000 kva for power-factor improvement of a graphitizing furnace. This type of furnace load has a negative-resistance characteristic and as the resistance decreases the power factor goes down to approximately 30 per cent or 40 per cent. This condition, of course, throws a very heavy reactive load on the supply source with resultant well-known ill effects. The furnace charge is resistive; the low power factor is a result of the reactive kilovolt-amperes required by the bus and furnace reactance. This reactive requirement, as previously mentioned, could have been supplied by either shunt or series capacitors. The use of the series capacitor proved a "natural" because it supplied reactive automatically with the changing requirements; its ohmic value was made equal to the ohmic value of the bus and furnace reactance. With the series capacitor the current drawn from the supply is substantially unity power factor over the entire range of the furnace loading. Fundamentally, of course, it is recognized that this application parallels that described by Mr. Levoy for welders, in which the supply-transformer voltage, welder voltage, and series-capacitor rating are all co-ordinated to make a workable unit.

One may conclude that this principle could not be applied to distribution circuits. True enough, the compensation cannot go as far but the only difference is in the degree of compensation. In general, series capacitors are not applied in voltage ratings in excess of 15 per cent of the circuit voltage. The application of a 15 per cent series capacitor to a circuit delivering a 70 per cent power-factor load would improve the power factor to 78 per cent on the source side of the capacitor. It is believed that such incremental improvements in power factor obtained with series capacitors should be credited to their installation and thus help justify their purchase. It is believed that with a given amount of money available for improving or increasing the rating of a given distribution area, a portion of it could be well spent for series capacitors when it is remembered that they give automatic instantaneous voltage regulation as well as that they supply reactive kilovolt-amperes equal to their rating, at full load, at which time it is most needed.

Another possible use of series capacitors is for obtaining the required load division between parallel circuits, such as a cable and an overhead line. This application is not new, but it should be noted that series capacitors can be installed in each line to give the required load division and at the same time provide both automatic voltage regulation for flicker or steady loads and power-factor improvement.

As the possibilities of the series capacitor become more generally recognized, it is believed that the application of series-capacitor equipments will show a marked increase over the notable record of recent years, both in number and type of use.

E. F. Dissmeyer (Commonwealth and Southern Corporation, Jackson, Mich.):

Engineers are encountering an increasing number of cases where it is necessary to shield power-supply systems from the voltage fluctuations caused by single-phase resistance-type welders. In many cases it has been necessary to provide special supply circuits or other methods of isolation for such loads. In general, these remedial measures have been expensive, and their cost cannot be justified by the power-supply companies due to the fact that resistance-type welders consume a comparatively small amount of energy. Occasionally it has been necessary for customers to install special motor generator sets to supply their welder loads.

It is, of course, recognized that a series capacitor installation, equipped with the electronic-type control described by Mr. Levoy, may not provide a solution for all welder supply problems, especially in those cases where a large number of small welders are used in a customer's plant. It appears, however, that the equipment described can be satisfactorily used on certain large welders.

There is no doubt that the proper application of series capacitors will provide an economical and satisfactory solution for many resistance-welding power-supply problems.

J. D. Stacy (General Electric Company, Pittsfield, Mass.): Mr. Levoy's worthy paper on the application of series capacitors to the resistance-welding-machine load problem emphasizes the necessity of frequent review of utilization problems from both technical and economical viewpoints. Although this problem might have been solved technically by such an application of capacitors several years ago, it has been the rapid development in capacitor design with attendant increase in reliability and lower costs that now makes this solution of the problem economically sound in many cases.

To apply this system successfully requires co-ordination of the supply voltage, the capacitor kilovolt-amperes, and voltage rating and the welder power factor, kilovolt-amperes, and voltage rating. In order to give a clearer conception of this statement a tabulation has been prepared in reference to several assumed welder conditions (see figure 1 and table I of this discussion).

Control devices using ignitron-type tubes are usually not supplied for voltages under 230 volts because of the starting characteristics of these tubes. In cases where the new supply must be below 230 volts, an intermediate transformer may be used at *B-B* having a kilovolt-ampere capacity equal to that of the welder. It is also shown that higher-voltage welder transformers require higher-voltage ratings of capacitors and since capacitor costs per kilovolt-ampere are lower at these higher voltages, a considerable gain can be obtained by using higher-voltage welder transformers which will permit the voltage transformation from the power lines to be located at *A-A* where the kilovolt-ampere capacity may be based on the lower, corrected power factor load. In many cases the welder transformer and capacitor voltage can be selected such that no transformation is needed, avoiding the necessity of providing an additional transformer.

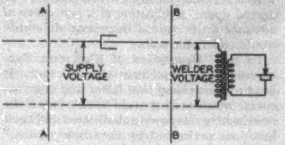

Figure 1

Table I. Capacitor Kilovolt-Amperes and Voltage and Supply Voltage Required to Correct a 100-Kva (Maximum) Welder to Unity Power Factor

Welder Voltage	Welder Power Factor	Capacitor Kva	Capacitor Voltage	Supply Voltage	Kva Demand
230	0.20	97.9	225	46*	20
230	0.40	91.6	210	92*	40
230	0.60	80.0	184	138*	60
460	0.20	97.9	450	92*	20
460	0.40	91.6	420	184*	40
460	0.60	80.0	368	276	60
575	0.20	97.9	563	115*	20
575	0.40	91.6	527	230	40
575	0.60	80.0	460	345	60
920	0.20	97.9	900	184*	20
920	0.40	91.6	840	368	40
920	0.60	80.0	736	552	60
1,150	0.20	97.9	1,126	230	20
1,150	0.40	91.6	1,054	460	40
1,150	0.60	80.0	920	690	60

* Indicates where synchronous control and ignitron contactors must be used with a transformation at *B-B* in order to secure proper operating voltage for these devices.

H. C. Louis (Consolidated Gas Electric Light and Power Company of Baltimore, Md.): Laboratory tests in Baltimore on series capacitors showed transient oscillations similar to those described in the paper by Mr. Levoy. These were especially serious in the case of transformer-coupled capacitors. A question of practical interest is whether the special method described for eliminating this transient can be applied to a transformer-coupled capacitor.

L. G. Levoy, Jr.: Mr. Butler's remarks are of interest in showing that the series capacitor is finding widespread use on distribution circuits. The application of series capacitors for power-factor correction of resistance-welding machines differs from the usual distribution-circuit application in two important respects; namely (1) resistance-welding-machine power-factor correction is usually calculated on the basis of bringing the load to unity power factor; (2) where the proper type of synchronous control is used, precharge is established on the capacitor to permit uniform transient-free operation, which is most important where precise welding conditions are required.

During the oral discussion following presentation of the paper, it appeared that some power companies were more concerned with small welding machines, since they made special provision for the large ones. Other companies were troubled only with large installations. The system of power factor correction described in this paper is applicable to all sizes of machines, and it is primarily a question of economics whether power-factor correction should be applied, or the system reinforced to serve the uncorrected load. The most economical solution for a given size machine will differ on different systems and also at different locations on the same system, consequently each case must be considered on its own merits.

It should be remembered when considering power-factor correction of small machines, that the cost of the corrective capacitor required diminishes almost in direct proportion to the kilovolt-ampere demand, and consequently such correction may be economically sound on relatively small welders in some cases. In the case of a large number of small resistance-welding machines in a single plant, as mentioned by Mr. Dissmeyer, the total capacitor kilovolt-amperes required to correct each machine individually would total the same as that required to correct one large machine having a demand equal to the combined demands of the small machines. For this reason the feasibility of power-factor correction should not be discarded just because a large number of small machines are involved. The cost of converting the controls when necessary, and co-ordinating the feeder and welding transformer voltages must be considered in the case of existing equipment, although this factor does not enter when laying out the design for new equipment.

Referring to Mr. Louis' question regarding the elimination of transients on a transformer-coupled capacitor, this can be accomplished with synchronous control, by establishing a precharge on the capacitor equal to the voltage which it would have in steady-state operation at the phase angle of closure of the switch. In order to establish such a precharge, it is necessary to disconnect the capacitor from the transformer to permit the establishment of this precharge. In the case of the resistance-welding machine with series capacitors, the synchronously controlled power tubes serve the function of controlling the flow of current as required, and also serve to disconnect the capacitor during the "off" interval so that the proper precharge voltage can be established or maintained.

The tabulation presented by Mr. Stacy is of interest in showing the kilovolt-ampere and voltage relations under a variety of assumed conditions. In interpreting this table it should be remembered that the power factor of a resistance-welding machine varies over a wide range from short circuit of the electrodes to higher values on various kinds of work. The "working" power factor is, of course, the one which is important in determining conditions during welding. The short-circuit values are used for design criteria only. The "kilovolt-ampere" is demand kilovolt-amperes under working conditions and not the welding machine name-plate value. Where electronic-type controls are used, suitable allowance must be made for tube arc drop. This factor will change both the supply voltage and kilovolt-ampere demand values given in the table, and must be considered where electronic controls are used. Present-day mercury-vapor tubes which are commonly used have an arc drop of approximately 15 volts. This arc drop is essentially independent of current in the operating range.

The requirement of voltages of 220 or more does not apply to magnetic-contactor controls, nor is it peculiar to synchronous controls, except in so far as these controls may use some types of electronic tubes which do not function well at extremely low values of voltage.

The many odd values of supply voltage listed suggest the use of the autotransformer circuit shown in the paper as figure 4. Ordinarily, however, the supply voltage is taken at some standard value and the welding transformer and capacitor operate at the odd values. A similar table can readily be made up on this basis.

Synchronizing Transients and Synchronizers for Large Machines

Discussion and authors' closure of paper 40-26 by R. D. Evans, F. H. Gulliksen, and C. B. Myhre, presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940, and published in AIEE TRANSACTIONS, 1940, pages 965–73.

H. T. Seeley (General Electric Company, Philadelphia, Pa.): The authors are to be complimented on their thorough analysis of the dependence of transient current magnitudes upon the differences in voltage magnitude, phase, and frequency, during synchronizing onto the sending bus of a transmission system, but the calculations and the design seem to be based on a maximum voltage difference of 8 per cent between machine and bus. This will almost certainly be exceeded during system emergency conditions, especially in the case of the first machine to be connected to the bus, and it is under just such conditions that prompt synchronizing is most needed. Allowance for operation at system voltages down to 80 per cent of normal has long been considered standard for control equipment in unattended installations; the synchronizer described by the writer in 1934 (see reference 4 of the paper) was designed to operate under such conditions, and will operate with voltage differences exceeding 30 per cent of rated voltage.

Referring again to this same synchronizer (reference 4), the test limit we have always used in regular production happens to be identical with the five-degree limit of error mentioned by the authors under "Requirements for Good Synchronizing," and this limit has been applied out to 45 degrees desired advance angle for breakers having closing times down to 0.375 second and out to a frequency difference of one-third cycle per second for faster breakers. Each relay is tested with a phase shifter driven by an adjustable-speed motor, the advance angle is determined for various frequency differences within the operating range, and adjusted so as not to exceed the plus or minus five-degree limit of error, and marked at the proper setting of the advance adjusting resistor. In the case of the relay described in the present paper, it would be desirable to know what limits of frequency difference must be accepted in order to maintain the error within this angular limit which seems to be agreed upon; publication of a test curve of advance angle versus frequency difference would cover this point.

In the "Description of Electronic Synchronizer" the statement is made that "It has become evident that faster and more accurate synchronizing could be obtained if the interlocking relays were eliminated and their functions performed by electronic means." This statement is not evident to the writer, because in the interlocking-relay type, the interlocking functions need affect only the accuracy of cutoff, which is relatively unimportant; and the total time of the internal relays involved in giving the closing indication is likely to be only about 0.1 second, which is automatically compensated for in the adjustment of the advance angle. It appears significant that the elimination of interlocking relays was simultaneous with the addition of two features that have been available in the market since 1934, namely, the compensation for voltage difference magnitude and the avoidance of errors due to variations in d-c control voltage; and it seems likely that the improved performance reported was obtained by the addition of these two features which experience has shown to be desirable, and not by the elimination of the interlocking relays.

The use of thyratrons and of smaller components in general has permitted a commendable reduction in size, but users will need to know what limits of ambient temperature are imposed by the thyratrons. They will also be interested in the volt-ampere burden, and in the possibility of applying this relay to line synchronizing where voltage differences in excess of five per cent are common and where the limitations of the thyratron filaments may determine the minimum percentage of rated voltage at which safe operation may be obtained.

E. E. George (Ebasco Services, Inc., New York, N. Y.): The authors have used a very effective method of determining synchronizing requirements and, having established these, have carried out a rather clean-cut electronic design job. The a-c calculating board is a very effective tool for such analyses. The electronic equipment described is unusually simple and should perform satisfactorily provided the thyratron tubes have reasonably permanent characteristics. In the past, thyratron devices have given considerable trouble due to the use of the ordinary types of thyratrons which have extremely variable characteristics with ambient temperature. Most of the types also require preheating of the filament circuit, and are inoperative for several seconds after power failure. The authors might reassure us on these two points; as to what has been done, or can be done to provide better operation under such conditions.

The conclusions of the authors to the effect that phase difference is more important than frequency difference applies particularly to generator synchronizing and not to the synchronizing of large interconnected systems. Perhaps this conclusion should be so limited. The *rate of change of frequency* is the important variable to be measured in paralleling large systems.

The authors' general approach to the problem of designing the best possible synchronizer is apparently that of providing a device which will synchronize with the least possible disturbance to the machine. This viewpoint is somewhat like that of the new operator who is proud of his skill in paralleling without any disturbance. Nevertheless, the operator who gets on the honor roll in the dispatching office is the operator who can get a machine on the line in the minimum time, with the frequency perhaps several cycles below normal and varying widely, while other plants or companies are also paralleling, and perhaps other system disturbances are occurring. In such emergencies, the shock to the machines or the system is seldom considered, as long as none of the windings come out and no other switches open from the synchronizing surge.

It would be a real contribution to the operation of large interconnected systems if such a synchronizing device as the authors have described were provided with two controls. One would be for normal operation in bringing machines or tie lines in service (as described by the authors), and would perform the operation as fast as consistent with minimum disturbance (perhaps less than full load current). The other control to be used in emergency would *parallel in the shortest possible time*, independent of the resulting disturbance so long as the equipment and systems would stay together after being paralleled. The inrush current might be more nearly comparable to full-voltage short circuit, rather than to normal load, but the permissible emergency limits for any particular machine or interconnection could likely be determined at the time of installation, and the equipment adjusted accordingly.

L. N. McClellan (Bureau of Reclamation, Denver, Colo.): The field acceptance tests which were made at Boulder power plant on the electronically-interlocked synchronizer described in the paper by Messrs. Evans, Gulliksen, and Myhre, have demonstrated that this equipment is reliable and quite accurate for synchronizing the large generators with circuit breaker closing speeds of approximately five-tenths second. This confirms the conclusion of the authors that the electronic synchronizer is superior to the interlocked-relay type of synchronizer, which was initially used at the Boulder power plant. The original interlocked-relay type synchronizer did not prove satisfactory in use on the 82,500-kva generators because of the extreme accuracy required and the need for greater speed in completing the synchronizing operations. With this type of synchronizer the voltage vector must make at least one full revolution before synchronizing can take place.

As pointed out in the paper, the 82,500-kva generators have low reactance and extremely large flywheel effect to afford stability for the Boulder Dam-Los Angeles transmission lines. These characteristics of the generators increase the importance of minimum phase and frequency differences when synchronizing. To minimize the shock of synchronizing, the phase angle must be kept as close to zero as possible and should not exceed three degrees. Frequency differences between the incoming and running machines are not permitted to exceed the figure of 40 seconds per revolution of the synchroscope given in the paper.

The typical system used by the authors in their calculations compares with the Boulder generator connections and transmission system, and although the authors' conclusions indicate that a frequency difference at the moment of synchronizing may cause less system disturbance than a phase angle difference, the large flywheel effect of the Boulder generators has resulted in a very exacting requirement in this respect. In this connection it might be well to mention that satisfactory full automatic synchronizing depends to a large extent on the ability of the speed matcher and governor to control the frequency of the incoming machine. Excellent results have been obtained at the Boulder power plant with a speed matcher consisting of two synchronous motors differentially geared to the speed-adjusting mechanism of the governor on a 40,000-kva generating unit. It should also be pointed out that the electronically-interlocked type of synchronizer at the Boulder power plant is used in connection with two recently installed 82,500-kva generating units, each of which is connected directly to an individual bank of transformers, and all synchronizing is accomplished with the 230-kv high-voltage circuit breakers. Extensive field tests were made with the synchronizer before actual synchronizing was attempted, the results of which were very satisfactory. The angle of advance adjustment was such that the phase angle at which the main breaker contacts actually closed was as near zero as could be determined with a breaker closing time of approximately five-tenths second.

The authors have mentioned the occurrence of torques due to synchronizing out of phase, but they have not discussed the possible severity of such torques. At the Boulder power plant the maximum possible torque due to synchronizing out of phase was computed to be 15 times normal, whereas the maximum possible torque due to a line-to-line short circuit at the terminals of a generator was computed to be 11 times normal. It appears that little information has been published about the method of computing torques due to synchronizing out of phase, and it is suggested that a paper on the subject of torques due to synchronizing out of phase would be timely.

S. B. Crary (General Electric Company, Schenectady, N. Y.): The authors have presented an interesting analysis of the effect of differences in speed, voltage, and phase angle on the synchronizing transients. From the results presented for the synchronizing range studied, it would appear that calculations could have been made on the usual two-machine basis rather than on a three-machine swing curve basis. That is, it would have been only necessary to have calculated the incoming machine against the system as one equivalent machine. This would greatly simplify the calculations and would yield results which are as accurate as those presented for a general discussion of this problem, particularly when it is considered that the load characteristics were only approximately represented. The conclusion that phase angle is the important quantity to keep to a minimum to avoid shock to a machine and in order to minimize the system disturbance when synchronizing is undoubtedly correct for the range of voltage, speed, and phase-angle differences investigated.

R. D. Evans and **C. B. Myhre:** With reference to Mr. Seeley's discussion, we wish to emphasize that the electronically interlocked synchronizer described in this paper was developed primarily for synchronizing large generators with extreme accuracy under conditions which are obtained in large base-load generating plants. Extreme accuracy in synchronizing was the criterion for this design and every effort was made to obtain that end. The elimination of moving parts, such as interlocking relays, naturally contributed to faster, more accurate and consistent performance under all conditions.

Mr. George and Mr. McClellan have pointed out that the rate of change in frequency difference, when synchronizing, is an important variable. For best performance, fast-closing breakers should be used and determination to close the breaker should be made as close to the synchronism point as possible. Direct electronic interlocking, without relays, permits this "determination" to take place much closer to the synchronism point than would be possible when the operating time of interlocking relays had to be compensated for. Furthermore, when the "determination" to close the breaker is made very close to the synchronism point, there will be very little chance for the frequency difference to deviate while the breaker is closing.

Line synchronizing, where voltage control is not available, does not ordinarily require the high order of accuracy that is desirable for heavy generator practice, because of the cushioning reactance that exists between the machines to be synchronized.

An automatic synchronizer is used only a few minutes every day. For this reason the tubes should have a very long life since the normal continuous life of a thyratron is in excess of 2,000 hours. The filaments are kept continuously energized at a reduced voltage in order to permit synchronizing without a long time delay for bringing the filaments up to temperature. This preheating does not appreciably reduce the tube life because the plate circuits are not energized except when the synchronizing operations take place.

Preheating of filaments keeps the tube temperatures within such limits that an ambient temperature range from freezing to 150 degrees Fahrenheit will not change the accuracy of performance. Safe operation, with a liberal margin of safety, is obtained over the entire AIEE standard operating voltage range.

The burden of the synchronizer is five volt-amperes on the bus, and eight volt-amperes on the machine potential devices. The circuits are so arranged that the breaker will not close in the event of tube failure when synchronizing. The synchronizer is adjustable for frequency differences from 0 to 0.2 cycle per second, and breaker speeds ranging from 0.3 to 0.8 second, and is compensated to operate accurately for all values of voltage differences that are permissible to the incoming generator when synchronized against other generators in the power house. The voltage difference limitations referred to in the paper are determined by the requirements for "quiet" synchronizing of large generators and not by the limitations of the synchronizer.

Mr. Crary has suggested that the two-machine solution is suitable for the study of synchronizing transients. Such a method gives fair results but requires the assumption that the sending-end and receiving-end machines maintain a fixed angular relationship. Actually these machines will oscillate with respect to each other as shown in figure 5 or 6. For this reason it seemed preferable to use the three-machine basis for preparation of the principal curves of the paper. Incidentally, the two-machine basis was used for the "approximate method" in connection with curve *D* of figure 7. Furthermore, certain synchronizing phenomena, as discussed in the paper, require curves such as shown in figures 5 and 6 for their proper interpretation.

Generalized Bridge Network for Dielectric Measurements

Discussion and authors' closure of paper 40-21 by J. C. Balsbaugh, A. H. Howell, and J. V. Dotson, presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940, and published in AIEE TRANSACTIONS, 1940, pages 950–6.

W. J. Seeley (Duke University, Durham, N. C.): There is available at the present time a mass of excellent literature dealing with bridge networks, the bulk of which, for the most part, being concerned with some particular network or application. It is a rather herculean task, however, to attempt to go through this literature for the purpose of arriving at a general over-all picture of what might be called a parent network, that is, a network of such generality that any particular bridge network might be derived from it as a particular case. A number of papers are available which tend toward such generality. These papers, in general, follow one of two lines of approach, namely, either by means of a generalized network, or else by reducing all possible networks to a classification. Examples of the first method are papers by Kouwenhoven and coauthors and Balsbaugh and coauthors, and of the second method those of Ferguson and Seletzky. What is needed now is a merging of these two methods, together with the one mentioned in the next paragraph, so as to make available a single parent network from which all possible networks may be derived. The development of the present paper falls in the first of the two categories mentioned above and is a distinct forward step toward the derivation of an ideal all-inclusive bridge network. Furthermore, it considerably clarifies the tie-up between network algebra and the required operating technique; that is, it shows distinctly the necessary manipulative procedure required to verify the various balance relations resulting from theoretical deductions, and it is simply done.

There seem to be two schools of thought influencing the design and construction of high-precision bridges. The one school, which is well represented by the present paper, relies upon numerous balancings of shield impedances and coupling impedances before the actual bridge balance may be obtained. It is a method requiring a skilled manipulation and complicated switching: the bridge must be calibrated, so to speak, each time a measurement is made. The other school relies upon complicated shielding structures, often in connection with a Wagner ground, to take care of the stray coupling unbalances, thus leaving a simple manipulation to the operator for obtaining the final balance. In this case the bridge is more or less precalibrated during the process of construction and requires less skill in use.

I should like to ask the authors if they had considered more complicated shielding and less manipulation, as manufacturers of bridges so strongly seem to advocate, before finally settling upon the structure described. In other words, what were the determining factors in the selection of this particular bridge structure rather than one containing more elaborate shielding?

Eric A. Walker (Tufts College, Medford, Mass.): There are two questions I would like to ask Professor Balsbaugh regarding his equations for the five-terminal bridge network.

First, I am interested to know what effect the capacitance of the generator to ground has on his calculations, and where this is taken into account. Is this capacitance fixed, or does it change in magnitude when the generator is shifted from the connections of figure 1*a* to figure 1*e*?

The other question involves the distributed capacitance to its surrounding shield along any balancing impedance which has physical length. This distributed capacitance has impressed upon it different voltages per unit length, depending on the total voltage on the impedance, and depending also on the position of the tap or slide connection. Undoubtedly this stray distributed capacitance can be represented by a fixed shunting capacitance, even though such a fixed capacitance is fictitious. Moreover, the actual value is of no consequence, because the object of the test is not to determine the stray shunt capacitance, but because there are distributed charging currents to the shield, the actual impedance of the balancing resistor will vary with the frequency of the impressed voltage, and therefore an error can be introduced into the results.

This defect is not peculiar to Mr. Balsbaugh's bridge, but is present in all a-c bridges. I would like to know if Mr. Balsbaugh considers such effect important, and if so, what steps have been taken to overcome it.

G. B. Hoadley (Massachusetts Institute of Technology, Cambridge): The authors have pointed out several interesting and important facts about the theory of the coupling between a bridge circuit and its Wagner ground. Perhaps the most important of these is contained in equation 11. The outstanding feature of this equation is that the unbalances in the shield and coupling circuits are combined as a product in their effect relative to the effect of unbalance in the main bridge circuit. As the authors point out, the product relationship means that if the shield and coupling circuits are balanced to the same degree, they need be balanced with a precision which is no greater than the square root of the precision desired in the bridge balance except in unusual circumstances. Thus, if a precision of 10^{-6} is required in the bridge balance, the shield and coupling circuits need be balanced to a precision of only 10^{-3}. Consequently less-expensive components can be used in the shield and coupling circuits, because they do not need to have exceedingly fine steps in their adjustments, and they need not be as stable as the components in the bridge proper.

Another advantage which arises from the appearance of this product is that the electrical properties of dielectrics which are changing can be followed with the bridge without adjusting either the shielding circuit or the coupling circuit, even though, as occurs when guard rings are used, the changing dielectric is causing almost as much change in the coupling circuit as it is causing in the bridge circuit proper. Thus a per-unit change up to 10^{-3} could be followed without causing an error of more than 10^{-6} in the measured value, if both the shield and the coupling circuits were originally balanced to a precision of 10^{-3}. It must be remembered that equation 11 is good only for conditions when the bridge, shield, and coupling circuits are all near balance. It is incorrect to conclude, for example, that when the dependency factor is small, the coupling balance may be dispensed with. The bridge for which the authors give data in row *j* of table I would be very difficult to balance if Z_4 were made infinite, even though the dependency factor calculated from equation 17 is approximately 10^{-3}.

The method by which the authors express unbalances is very satisfactory. Their equations 18 to 23 show that when unbalance is expressed on a per-unit basis, it matters not, except for sign, which one of the four bridge arms shall be considered to be out of adjustment. Usually, bridge detectors are insensitive to phase angle and thus to sign, so $\Delta Z_1/Z_1$ is a general term indicating the unbalance of the bridge proper. It may also mean $\Delta Z_2/Z_2$, $\Delta Z_7/Z_7$, or $\Delta Z_8/Z_8$. Likewise $\Delta Z_6/Z_6$ is a general term for the shield unbalance which could equally well mean $\Delta Z_3/Z_3$, and $\Delta Z_4/Z_4$ is a general term for the coupling circuit unbalance which could equally well mean $\Delta Z_5/Z_5$.

The generality of these unbalance expressions which occur in equation 11 leads to the conclusion that the expression for *D* should be symmetrical with respect to the bridge structure. However, the expressions for *D* in equations 12 and 17 appear to be very lacking in symmetry. Nevertheless, by judicious manipulation, equation 17 may be shown to be symmetrical. Upon factoring, this equation becomes

$$\frac{1}{D}=Z_5\left(\frac{1}{Z_2}+\frac{1}{Z_8}\right)+Z_3\left(\frac{1}{Z_1}+\frac{1}{Z_2}\right)+1$$

The first of these terms, $Z_5(1/Z_2+1/Z_8)$ is the ratio of Z_5 to the parallel impedance of Z_2 and Z_8. The balance equations 3 and 4 can be combined to get

$$\frac{Z_5}{Z_4}=\frac{Z_8}{Z_7}=\frac{Z_2}{Z_1}$$

whence it is evident that

$$Z_5\left(\frac{1}{Z_2}+\frac{1}{Z_8}\right)=Z_4\left(\frac{1}{Z_1}+\frac{1}{Z_7}\right)$$

The right-hand side of this is the ratio of Z_4 to the parallel impedance of Z_1 and Z_7. This term is then really a symmetrical one which could be thought of as a factor which indicates the relation of the coupling-circuit impedances to those of the bridge proper.

By following a similar line of reasoning, the term $Z_3(1/Z_1+1/Z_2)=Z_6(1/Z_7+1/Z_8)$ becomes the factor which indicates the relation of the shield circuit impedances to those of the bridge proper. Consequently the expression which the authors give for *D* is a symmetrical one containing the relation of the coupling circuit to the bridge proper, and the relation of the shield circuit to the bridge proper.

J. C. Balsbaugh: Professor Seeley has given a very interesting analysis of bridge circuits and methods. The determining factors in designing the bridge discussed were: (*a*) sufficient flexibility to permit operation over extended ranges of voltage, frequency, and power factor and capacitance of test sample, (*b*) use of the conjugate Schering or detector-symmetrical bridge in view of its high inherent sensitivity for precise measurements on small samples, of the order of five micromicrofarads, (*c*) use of the Schering or source-symmetrical bridge for measurements at relatively high applied voltages, and (*d*) a generalized bridge network for experimental study of bridge theory.

With regard to Doctor Walker's questions, the effect of the generator or source may be represented by a three-terminal network which in the bridge and shield balances is connected between points *A*, *B*, and *G*. Thus the capacitances to ground are included in Z_3 and Z_6. The other impedance, being across points *A* and *B* or the source, has no effect on the balances. Thus the effect of source capacitances to ground are controlled by the shield or guard balance, and are not changed in switching from the bridge to the guard balance. In the coupling balance, in which *A* and *B* are tied together and the source connected between this point and ground, the foregoing impedances are shunted out or are directly across the source, thus producing no effect. Doctor Walker has raised an interesting question with respect to the effects of distributed capacitance. It is believed that the effect is sufficiently small over the present frequency range of the bridge so as not to be a determining factor in the precision of the measurements. However, there is no doubt that this effect may become significant in certain cases.

Doctor Hoadley has given an interesting discussion with respect to the coupling balance. His analysis with respect to the dependency factor *D* is an important contribution.

Transient Analysis of Symmetrical Networks by the Method of Symmetrical Components

Discussion and author's closure of paper 40-2 by Louis A. Pipes, presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940, and published in AIEE TRANSACTIONS, 1940 (August section) pages 457–9.

W. V. Lyon (Massachusetts Institute of Technology, Cambridge): A method, such as Doctor Pipes proposes in his paper, which avoids solving a high-order determinantal equation, is welcome. I should like to point out two things. First, the condition of symmetry which Doctor Pipes imposes is more severe than necessary. Second, the resolution of the determinantal equation into factors can be accomplished by means of symmetrical components *alone* without recourse to matrix theory. For example, consider six equal circuits, each having the same operational impedance. Let each of these circuits be coupled to one of six equal coils equally spaced around a uniform magnetic ring, so that the mutual inductances between adjacent coils are equal, between alternate coils are equal, and between diametrical coils are equal. Let Z_{ab} be the operational coupling impedance between adjacent coils, Z_{ac} between alternate coils, and Z_{ad} between diametrical coils; and let Z be the resulting operational self-impedance of each of the six loops. Since the self-impedances of the six loops are equal, and because of the symmetry imposed on the coupling, the potentials of each sequence are proportional to the currents of that sequence *alone*. For simplicity, assume that an electromotive force, E, is impressed on one loop a and all other loops, b, c, d, e, f are short-circuited, there being no initial currents or charges. The symmetrical components of the applied electromotive force are each $E/6$. Consequently the zero-sequence equation is

$$E_0 = E/6 = Zi_0 + Z_{ab}i_0 + Z_{ac}i_0 + Z_{ad}i_0 + Z_{ac}i_0 + Z_{ab}i_0$$

The last two terms represent the mutual effect of the zero-sequence currents in coils e and f. Hence,

$$E_0 = E/6 = (Z + 2Z_{ab} + 2Z_{ac} + Z_{ad})i_0 \qquad (1)$$

Similarly,

$$E_1 = E/6 = Zi_1 + Z_{ab}(\alpha i_1) + Z_{ac}(\alpha^2 i_1) + Z_{ad}(\alpha^3 i_1) + Z_{ac}(\alpha^4 i_1) + Z_{ab}(\alpha^5 i_1)$$

where $\alpha = \epsilon^{-j2\pi/6}$ is the characteristic operator for a six-phase circuit. Since $\alpha + \alpha^5 = 1$, and $\alpha^2 + \alpha^4 = -1$, and $\alpha^3 = -1$,

$$E_1 = E/6 = (Z + Z_{ab} - Z_{ac} - Z_{ad})i_1 \qquad (2)$$

Similarly it is readily shown that

$$E_2 = E/6 = (Z - Z_{ab} - Z_{ac} + Z_{ad})i_2 \qquad (3)$$

$$E_3 = E/6 = (Z - 2Z_{ab} + 2Z_{ac} - Z_{ad})i_3 \qquad (4)$$

$$E_4 = E/6 = (Z - Z_{ab} - Z_{ac} + Z_{ad})i_4 \qquad (5)$$

$$E_5 = E/6 = (Z + Z_{ab} - Z_{ac} - Z_{ad})i_5 \qquad (6)$$

Equations 2 and 6 show that $i_1 = i_5$. Also equations 3 and 5 show that $i_2 = i_4$.

The impedance operators in equations 1, 2, 3, and 4 are the factors of the determinantal equation. Having determined the component currents, i_0, i_1, i_2, i_3 from equations 1, 2, 3, and 4, the currents in the loops a, b, c, etc., are

$$i_a = i_0 + 2i_1 + 2i_2 + i_3 \qquad (7)$$
$$i_b = i_0 + \alpha i_1 + \alpha^2 i_2 + \alpha^3 i_3 + \alpha^4 i_4 + \alpha^5 i_5$$

Since $i_1 = i_5$ and $\alpha + \alpha^5 = 1$, and since $i_2 = i_4$ and $\alpha^2 + \alpha^4 = -1$,

$$i_b = i_0 + i_1 - i_2 - i_3 \qquad (8)$$

$$i_c = i_0 - i_1 - i_2 + i_3 \qquad (9)$$

$$i_d = i_0 - 2i_1 + 2i_2 - i_3 \qquad (10)$$

$$i_e = i_c \qquad (11)$$

$$i_f = i_b \qquad (12)$$

Note that the same principles which apply in formulating equations 1 to 6, inclusive, also apply in writing equations 7 to 12, inclusive, for the loop currents.

R. D. Evans and A. C. Monteith (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): Doctor Pipes has presented from the mathematical point of view, an interesting exposition of the transient analysis of networks by the method of symmetrical components. While it appears true, as Doctor Pipes has suggested, that the mathematical phase of the subject has been neglected, the subject has, nevertheless, received considerable attention from the engineering point of view. A pertinent reference in this connection is the paper "The Determination of Circuit Recovery Voltages by Analytical and A-C Calculating Board Methods", presented by Evans and Monteith at the 1937 AIEE summer convention in Milwaukee (AIEE TRANSACTIONS, volume 56, 1937, pages 695–705). Examination of that paper will show that the method of symmetrical components was used in the analytical determination of recovery-voltage transients. Of perhaps greater interest is the use of the a-c calculating board to provide miniature circuits that are equivalent from the transient point of view to the actual power system under consideration. In this method the various power-system elements were represented by corresponding types of equivalent circuits having the same sequence impedance characteristics. Furthermore, sequence networks were used in various connections to give transient results equivalent to those of a three-phase system subjected to various disturbances. The paper also gives the results of field tests substantiating the method. This method has subsequently been used by several investigators for various studies of circuit recovery voltages and other switching transients. For such general investigations of power-system transients this method of using equivalent circuits on the a-c network calculator is considered, from an engineering point of view, as the most suitable method available.

Murray F. Gardner (Massachusetts Institute of Technology, Cambridge): The method which Doctor Pipes presents requires: (1) the Laplace transformation of the integro-differential equations of the electrical network, introducing therewith general initial conditions, (2) resolution of the transformed loop voltages and currents into symmetrical components, (3) formation of the sequence impedances from the loop and mutual impedance functions, (4) solution separately for the (symmetrical) component currents, and (5) the synthesis of these components to gain the actual loop currents. He uses matrix algebra, particularly for steps (2), (3), and (5). This is an unjustifiably long process for handling the class of problems to which he restricts his discussion. The major claim for the method seems to be that by use of it, solution of the characteristic equation of the network for its roots in the usual way can be avoided.

One acquainted with the theory of symmetrical components and also the Laplace transformation (or even operational calculus of the Heaviside type) can write the separate sequence equations directly; and, once each is solved, can combine the components to secure the actual currents—and do this without the use of matrix algebra. Even one not acquainted with symmetrical-component theory can solve problems of the special class treated here in direct manner by: (1) modifying the determinant of the network so that the invariant factors of the characteristic equation become readily apparent, (2) making a partial fraction expansion of the transforms for the actual currents, based on these factors, and (3) carrying out the inverse Laplace transformation of these expansions to gain at once the actual loop currents

As an example of the latter method, consider a four-loop, electrically symmetrical network in which all the loop self-impedance functions are alike and the mutual-impedance functions are one of two forms. This is a slightly more general problem than any discussed by Doctor Pipes, as he restricted his treatment to networks in which *all* the mutual impedances are alike. Here, with s a complex variable,

$$\begin{aligned} z_{11} = z_{22} = z_{33} = z_{44} = z_a &= Ls + \frac{1}{Cs} \\ z_{12} = z_{23} = z_{34} = z_{41} = z_b &= M_1 s \qquad (1) \\ z_{13} = z_{24} = z_c &= M_2 s. \end{aligned}$$

Then, if $I(s)$ is the Laplace transform of a loop current $i(t)$, and $T(s)$ is a loop excitation function composed of the sum for that loop of: (1) the Laplace transform of the net driving voltage, (2) the initial net flux linkage, and (3) the initial net capacitor voltage divided by s, the system of transform equations can be written

$$\sum_{k=1}^{4} z_{jk}(s)I_k(s) = T_j(s),\ j = 1, 2, 3, \text{ and } 4 \qquad (2)$$

Solution for $I_k(s)$ gives

$$I_k(s) = \sum_{j=1}^{4} Y_{kj}(s)T_j(s),\ k = 1, 2, 3, \text{ and } 4 \qquad (3)$$

in which

$$Y_{kj}(s) = \frac{N_{jk}(s)}{\Delta(s)} \qquad (4)$$

$\Delta(s)$ being the determinant of the system, and $N_{jk}(s)$ the cofactor of z_{jk} in $\Delta(s)$.

Here

$$\Delta(s)=\begin{vmatrix} z_a & z_b & z_c & z_b \\ z_b & z_a & z_b & z_c \\ z_c & z_b & z_a & z_b \\ z_b & z_c & z_b & z_a \end{vmatrix}=$$

$$(z_a-z_c)^2(z_a+z_c+2z_b)(z_a+z_c-2z_b) \quad (5)$$

These factors can be readily found by: (1) transforming the determinant into a factor times a determinant having the first element of the first row unity, and all other elements of this row zero; (2) reduction of this determinant to a third-order determinant; and (3) transformation of this third-order determinant into a factor times a determinant having the first element of its first column unity, and all other elements of this column zero. A similar but briefer procedure reduces $N_{jk}(s)$ to a product of factors.

To complete the example, the current in loop 1 will be found, considering T_2, T_3, and T_4 are zero, and $T_1=\gamma/s$, γ being the net initial condenser voltage in loop 1. Here

$$I_1(s)=\frac{N_{11}(s)}{\Delta(s)}=$$

$$\frac{(z_a-z_c)(z_a^2+z_az_c-2z_b^2)}{(z_a-z_c)^2(z_a+z_c+2z_b)(z_a+z_c-2z_b)}\frac{\gamma}{s}=$$

$$\left[\frac{K_1}{z_a+(z_c+2z_b)}+\frac{K_2}{z_a-z_c}+\frac{K_3}{z_a+(z_c-2z_b)}\right]\frac{\gamma}{s} \quad (6)$$

in which

$K_1=K_3=0.25$ and $K_2=0.5$

It will be noted that the partial fraction expansion has been made considering z_a as the variable.

In the terminology of symmetrical components, $(z_a+z_c+2z_b)$ will be recognized as the zero-sequence impedance, (z_a-z_c) as the first- and third-sequence impedances, and $(z_a+z_c-2z_b)$ as the second-sequence impedance. Taken with the factor γ/s, the first, second, and third terms are the Laplace transforms, respectively, of the zero-sequence component, the combined first- and third-sequence components, and the second-sequence component of the current of loop 1.

Replacing z_a, z_b, and z_c by their respective functions of s,

$$I_1(s)=\gamma\left(\frac{A_1}{s^2+\beta_1^2}+\frac{A_2}{s^2+\beta_2^2}+\frac{A_3}{s^2+\beta_3^2}\right) \quad (7)$$

in which

$A_1=0.25(L+2M_1+M_2)^{-1}$
$A_2=0.5(L-M_2)^{-1}$
$A_3=0.25(L-2M_1+M_2)^{-1}$
$\beta_1^2=[C(L+2M_1+M_2)]^{-1}$
$\beta_2^2=[C(L-M_2)]^{-1}$
$\beta_3^2=[C(L-2M_1+M_2)]^{-1}$

Finally, the inverse Laplace transformation of $I_1(s)$ gives

$$i_1(t)=\left(\frac{A_1}{\beta_1}\sin\beta_1t+\frac{A_2}{\beta_2}\sin\beta_2t+\frac{A_3}{\beta_3}\sin\beta_3t\right) \qquad 0\leqq t \quad (8)$$

Since this four-loop network was electrically symmetrical (its constants being the same, viewed from any loop), its determinant could be readily factored, and it was possible to avoid the solution of the characteristic equation for its roots in the usual manner. It was not necessary to employ matrices, nor the aid of symmetrical-component theory. Furthermore the procedure was the usual one throughout, being shortened simply by the ease with which the determinant could be factored.

In this discussion the direct Laplace transformation used is the ordinary form, that is,

$$[f(t)]=\int_{\sigma_a<\sigma}^{\infty} f(t)e^{-st}dt=F(s) \quad (9)$$

in which $s=\sigma+j\omega$, $j=\sqrt{-1}$; t, σ, and ω are real variables; and σ_a is the abscissa of absolute convergence for the integral with the function $f(t)$ present. The transformation differs from the "s-multiplied" form used by Doctor Pipes by the factor s.

P. C. Cromwell (New York University, New York): I am glad to see this paper by Doctor Pipes. Although the method of symmetrical components is well known in the study of electrical transients, to my knowledge no systematic proof of its value in the solution of symmetrical systems has been published.

As I read Doctor Pipes' paper I began to wonder why a simple multiplying process made it unnecessary to solve for the roots of the determinantal equation. Let us take a perfectly general symmetrical two-mesh network quite similar to the first example in the paper. Using the same symbols we have

$$\begin{aligned} Z_0i_1+Zi_2&=E \\ Zi_1+Z_0i_2&=0 \end{aligned} \quad (1)$$

Solving for i_1

$$i_1=\frac{Z_0E}{Z_0^2-Z^2}=\frac{Z_0E}{(Z_0+Z)(Z_0-Z)} \quad (2)$$

The denominator of the first term in equation 2 factors readily and the second term may be evaluated directly in any numerical case by using a table of operational transforms.

For a three-mesh system

$$\left.\begin{aligned} Z_0i_1+Zi_2+Zi_3&=E \\ Zi_1+Z_0i_2+Zi_3&=0 \\ Zi_1+Zi_2+Z_0i_3&=0 \end{aligned}\right\} \quad (3)$$

and the expression for i_1 is

$$i_1=\frac{(Z_0^2-Z^2)E}{Z_0^3+2Z^3-3Z_0Z^2} \quad (4)$$

which is easily shown to be

$$i_1=\frac{(Z_0-Z)(Z_0+Z)E}{(Z_0-Z)^2(Z_0+2Z)} \quad (5)$$

After dividing numerator and denominator by (Z_0-Z) equation 5 could be evaluated in the usual manner.

I have also been able to "solve" a four-mesh equation in a similar fashion although in this case it was necessary to solve a quadratic equation.

In every one of the simple cases considered it was unnecessary to solve for the roots of the determinantal equation in the usual sense of the word. I should like to suggest that perhaps the proof given in the paper could be extended to show that the use of symmetrical components can be replaced by an entirely new and much simpler set of relations which would automatically (*a*) solve for the roots, and (*b*) expand the operational form of the equation in partial fractions.

K. Y. Tang (The Ohio State University, Columbus): The currents for the circuit shown in figure 1 of this discussion are determined in two ways:

1. Pipes' method
2. Another method

The amount of work involved in Pipes' method of solution of this problem is very much less than that of the second method.

METHOD 1

Following the procedure given by Pipes and with the boundary conditions when $t=0$,

$i_1^0=0,\ i_2^0=0$
$q_1^0=0,\ q_2^0=0$

equations 36 and 37 reduce to

$$I_{1S}(p)=\frac{E/2}{Lp+\frac{1}{Cp}+Mp}=$$

$$50\,\frac{10^{-4}p}{1.1\times10^{-4}\left\{p^2+\frac{10^4}{1.1}\right\}}$$

$$I_{2S}(p)=\frac{E/2}{Lp+\frac{1}{Cp}-Mp}=$$

$$50\,\frac{10^{-4}p}{0.9\times10^{-4}\left\{p^2+\frac{10^4}{0.9}\right\}}$$

Substituting $\frac{\sin\omega t}{\omega}$ for $\frac{p}{p^2+\omega^2}$ then

$$i_{1S}=\frac{0.5}{\sqrt{1.1}}\sin\frac{100}{\sqrt{1.1}}t$$

$$i_{2S}=\frac{0.5}{\sqrt{0.9}}\sin\frac{100}{\sqrt{0.9}}t$$

From equation 43,

$$i_1=i_{1S}+i_{2S}=\frac{0.5}{\sqrt{1.1}}\sin\frac{100}{\sqrt{1.1}}t+\frac{0.5}{\sqrt{0.9}}\sin\frac{100}{\sqrt{0.9}}t$$

$$i_2=i_{1S}-i_{2S}=\frac{0.5}{\sqrt{1.1}}\sin\frac{100}{\sqrt{1.1}}t-\frac{0.5}{\sqrt{0.9}}\sin\frac{100}{\sqrt{0.9}}t$$

METHOD 2

Start with Kirchhoff's electromotive-force equations

$$L\frac{di_1}{dt}+\frac{1}{C}\int i_1dt+M\frac{di_2}{dt}=E$$

$$L\frac{di_2}{dt}+\frac{1}{C}\int i_2dt+M\frac{di_1}{dt}=0$$

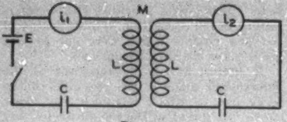

Figure 1

$L = 1.0$ henry
$C = 10^{-4}$ farad
$M = 0.1$ henry
$E = 100$ volts

Capacitors are initially uncharged

These can be written

$$\left(Lp+\frac{1}{Cp}\right)i_1+Mpi_2=E$$

$$Mpi_1+\left(Lp+\frac{1}{Cp}\right)i_2=0$$

The roots of the determinantal equation (a fourth-degree equation) are

$$p_1=j\frac{100}{\sqrt{0.9}} \qquad p_3=j\frac{100}{\sqrt{1.1}}$$

$$p_2=-j\frac{100}{\sqrt{0.9}} \qquad p_4=-j\frac{100}{\sqrt{1.1}}$$

By examination of the circuit, the forms for the two currents are:

$$i_1=I_1'e^{p_1t}+I_2'e^{p_2t}+I_3'e^{p_3t}+I_4'e^{p_4t}$$
$$i_2=I_1''e^{p_1t}+I_2''e^{p_2t}+I_3''e^{p_3t}+I_4''e^{p_4t}$$

Determining the coefficients of the different terms on the right-hand side and substituting them in the equations, the expressions obtained for i_1 and i_2 are the same as those given by Pipes' method. By substitution, the currents satisfy the two Kirchhoff's electromotive-force equations.

Louis A. Pipes: The method of obtaining the transient solution of networks presented in this paper is a special case of a more general method which may be briefly described as follows:

Following the notation of the paper, let

$$(e)=[Z](i) \tag{1}$$

represent the canonical equations of the general n-mesh circuit under consideration. As in the paper, let the equation (1) be subjected to a Laplacian transformation of the p-multiplied type. The equation is transformed to:

$$[Z(p)](I)=(E)+p[L](i^0)-[S](q^0) \tag{2}$$

Now let the transformed current and voltage matrices be subjected to a linear transformation of the type:

$$[B]^{-1}(I)=(I)_t \tag{3}$$

$$[A](E)=(E)_t \tag{4}$$

where $[B]^{-1}$ and $[A]$ are nonsingular matrices whose elements are complex numbers. If we substitute for (I) and (E) the expressions given in (3) and (4) into (2), we obtain:

$$[Z(p)][B](I)_t=(E)+p[L](i^0)-[S](q^0) \tag{5}$$

If (5) is premultiplied by $[A]$, we obtain:

$$[A][Z(p)][B](I)_t=[A](E)+p[A][L](i^0)-[A][S](q^0) \tag{6}$$

Now, if we let:

$$[A][Z(p)][B]=[Z]_t \tag{7}$$

we have:

$$(I)_t=[Z]_t^{-1}\{(E)_t+p[A][L](i^0)-[A][S](q^0)\} \tag{8}$$

If we choose the elements of $[A]$ and $[B]$ so that $[Z]_t$ has the diagonal form, then $(I)_t$ may be readily computed from (8) and the inverse transform $(i)_t$ is then obtained by the usual operational methods. The actual currents are obtained from $(i)_t$ by the equation:

$$(i)=[B](i)_t \tag{9}$$

In the method of the paper, the matrices $[A]$ and $[B]$ were defined by the equations:

$$[A]=[C]^{-1} \tag{10}$$

$$[B]=[C] \tag{11}$$

where $[C]$ is the fundamental matrix of the theory of symmetrical components. If $[A]$ and $[B]$ are specified in this manner, the matrix $[Z]$ must have a certain symmetry for it to be diagonalized. The reduction of a given matrix to the diagonal form by a transformation of the type (7) is one of the fundamental problems of matrix algebra.

In his discussion, Professor Lyon points out that the assumed symmetry of the matrix $[Z]$ which was considered in the paper is more severe than necessary. He shows that the matrices of circuits that are coupled in a certain manner so that they have "ring symmetry" are diagonalized by the symmetrical-component transformation. The fact that the symmetrical-component transformation diagonalizes the matrices of networks having "ring symmetry" makes the method applicable to a much larger class of problems.

It would appear from this that an investigation of the sufficient conditions that must be satisfied by the elements of the impedance matrix $[Z]$ of the general n-mesh network in order that this matrix may be diagonalized by a symmetrical-component transformation is in order. A brief treatment of this question will now be given.

The general transformation matrix, $[C]$, of the theory of symmetrical components may be written in the form:

$$[C]=\begin{bmatrix} 1 & 1 & 1 & \cdots & 1 \\ 1 & a^{-1} & a^{-2} & & a^{-(n-1)} \\ 1 & a^{-2} & a^{-4} & & a^{-2(n-1)} \\ \cdots & \cdots & \cdots & \cdots & \cdots \\ 1 & a^{-(n-1)} & & \cdots & a^{-(n-1)(n-1)} \end{bmatrix} \tag{12}$$

where $a=\epsilon^{j\frac{2\pi}{n}}$

Now, from the basic equation connecting the sequence currents and the sequence voltages, we have:

$$[C](E)_s=[Z][C](I)_s \tag{13}$$

Let us assume that only the rth sequence voltage is impressed on the system and that this produces only rth sequence currents. This is equivalent to stating that the matrix $[Z]_s$ is diagonalized by the transformation

$$[Z]_s=[C]^{-1}[Z][C] \tag{14}$$

If we introduce a column matrix defined by:

$$(P_r)=\begin{bmatrix} 1 \\ a^{-r} \\ a^{-2r} \\ \cdots \\ \cdots \\ a^{-(n-1)} \end{bmatrix} \tag{15}$$

Then the assumption that the rth sequence voltage produces only rth sequence current leads to the matrix equation:

$$E_r(P_r)=[Z](P_r)I_r \tag{16}$$

These equations may be solved for the ratios of E_r to I_r and we have n equations of the type:

$$\left.\begin{aligned} Z_r=E_r/I_r&=Z_{11}+a^{-r}Z_{12}+a^{-2r}Z_{13}+\\ &\qquad\ldots+a^{-(n-1)r}Z_{1n}\\ Zr=E_r/I_r&=a^rZ_{21}+Z_{22}+a^{-r}Z_{23}+\\ &\qquad\ldots+a^{-(n-2)r}Z_{2n}\\ &\cdots\cdots\cdots\cdots\cdots\\ Z_r=E_r/I_r&=a^{(n-1)r}Z_{n1}+a^{(n-2r)}Z_{n2}+\\ &\qquad\ldots+Z_{nn}\end{aligned}\right\} \tag{17}$$

The sufficient condition that the matrix $[Z]$ be diagonalized by a transformation to symmetrical components is obtained by equating the n values of Z_r. This may be done for all the sequences. When this has been done, it will be apparent that if the matrix $[Z]$ has all the elements of its principal diagonal equal, and its other elements have the ring symmetry that Professor Lyon mentions, then the various Z_r quantities are equal and the matrix $[Z]$ is diagonalized by this type of transformation. When this sufficient condition is satisfied, then the first of the equations (17) may be used to compute the various elements of the diagonal matrix.

In the example discussed by Professor Lyon, we have for the impedance matrix:

$$[Z]=\begin{bmatrix} Z & Z_{12} & Z_{13} & Z_{14} & Z_{13} & Z_{12} \\ Z_{12} & Z & Z_{12} & Z_{13} & Z_{14} & Z_{13} \\ Z_{13} & Z_{12} & Z & Z_{12} & Z_{13} & Z_{14} \\ Z_{14} & Z_{13} & Z_{12} & Z & Z_{12} & Z_{13} \\ Z_{13} & Z_{14} & Z_{13} & Z_{12} & Z & Z_{12} \\ Z_{12} & Z_{13} & Z_{14} & Z_{13} & Z_{12} & Z \end{bmatrix} \tag{18}$$

The diagonal elements of the transformed matrix are given by:

$$Z_r=Z_{11}+a^{-r}Z_{12}+a^{-2r}Z_{13}+a^{-3r}Z_{14}+a^{-4r}Z_{13}+a^{-5r}Z_{12} \tag{19}$$

where $a=\epsilon^{j\pi/3}$

Combining terms, we obtain:

$$[Z]_s=[C]^{-1}[Z][C]=\begin{bmatrix} Z_0 & 0 & 0 & 0 & 0 & 0 \\ 0 & Z_1 & 0 & 0 & 0 & 0 \\ 0 & 0 & Z_2 & 0 & 0 & 0 \\ 0 & 0 & 0 & Z_3 & 0 & 0 \\ 0 & 0 & 0 & 0 & Z_4 & 0 \\ 0 & 0 & 0 & 0 & 0 & Z_5 \end{bmatrix} \tag{20}$$

where:

$$\left.\begin{aligned} Z_0&=(Z+2Z_{12}+2Z_{13}+Z_{14})\\ Z_1&=(Z+Z_{12}-Z_{13}-Z_{14})=Z_5\\ Z_2&=(Z-Z_{12}-Z_{13}+Z_{14})=Z_4\\ Z_3&=(Z-2Z_{12}+2Z_{13}-Z_{14})\end{aligned}\right\} \tag{21}$$

In the general case, the diagonal elements of a general matrix having ring symmetry may be computed from the first of the equations (17).

Professor Gardner points out that it is not necessary to use matrix algebra or symmetrical-component theory to solve problems whose impedance matrices involve ring-symmetry. He discusses the solution of a problem whose impedance matrix has ring-symmetry and is given by:

$$[Z]=\begin{bmatrix} Z & Z_{12} & Z_{13} & Z_{12} \\ Z_{12} & Z & Z_{12} & Z_{13} \\ Z_{13} & Z_{12} & Z & Z_{12} \\ Z_{12} & Z_{13} & Z_{12} & Z \end{bmatrix}= \begin{bmatrix} Z_a & Z_b & Z_c & Z_b \\ Z_b & Z_a & Z_b & Z_c \\ Z_c & Z_b & Z_a & Z_b \\ Z_b & Z_c & Z_b & Z_a \end{bmatrix} \tag{22}$$

This matrix may be readily diagonalized to the form:

$$[Z]_s=[C]^{-1}[Z][C]=\begin{bmatrix} Z_0 & 0 & 0 & 0 \\ 0 & Z_1 & 0 & 0 \\ 0 & 0 & Z_2 & 0 \\ 0 & 0 & 0 & Z_3 \end{bmatrix} \tag{23}$$

where

$$\begin{aligned} Z_r &= Z_a+a^{-r}Z_b+a^{-2r}Z_c+a^{-3r}Z_b \\ a &= e^{j\pi/2} \end{aligned} \tag{24}$$

in this case we obtain:

$$\left.\begin{aligned} Z_0 &= (Z_a+2Z_b+Z_c) \\ Z_1 &= (Z_a-Z_c)=Z_3 \\ Z_2 &= (Z_a+Z_c-2Z_b) \end{aligned}\right\} \tag{25}$$

Having diagonalized the impedance matrix, the remaining work by the method of the paper is very straightforward. It may be pointed out that Professor Gardner's equation 2 is essentially a matrix equation, and his procedure of solving for $I_k(s)$ in his equation 3 involves essentially the concept of the determination of the inverse of a matrix. It may be also mentioned that the method of the paper involves merely the concept of naive matrix multiplication and avoids troublesome partial-fraction decompositions.

It must be realized that the method presented in this paper is only a special case of the general method discussed above. This general method is applicable to the solution of sets of linear operational equations with constant coefficients. The essential features of the method are the determination of two nonsingular matrices, $[A]$ and $[B]$ so that the matrix $[Z]_t$ given by $[Z]_t=[A][Z(p)][B]$ has the diagonal form.

As has been mentioned, this is one of the fundamental problems of matrix algebra. The concept of transforming a given matrix to the diagonal form, appears to have been due to H. J. S. Smith in 1861. The method was later extended by Frobenius in 1878. He seems to have been the first one to use the term, "invariant factor" for the elements of the diagonal matrix $[Z]_t$. An excellent account of the development of the theory is given in Sir Thomas Muir's "History of Determinants," volume 4, pages 435–53.

The application of the theory presented in this paper is based on a certain choice of the general matrices $[A]$ and $[B]$ as defined by equations 10 and 11 herein. By such a choice we are able to diagonalize the impedance matrices of circuits having symmetrical "ring coupling" as pointed out by Professor Lyon.

Further research along the lines of the general theory will no doubt result in the discovery of other choices for the matrices $[A]$ and $[B]$ that will diagonalize the impedance matrices of networks having different types of symmetry. To advance the theory in this direction, matrix notation will prove indispensable.

Lightning Currents in Arresters at Stations

Discussion and authors' closure of paper 40-59 by I. W. Gross and W. A. McMorris, presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940, and published in AIEE TRANSACTIONS, 1940 (August section) pages 417–22.

S. K. Waldorf (Pennsylvania Water and Power Company, Baltimore, Md.): Messrs. Gross and McMorris have presented a valuable analysis of the burden placed upon station arresters. There is one factor which they have not evaluated and which is believed to be of importance. This factor is tower-footing resistances on a shielded line and I wish to inquire of the authors if their original data will enlighten us on this point. The experience of the Pennsylvania Water and Power Company may also shed some light upon it.

The authors of the paper under discussion show in their table III no appreciable advantage resulting from the use of overhead ground wires on steel-tower lines. Without overhead ground wires, the number of single-pole discharges recorded per number of three-pole arrester years is 0.81 as compared to 0.79 for the same quantity where ground wires exist. This is no surprise, as lightning surges are transmitted to station equipment when flashovers occur, even though the lines may be provided with well placed overhead ground wires. However, when ground wires provide good shielding and footing resistances have been co-ordinated with line insulation level, the duty of lightning arresters is practically nil. This is because flashovers are then very infrequent and induced surge effects on higher voltage lines are negligible.

Since 1937, surge-crest-ammeter links have been installed on the lightning arresters connected to transmission lines of the Pennsylvania Water and Power Company. Arresters on the three well-protected lines of the company have shown no discharges through them during the three lightning seasons during which observations have been made, even though the lines have received an average of 1.26 strokes per mile per year. These lines are a 66-kv line, 23 miles long, a 132-kv line, 32 miles long, and a 220-kv line, 92 miles long.

The experience on the 132-kv line is of particular interest as two of its four circuits have operated successfully without any lightning arresters since the end of 1934. Its other two circuits have had arresters on them only for the last two years. These latter circuits were provided with arresters because of the connection to them in 1938 of two new circuits which were not as well protected as the two original ones.

Of interest also is a comparison of the observations made at the two ends of the 66-kv line to which reference was made above. As stated, at the well-protected end of the line, no discharges through the arresters were recorded. At the other end, where the well-protected steel-tower line connects to an unprotected wood-pole line, once each year for two of the three years that observations have been made, discharges through the arresters have been recorded. These can be accounted for by the presence of the unprotected wood-pole line.

Lightning arresters connected to a line provided with expulsion tubes and to other lines relatively unprotected, have experienced numerous discharges during the three years' study outlined here.

The data presented in this discussion strongly indicate that lightning arresters are of relatively small importance when connected to circuits well protected from flashovers and direct strokes to conductors. If, as seems to be the case, surges of appreciable magnitude can reach the terminals of a well-protected line only through the medium of a flashover, and as it is probable that the flashover will itself cause tripout, a lightning arrester does not seem to offer any advantage over a suitable spillgap. The latter is the simpler, cheaper, and more easily maintained of the two.

L. G. Smith (Consolidated Gas, Electric Light and Power Company of Baltimore, Baltimore, Md.): The collection of data initiated by the authors provides information of considerable interest to the industry. It is gratifying to note that the authors plan to continue the study. To be of maximum value, the collection of discharge currents in arresters at stations should be extended to other systems. The fact that no surge currents greater than 19,000 amperes were measured is of considerable interest. Might not this lead to the conclusion that the probability of direct strokes occurring in the immediate vicinity of substations is low?

Herman Halperin (Commonwealth Edison Company, Chicago, Ill.): In Chicago, we have obtained by means of surge-crest ammeters some data on magnitude of lightning currents through arresters on our relatively small amount of overhead lines on the 12-kv three-phase neutral-grounded system. The lines are on wood poles and have no ground wires. The maximum current, 16,000 amperes, was comparable to the maximum reported by the authors. The next largest current was 5,500 amperes and then the values drop to about 2,000 amperes or less. Most of the currents, including the two largest ones, were of negative polarity. No troubles with arresters resulted from these surges.

The authors seem to focus attention on surges of about 5,000 amperes, but it appears desirable in connection with lightning and equipment to figure on the basis of much higher currents from the standpoint of having freedom from trouble.

Edward Beck (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): The paper by Messrs. Gross and McMorris is a most interesting report on arrester performance. There have been in the past other reports on arrester performance in the field; but usually these have left considerable question in many users' minds whether arresters did any good, and little, if anything, was ever said about the trouble they had prevented. This paper gives a definite estimate of the number of times that arresters have prevented outage or equipment damage in the sixth column and the last column of table VI. One might say that finally the arrester has become articulate and found means of expressing itself when it has accomplished something. If now we could have some estimate of dollars saved by those operations which prevented damage, a valuable entry could be made in the economics of lightning protection.

In this connection it is significant that several of the contemporary papers dealing with insulation co-ordination and basic insulation levels also place considerable and deserved reliance on the arrester as a determinant of protected level.

In regard to discharges through arresters, some current measurements recently obtained on a high-voltage installation are of interest. The fulchronograms shown by figure 3 of a contemporary paper on "Lightning and Lightning Protection on Distribution Systems" by Bergvall and Beck (AIEE TRANSACTIONS, volume 59, 1940, pages 442–9) were recorded on a high-voltage station-type arrester. These show currents of 1,600, 5,200, and 6,400 ampere crest with total durations of 200 to 350 microseconds. There had been, previous to the recording of these currents, De-ion protector tubes installed at three locations on the transmission line ahead of the arrester. While the tubes were installed, several discharges occurred as shown by an automatic cathode-ray oscillograph connected to record discharge current. These currents were small, 100 amperes and less. However, the oscillograms obtained showed the reflections between the arrester and the tubes, proving that the tubes had discharged and limited the discharge currents through the arresters. In order to increase the duty on the arrester and find out what it might be called upon to discharge without tubes, the tubes were removed and the fulchronograms shown in the Bergvall and Beck paper were obtained. These are all of much greater magnitude than those recorded before the removal of the tubes. These records are in line with the Gross and McMorris data and they are indicative of the effect of protector tubes in limiting the duty on arresters. The careful investigation described in the paper presents excellent evidence for the lightning arrester as an important link in the economics of system operation.

I. W. Gross and W. A. McMorris: Mr. Smith has suggested that the absence of currents in excess of 19,000 amperes in this investigation might lead to the conclusion that the probability of direct strokes occurring in the immediate vicinity of substations is low. The 19,000-ampere value was obtained by adding together the currents in three arresters that discharged in parallel, the highest measured current in any one pole of an arrester being 15,000 amperes.

The exposure to lightning of many lines is less in the immediate vicinity of the stations, than over the rest of their length. However, we do not believe that the absence of higher currents through the arresters necessarily means that there were no direct strokes near the stations. Rather it indicates that if such strokes occurred, much of the direct-stroke current flowed to ground through other paths.

We have records from a location not included in this particular co-operative investigation, where a direct stroke one span from the end of a 115-kv steel-tower line resulted in an arrester discharge current at the station of 2,400 amperes, and another direct stroke two miles out resulted in an arrester current of 1,200 amperes. These values are far below the usual crest current values of direct strokes. Flashover of the line occurred in both cases, thereby reducing the duty on the arresters. In neither case did line flashover obviate the need of arresters, for as shown by table VI, both of the above currents represent traveling waves that would have been dangerous to station equipment in the absence of arresters.

We agree with Mr. Waldorf in that well-located overhead ground wires in combination with low tower-footing resistances are effective in reducing the duty on arresters, but they do not make arresters unnecessary unless all of the following conditions are met:

1. There must be enough ground wires and they must be so located that they will successfully intercept *all* direct strokes, allowing *none* to terminate on the line conductors.

2. Tower-footing resistances must be low enough to limit tower potentials, even when the tower is conducting the highest lightning currents, to values below the line insulation level.

3. Tower heights, span lengths, and ground-wire clearances must be such that steep-front strokes contacting the ground wires cannot flash over to the line wires before the voltage is relieved by a reflected wave from ground. Such flashovers are theoretically possible even with perfect shielding and zero ground resistance.

4. There must be no voltages of dangerous magnitude induced on the line conductors by the release of bound charges.

It is not sufficient to limit traveling-wave voltage at the ends of lines to the transformer insulation strength. Since the voltage may approximately double there because of reflection, the voltage of the incoming traveling wave must not exceed about *one-half* the transformer insulation strength.

Measures which are designed to meet the above requirements may involve much greater expense than the installation of arresters for the protection of equipment at the station, and at the present stage of the art it cannot be insured that the requirements will be fully met. In some locations low footing resistances cannot be obtained. The fact that these requirements are not easily achieved is forcefully illustrated by a recent case on a thoroughly modern high-voltage line. Every effort had been made to make the line immune to the effects of lightning; yet a direct stroke of lightning missed well-placed ground wires, and contacted a line conductor.

Mr. Waldorf is fortunate in having a location where low footing resistances can be obtained. Performance records from his lines and other similar ones over a period of several years will be required to establish very definitely how free they are from lightning trouble. In this connection it is significant that it has been the experience of several operating companies to have little trouble from lightning for several years, and then to suffer considerable damage in one severe storm.

All of the data presented in table VI for 132-kv circuits were obtained on steel-tower lines with ground wires. About one-quarter of the cases in which dangerous voltages at stations are indicated, if arresters had not been used, were on lines with tower-footing resistances of the order of 15 to 20 ohms, and three-quarters were on lines with footing resistances of the order of 50 ohms. The former group has considerably lower footing resistances than the probable average for all lines, and the latter is about average. Considering the type of line construction of all of these circuits, and the lower-than-average footing resistances of many of them, it is evident that the lightning duty on 132-kv arresters as shown by table VI was obtained on circuits with better-than-average line protection.

In most cases data are not available which would show whether or not line flashover occurred coincident with the recording of arrester discharge currents at the stations. Among the cases for which data are available, are 62 records of arrester discharge which did not correlate with line tripouts or any other evidence of line flashover. Nearly 70 per cent of these discharges represented waves that would have been dangerous without arresters. The proportional number of these waves of dangerous magnitude which definitely did not correlate with tripouts was only five per cent less for 132-kv steel-tower lines with ground wires and tower footing resistances of 15 to 20 ohms, than for the average of the entire investigation.

Even though this proportion may be altered some as the study continues, the data certainly do not bear out Mr. Waldorf's contention that waves of dangerous magnitudes will appear on such lines only as a result of line flashover, and will therefore almost certainly be coincident with line tripout. The use of spillgaps at the stations in place of arresters probably would have resulted in a considerable increase in the number of line tripouts, and an appreciable sacrifice of the low impulse protection level provided by the arresters.

Since it is so difficult in many cases to build a line that is substantially immune to lightning flashover, the money required to provide elaborate ground-wire systems, counterpoises, and low footing resistances can often be used to better advantage in providing protector tubes. Lightning voltages that occur on the line, if of sufficient magnitude, will be discharged by the tubes, and line tripouts will be minimized. Since the line flashover voltage is reduced, the duty on the arresters is less, but in general the expected reduction would not be as great as in the case referred to by Mr. Beck. When the currents which an arrester must discharge are reduced, a lower level of protection results for the station equipment.

We would like to emphasize the variation in lightning severity from year to year and between different locations, as illustrated by figure 6, and to point out that because of such variations, conditions are likely to be encountered in service which may be quite different from those reported here. It also follows that any accurate determination of the average or the extreme conditions which exist in service must be based upon experience over a period of several years, a wide range of localities, and with different types of line construction.

Lightning and Lightning Protection on Distribution Systems

Discussion and authors' closure of paper 40-60 by R. C. Bergvall and Edward Beck, presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940, and published in AIEE TRANSACTIONS, 1940 (August section) pages 442–9.

D. D. MacCarthy (General Electric Company, Pittsfield, Mass.): Messrs. Bergvall and Beck have presented an informative discussion of the division of long-duration lightning currents between arresters and the transformers connected to grounded-neutral circuits. This analysis confirms the prediction made by Doctor K. B. McEachron[1] in February 1939 when he discussed some of the long-time discharges which he recorded oscillographically as early as 1937. In this article Doctor McEachron states, regarding continuing lightning discharges to grounded neutral systems: "... the transformer winding represents a relatively small impedance to the flow of such unidirectional currents."

Following Doctor McEachron's suggestion, the writer and his associates in Pittsfield investigated the discharge of unidirectional currents through distribution transformers. The results presented by Messrs. Bergvall and Beck seem to agree with ours and show that the transformer inductance is reduced due to saturation of the iron. This reduction of inductance occurs in a time sufficiently short so that continuing lightning will cause appreciable currents to flow in grounded-neutral transformers, and our tests show this to be true, even though the transformer secondary circuit is open.

Messrs. Bergvall and Beck confined the discussion of current drainage to the case of a grounded-neutral feeder supplied from a single-phase transformer. Many single-phase feeders branch out from three-phase systems supplied from a three-phase bank of transformers. From our investigation it appears doubtful that the analysis given by Bergvall and Beck for the current drainage through substation transformers applies to such circuits.

We agree with the authors that more data are needed in order to establish the wave shape of the currents which arresters discharge in service. Comprehensive data have been published by McEachron and McMorris[2,3] on the magnitudes of arrester discharge currents. At the time of publication of the first paper[2] records were available from 1,225 installations which had been in operation for slightly more than one year in territories which were widely separated. A large amount of data was necessary to establish typical values for discharge currents because of the extreme variability of lightning due to seasonal variations and differences due to locality and perhaps type of circuit construction. Similarly it seems likely that several hundred measurements must be obtained in order to establish an accurate criterion for the wave shapes of arrester discharge currents.

Figure 7 of the paper has been prepared to permit estimates to be made of the magnitude and duration of the discharges to which distribution arresters may be subjected. It is based on the assumption that the continuing part of the lightning stroke consists of a constant current of 1,000 amperes lasting for times as long as 5,000 or 6,000 microseconds. The authors do not establish that such a discharge is typical of lightning. However, we feel that the difference in current drainage on urban and rural circuits may account for the higher failure rates of lightning protective devices sometimes experienced on rural circuits.

Figure 10 shows the current, measured by a fulchronograph, which was successfully discharged through a new Autovalve arrester. It is of interest to inquire if rated power voltage were applied to this arrester when the discharge occurred. In case no power voltage were applied, do the authors consider this operation to indicate that the arresters will stand such discharges in service?

There appears to be some inconsistency in the data on arrester protective characteristics given in table I. Using 58 kv for the breakdown of the 9-kv arrester and the data from table I for the 3- and 6-kv arresters, we obtain:

Arrester Rating (Volts)	Impulse Ratio
3,000	1.01
6,000	1.18
9,000	1.17

The impulse ratio of the 3,000-volt arrester is much lower than the impulse ratios for the arresters rated 6 and 9 kv which use the same type of gaps which seems inconsistent. In his contemporary paper (AIEE TRANSACTIONS, volume 59, 1940, pages 429–33) Mr. Berkey of the Westinghouse Company gives impulse ratios of 1.05 for single mica-spaced gaps and 1.20 for single ionization gaps which are at the top of the Autovalve arresters. Neither of these gaps has an impulse ratio as low as 1.01.

D. R. Pattison (nonmember; Pennsylvania Electric Company, Johnstown): The authors of this paper have approached the lightning-protection problem from a new angle to explain the high distribution-arrester failure rate under operating conditions. Their investigation does explain some of the high failure rate and operating men have often suspected something of this sort being responsible for the blowing of heavy arrester fuses and heavy cutout fuses or leads burned off in small transformers but could just never put their finger on the cause.

Referring to their summary in which it is stated that the most important problem is the matter of eliminating arrester failures, I believe that the weight of operating evidence indicates that a most important point in their investigation has been overlooked, that is, the problem of permanent sealing of the arresters.

Our operating experience has indicated that a large percentage of the distribution failures is caused or in some way effected by the deterioration of the gasket seal which allows the arrester to breathe and results in the entrapment of moisture and finally the failure of the arrester. Even the most recent developed units after short service periods show signs of leaking. Several test methods have been developed and used with varying results. Of these the sectional dielectric loss test and the high-voltage resistance tests seem to be the most reliable, but, oddly, units which have tested good with the above methods, have shown definite signs of moisture when subjected to sudden chilling of the gap ends with dry ice and immediately broken open. We do not believe this moisture got there during the manufacturing process for we have found some dry ones.

There is little doubt in anyone's mind that entrapped moisture does effect the arrester in several ways.

First, it does lower thermal capacity of the valve element and when the arrester is called on to pass current, the moisture is vaporized and the resulting pressure explodes the shell.

Second, a process develops in which the moisture condenses in the gap structure, and the higher potential gradient on the gaps at the line side is effective in breaking down the air at this point, the moisture becoming mixed with it to form corrosive acids which build up conducting salts finally causing sparking and more or less *permanent radio interference* until the first gap unit is completely short circuited. This process is again repeated on the next gap unit until enough of the gap structure has been short circuited to cause permanent breakdown and eventually failure of the arrester.

Third, during rapid temperature drops moisture is condensed on the inside of the arrester shell and becomes mixed with the other parts of broken-down air to form conducting islands and raises the potential gradient to a point where sparking occurs, causing *temporary radio interference*. Then as the temperature equalizes the moisture either freezes and becomes nonconducting or it is thrown off in suspension and the noise stops. This effect is probably the most troublesome item in the operating field for it starts the noise up with Lowell Thomas and usually ends with Paul Sullivan, requiring repeated investigation to clear the trouble.

Fourth, there is simply the result of numerous temperature cycles which eventually produce a conducting path on the inside of the shell which entirely short circuits the gap structure and impresses line voltage on the valve element and finally results in the failure of the arrester.

In the light of the foregoing, we believe that the problem of standardizing radio-noise levels, referred to in the paper, is not so necessary but rather the permanency of any adopted level would seem to be the important object and this cannot be had without some type of fused seal. Our operating experience with all types of gaskets has indicated that any gasket in contact with oxygen has a very short natural life, possibly around five years, and that anything done to increase the arrester capacity to provide for higher surge current or long-tailed waves would seem to be all the more justification for permanent sealing as an approach toward the perfect arrester.

Certainly the distribution engineer will anxiously await the full investigation of the subject of this paper for besides being a general nuisance it has been a costly item. Therefore, it deserves the full co-operation of both the manufacturers and the users of distribution lightning arresters.

H. A. P. Langstaff (West Penn Power Company, Pittsburgh, Pa.): The paper presented by Messrs. Bergvall and Beck reviews briefly the lightning-arrester problem and its many diversities involving performance, inspection, records, new designs, and means for obtaining more complete lightning discharge characteristics. This is all of great importance to a further improvement in the continuity of electrical service.

They prove that there is necessary further information with respect to the characteristics of lightning discharges which materially affect the arrester design. Many improvements have already been made and it is to be hoped that these improvements will continue. The West Penn Power Company has for several years been securing actual lightning discharge-current records for a number of lightning arrester installations varying in voltage from 132 kv down to 6,900 volts. Our studies have been confined mostly to the 132-kv and 25-kv systems.

We have installed a number of surge recorders consisting of two metal electrodes separated by a thin paper disk. A "densometer" and calibrated curves provide our means of obtaining approximate current values from the paper disks. The results of these records are shown in tables I and II of this discussion.

We have no record of surge current value over 5,000 amperes on 132-kv solidly grounded system.

Table II. Number of Records for 25-Kv System

Amperes	1935	1936	1937	1938	1939	Total
Up to 250	15	8	3	0	7	33
251–500	12	7	0	2	3	24
501–1,500	11	10	0	1	12	34
1,501–5,000	1	0	1	3	8	13
5,001–10,000	2	0	0	1	2	5
10,001–20,000	1	1	0	1	5	8
20,001–30,000	0	1	0	0	3	4
75,000	0	0	0	0	1	1
Total	42	27	4	8	41	122

From table II it is noted that 75 per cent of the discharges have been 1,500 amperes or less and 25 per cent above this value and up to 75,000 amperes. Our records show an accumulative percentage failure of approximately 2 per cent per year. We have for the past several years and are continuing to apply only line-type arresters on all voltages up to and including 44 kv. We have one 132-kv line-type application and probably would have more if erection facilities for this type of arrester were more feasible.

We have secured discharge records from all but one of our surge recorders. This has been in service for approximately five years at an indoor station supplied by seven 25-kv circuits protected by station-type arresters. The recorder is in the ground circuit of three 20-kv arresters connected to the main transformer bus.

During August 1939 we installed a fulchronograph recording unit in the ground circuit of three 25-kv line-type arresters located at the end of a $3^1/_2$-mile 25-kv circuit. Several arresters had been demolished at this station. We have obtained only one record of less than 100 amperes for approximately 100 microseconds. We hope to secure more records in 1940.

It may be of general interest to outline briefly several outstanding discharge records as they have a bearing on general applications.

Example 1. At one station in vulnerable lightning-discharge territory, we have a transformer bank protected by three 20-kv arresters connected to the 25-kv system with neutral grounded through resistance. This station has given 25-kv incoming lines each protected by a 25-kv electrolytic arrester. There are several 6,900-volt low-voltage feeders each protected with low-voltage arresters. In 1935 our records show 17,000 amperes discharge through the recorder with no equipment failure or outage. At a later date there was recorded a 28,000-ampere discharge through these same arresters with no equipment failure or outage.

Example 2. At another substation on the end of a $9^1/_2$-mile 25-kv line we have the transformers protected by three 20-kv line-type arresters and one record shows a discharge of 30,000 amperes arrester was destroyed.

Table I. Number of Records for 132-Kv System

Amperes	1935	1936	1937	1938	1939	
Up to 250	41	11	6	0	4	62
251–500	2	2	0	0	0	4
501–1,500	4	0	1	0	2	7
1,501–5,000	2	0	0	3	0	5
Total	49	13	7	3	6	78

Example 3. At another station having three 25-kv lines we have a record of 19,000 amperes discharge through 20-kv line-type arresters protecting the transformer bank with no equipment failure or outage.

Example 4. At a station fed by three 25-kv lines each protected by 25-kv line-type arresters we have the transformer bank protected by three arresters approximately 13 years old but reduced to the equivalent of a 20-kv arrester. Our records show a 12,000-ampere discharge through these old arresters with no equipment failure or outage.

Example 5. At the station where we have installed the fulchronograph recorder we have a record of 25,000 amperes discharge through 25-kv line-type arresters where one arrester was destroyed. We have lost a total of 11 arresters; five 20 kv and six 25 kv at or adjacent to this station.

Example 6. We have one record showing 75,000 amperes discharge through a 25-kv arrester and one of the three units was demolished with no other equipment failure. One of the $9^1/_2$-inch gaps on transformer bushing flashed over.

Based on our arrester experience, I suggest that the manufacturers continue to consider in their line-type arrester designs an arrangement whereby the arrester will clear itself in case of failure. Horizontal rather than vertical mounting might be considered. The mounting of 132-kv arresters would be simplified if the arrester columns could be made self-supporting.

Edward Piepho (The Detroit Edison Company, Detroit, Mich.): The authors have indicated some changes in our thinking with reference to distribution arresters which will be necessary considering the new conception of long-duration lightning strokes. There are other aspects of the lightning-protection problem which must also be reconsidered. For instance, flashovers caused by long-duration strokes will limit the benefits to be realized by high-speed switching or other similar schemes directed toward rapid fault interruption and reclosure.

It is also to be expected that long-duration strokes will increase the erosion rate and shorten the life of expulsion-tube arresters. During the past lightning season three cases of excessive tube-arrester erosion occurred on the Detroit Edison system which could be explained only by assumption of multiple or long-duration strokes.

The practice of interconnection of arrester grounds with other ground circuits is also involved in this problem. In some cases it may be undesirable to risk bringing long-duration lightning currents into other circuits by interconnection of arrester ground leads with these circuits, even though the anticipated lightning current may be low in magnitude. During one of last summer's storms in Detroit, an area of approximately nine square miles was subjected to severe lightning. Observers described some of the strokes as "flickering" in nature. Numerous customers' complaints resulted, some of which were due to low voltage caused by blown transformer fuses, and others due to troubles in customers' premises such as blown fuses and damaged wiring, or simply blown fuses. There were also four distribution transformer failures and seven watt-hour meters damaged in this area by the storm. An unusual feature of these troubles was the large number of customers' branch fuses blown without blowing of main fuses or apparent trouble in the house wiring. These troubles may have been caused by insulation failure between transformer primary and secondary which brought primary voltage in on secondary wires, or they may have resulted from direct strokes to customers' service wires. It is also possible that the trouble may have been caused by long-duration lightning currents flowing from the arrester ground wire to the secondary neutral by way of the interconnection, and thence through the transformer winding onto secondary wires and into customers' wiring.

I should like to inquire concerning the type of failure of arresters 4 and 5 whose electrodes are shown in figure 1*b*. Were the failures by flashover or puncture of the characteristic element?

In connection with impulse tests on the arrester described, oscillograms of which are shown in figures 9, 11, and 12, it is of interest to note that crest values of discharge voltage for the current surges used may be approximately duplicated with current waves having the same ampere-per-microsecond wave front but not necessarily as high crest values. Thus for example, a current wave of only 1,000-ampere crest but with 1,000-amperes-per-microsecond front will produce approximately as great crest discharge voltage as the wave shown in oscillogram 5 of figure 9. This relation appears to hold generally for all arresters having characteristic elements which discharge current partly by an ionization process.

I. W. Gross (American Gas and Electric Service Corporation, New York, N. Y.): In the early days of applying lightning arresters for protection, very little was heard about the 60-cycle rating of the arrester itself. It was customary to accept the manufacturer's rating of such a device and hope that it would supply the desired protection under lightning conditions about which very little was then known.

Many of the early lightning-arrester installations were made under conditions where the arrester was so well protected from 60-cycle failure by excess 60-cycle rating that it was not possible for such arresters to supply protection to equipment which in many cases had inherently lower insulation than the level maintained by the arrester. On our own system, as early as 1928, we reduced the 60-cycle rating of many arresters then in use by removing part of the active element, thus lowering the protective level provided by the arrester. This was done, as shown by operating experience since that time, without in any way encroaching on the lightning arrester permissible 60-cycle voltage.

From the days when lightning-arrester failures were often attributed to direct strokes, we have now come to the stage where only isolated cases of arrester failure can be charged to the magnitude of lightning currents.

To account for the low percentage of arrester failures which has been observed in practice, the authors have suggested that this is due in large part to long-tail current waves and not the old bug-a-boo of high lightning currents. From our experience where arresters have failed, and from spot-checking of arrester conditions in the field, it is believed that some of these failures may be attributed to arrester design or deterioration or a combination of both; just how large a part, at the present time, is uncertain. In other words, gap corrosion observed in the field has undoubtedly been responsible for many arrester failures. If long-tail current waves are responsible for a large part of the arrester failures which have been reported, it would seem that the frequency of such long-tail waves would have been observed to some extent at stations as well as at isolated installations on distribution lines. Our experience with lightning-arrester failures at stations does not indicate that the long-tail current wave has been the major cause of the relatively few arrester failures at stations.

If I understand the author's line of reasoning, they maintain that long-tail lightning-current waves are a hazard to arresters on rural lines remote from the source of power supply. But at the source of power, such currents do not impose as severe a condition on the arrester because the tail of the wave is drained off through the impedance of the station equipment and ground which is usually inherently low.

If such is the case, it would appear that the high-capacity station-type arresters properly belong out on the line, and the distribution-type low-capacity arrester may more properly be installed at the station if its protective characteristics are suitable. Since the economics of the situation does not permit this, would it not be possible to use distribution or line-type arresters at the station, with considerable resultant economy, and no increased hazard as regards arrester failure?

Herman Halperin (Commonwealth Edison Company, Chicago, Ill.): Operating experience showing that distribution arresters fail due to lightning, in spite of the general absence of the high-current surges, tends to support the authors' suggestion that these failures are often caused by surges of low current magnitude but long duration. I am wondering whether multiple surges could also be considered a factor in some cases. I am sure that those concerned with the protection of distribution-line equipment will await with interest the additional measurements of lightning surges on such systems which the authors are conducting to augment their preliminary investigations.

Following the authors' reasoning, we should expect low rates of arrester failure on the four-kv neutral-grounded system in Chicago. There is usually about one mile of cable from the substation transformer to the center of each circuit, with overhead extensions spreading out for a few blocks from cable taps to the main cable. The density of arresters is high and the average circuit has approximately 55 distribution transformers with a total capacity of over 2,000 kva. These factors apparently all work together to provide a low-impedance path for drainage of surge currents of long duration. The average rate of failure of arresters due to lightning is about 0.2 per cent per year, or about the same as some national figures, although many of the arresters are unusually old, that is, 15 or 20 years or older, and have a discharge capacity of only 1,000 or 1,500 amperes. For modern types of arresters, the annual rate is roughly $^1/_{40}$ of one per cent.

While the paper deals exclusively with the problem of arrester failures, it should be emphasized that we are primarily interested in protection of equipment. Nevertheless, it is quite gratifying to note the improvements in the arrester to make it more resistant to failure, while retaining good protective characteristics.

L. G. Smith (Consolidated Gas, Electric Light and Power Company of Baltimore, Baltimore, Md.): If, as the authors state, the cause of the disproportionate rate of lightning-arrester failures on some distribution systems has been determined, a considerable advance has been made. As is stated in the paper, data collected on the length of surges, the tests on arresters in the laboratories, the examination of arresters failing in service, and theoretical considerations all indicate the presence of long-tailed waves and therefore justify further intensive investigation to obtain probability data concerning these impulses of extremely long duration.

From the theoretical analysis presented, it appears that the sole limitation upon the length of that part of the wave that passes

Table III

Range of Average Ground Resistance (Ohms)	Lightning-Arrester Failures Per 100 Transformers			
	Standard Connection		Interconnection	
	All Types of Territory	Rural Territory	All Types of Territory	Rural Territory

through the arrester when a line flashover does not occur is the relative values of (R_1+R_2), (X_1+X_2), and R_3 (see figure 4 of the paper). The greater the value of R_3 (ground resistance of arrester grounds), the higher will be the voltage forcing drainage current through other paths. Since this theory is presented to explain why the arrester failure rate is low on one system and high on another, it is necessary to examine the probable variables in order to account for the differences. For similar types of areas served, R_1, X_1, and X_2 should not differ greatly for various systems. However R_2 (substation ground resistance) may vary. Likewise R_3 (arrester ground resistances) may vary. It would be of interest to correlate arrester failure rates with these factors. It is believed that substation ground resistances are substantially lower in urban and suburban areas than in rural areas. Therefore, it follows that arrester failure rates in rural areas should be higher than in urban and suburban areas.

In order to check this conclusion, the data summarized in reference 2 of the paper has been examined. For 1934 to 1936 lightning seasons the comparison in table III of this discussion is drawn. While not entirely conclusive, these data indicate somewhat higher failure rates in rural areas. Failure rates also increase with arrester ground resistances.

Although operating data indicate that as the arrester ground resistance increases the arrester failure rate becomes greater as the authors predict, theoretical considerations seem to show a reverse trend. It would be interesting if the authors demonstrated the theoretical basis for this contention. Arrester failure rates from data collected from various companies since 1934 have been analyzed by type of territory, grounded or ungrounded neutral, and ground resistance. An inspection of charts on which shotgun diagrams of the data were plotted indicates:

1. No definitely defined trends can be observed.
2. It cannot be concluded that arrester failure rates are higher on delta systems than on grounded-neutral star systems.
3. There seems to be a slight increase in arrester failure rates with increasing arrester ground resistance.

J. R. North (The Commonwealth and Southern Corporation, Jackson, Mich.): This paper presents a very interesting "story behind the development", and it is gratifying to learn of the studies made to improve the characteristics of these lightning arresters.

In paragraph 3, some rather definite statements are made concerning the distinctive markings left by surge discharge currents on the gap electrodes of lightning arresters, and it would be interesting to have supporting data in addition to that shown in figure 1a. We should also like to learn if these same types of markings occur irrespective as to the type of gap and with different types of arresters.

The paragraph under "Effect of System Characteristics" and figures 11 and 12 are apparently intended to illustrate tests which have been made on the new type of arrester. It would be interesting to have a direct comparison of these characteristics with those of the former design.

Referring to the first paragraph under "Summary", the fifth line states that ". . . it is believed that the most important problem is the matter of eliminating, as far as possible, the failures of protective devices. . ." True enough, the reduction in failures of lightning surge protective devices represents an important problem but, in our opinion, the "most important" problem is the matter of apparatus protection, and the infrequent failure of a lightning-surge protection device may be preferable to the failure of the equipment being protected. In years past, several very unfortunate failures of apparatus have occurred due to the inadequate protection afforded by what might be termed "self-protecting arresters".

The results of these studies suggest that further thought be given to modifying the present standard lightning-arrester test waves to test adequately the ability of arresters on long waves as well as on short ones. This subject is being given consideration by the AIEE lightning-arrester subcommittee.

P. L. Bellaschi (Westinghouse Electric and Manufacturing Company, Sharon, Pa.): Messrs. Bergvall and Beck have presented an interesting and important contribution on the influence of the network on the relative amount of lightning currents discharged through lightning arresters. The high-current component, because of its short duration and the high voltage associated with it, finds its way to ground within a short distance from the point of incidence of the stroke to the line, either as a flashover or directly through a protective device in the vicinity. The long-duration current components can travel over greater circuit distances, because of their relatively long time constants, and accordingly are partly by-passed to ground through transformers, etc.

In regard to long-duration components in lightning-stroke discharges, laboratory research and the correlation of the test results with field data ("Lightning Strokes in Field and Laboratory", P. L. Bellaschi, Electrical Engineering, November 1939) have established that the effective current may range from a few hundred amperes and less to several thousand amperes. The corresponding duration ranges from approximately one second to a millisecond. In this investigation, the electric charge has been estimated to range from possibly as high as 200 coulombs to a few coulombs, and to average between 25 to 50 coulombs.

The analysis and the correlation with experience, given in the paper, anticipate with apparently dependable assurance the performance expected of lightning arresters on various networks. The most severe duty to be expected would be from isolated-neutral systems which, however, are not common in this country. While detailed statistical data were not available at the time, the writer noted from his 1937 and 1939 experiences abroad, where the isolated neutral is common, that the service severity on lightning arresters was greater than originally expected—due, perhaps, in part also to switching surges.

An important aspect which affects the protection problem resides in the characteristics of the protective device itself. The protector tube is a very fitting illustration. By virtue of its operating principle, this and similar devices are relatively unaffected by the thermal and heating effects associated with long duration current components. The various applications and services (high-voltage lines, distribution circuits, and distribution transformers), for which this type of device has been developed and applied, give ample proof that not infrequently this type of device has been subjected to the test of full lightning-stroke discharges, yet, its performance on this score has been good. In fact, if anything, as the paper by Messrs. Sels and Gothberg (AIEE Transactions, volume 59, 1940, pages 328–31) indicates, there has been a demand for greater high-current-carrying capacity. Thus, it appears that given the inherent characteristics of the type of protective device and, in a measure, the nature of the protection problem is established.

R. C. Bergvall and **Edward Beck**: Mr. MacCarthy comments that many single-phase feeders branch out from three-phase systems supplied from a three-phase bank of transformers and that from his investigation he is doubtful that the analysis given by the authors of the paper for the substation transformer applies to such circuits. The authors' analysis was based on such installations and used conventional line-to-neutral methods of calculation. The system may be either three or single phase. If Mr. MacCarthy has some definite misgivings, we regret that he did not go into sufficient detail for us to give a more specific answer.

We acknowledge the important work done by McEachron and McMorris on arrester discharge currents referred to in Mr. MacCarthy's discussion. As a matter of fact, we have referred to it in the text of our paper and have used the observations of McEachron and McMorris in reaching our conclusions. As mentioned in our paper, the McEachron-McMorris data cover only crest current magnitudes and give no data on the duration of the discharge current. We believe that a number of measurements of arrester-discharge-current wave shapes must be obtained before any conclusions can be reached regarding prevalent types. Probably, it will develop that no one wave can be selected as typical.

Regarding the assumption of 1,000 amperes as the long component of the lightning-stroke current, this figure has been selected more or less arbitrarily. It is, however, true that the fulchronogram introduced as figure 10 of our paper, shows a long component of between 1,000 and 600 amperes. The calculations can be made and the curves derived on the basis of any magnitude of current; 1,000 amperes was selected by us because it appears at the present time not only a round, but also a reasonable figure.

Regarding Mr. MacCarthy's question in reference to figure 10 of our paper, which shows a stroke current discharged through an Autovalve arrester and recorded on the Cathedral of Learning, the arrester was not subjected to rated power voltage at the time of the discharge. The installation on the Cathedral of Learning was made to measure the complete stroke current and also to test the arrester with such a discharge current. If a transformer had paralleled the arrester in order to apply power voltage to it, a great part of the long component of the stroke would have passed through the transformer and not through the arrester, thereby considerably lightening the duty on the arrester. The follow current which an arrester of this type will pass following a surge discharge is small, in the order of 15 to 20 ampere crest at full rated voltage. Although we do not know definitely, it is our opinion that the performance of the arrester in this case would not have been altered by follow current. We wish again to call attention to the opinion expressed in the paper; that the current discharged through lightning arresters in service and the current in direct strokes may be quite different. At any rate, it is not possible at this time to correlate the two. It is our opinion that the discharge current through arresters in service would not be as severe as in the stroke which hits the system and produces the arrester discharge current. On the other hand, undoubtedly currents more severe than that shown in figure 10 will be experienced in a small percentage of cases.

Mr. MacCarthy calls attention to variations in the impulse ratio of breakdown of the arresters of different ratings. The 3,000-volt arrester is most favorable because of the short gap and the small number of its component parts. We have found that as the length and number of parts of the gap is increased, the impulse ratio is also increased slightly. It is to be noted, however, that the impulse ratios found on the 6,000- and 9,000-volt arresters are low and that the impulse breakdowns are consistent. Mr. Berkey's tests were made on single gaps. The data given in our paper are the results of tests on complete arresters in which the gap consists of a combination of both the quenching and ionization gaps described by Mr. Berkey. Additional information on this subject is given in the discussion of Mr. Berkey's paper by one of the authors.

The discussion by Mr. Pattison is of considerable interest to arrester manufacturers because it describes factors in the construction and application of apparatus which are of great moment from an operating standpoint. The point raised by Mr. Pattison about avoiding the entrance or effects of moisture in arresters with the resulting possibility of moisture causing arrester failure and the much greater possibility of moisture causing radio interference is important. We believe this factor is given much weight by all arrester manufacturers. Some years ago when radio broadcasting really became a popular pastime, probably all arrester manufacturers went through a period of excitement and trouble. In view of this experience, much attention has been given the matter of moisture. We believe that in arresters built in recent years the problem of moisture exclusion is negligible; at least it is so in the type of arrester construction and housing described in our paper. Regarding the matter of the fused seal mentioned by Mr. Pattison, we acknowledge that this is desirable. It is being used to a considerable extent in Autovalve arresters of the higher voltage ratings. This subject is receiving continual study but no economical way has yet been found of commercially incorporating this method of sealing in the lower-voltage arresters.

In connection with the matter of radio interference, it has been the authors' experience that occasional complaints are received that modern arresters are causing radio interference. It has been our practice always to investigate each case in the laboratory, and we have found only a negligible percentage of arresters in which there might be a bare possibility of interference with radio reception in the field. It has been quite difficult for us to coordinate the complaints with our laboratory tests and usually upon requesting further information as to how the tests in the field were made and how the interference was run down to the arrester, the subject dies. We have found cases of complaints where some microvolts of noise current were registered in the laboratory on arresters which were returned with conductors still spliced to them. In these cases it developed that the seat of the noise current was the splice, and that removal of it, or an improvement in the splice, eliminated the noise current or reduced it to a negligible value. Although we do not mean to assert that there may not occasionally occur a case of radio interference on an arrester which is made in mass production, we would like to call attention to the fact that in many cases the interference which was experienced in the field will have been caused by the connections.

Mr. Pattison calls attention to a method of determining the moisture content of the air in an arrester by chilling it with dry ice. There is always some amount of moisture in the atmosphere at room temperature such as exists on a manufacturing floor. If this atmosphere is chilled sufficiently to pass the dew point, then moisture will be precipitated. This possibility of moisture in sufficient quantity to be hazardous being introduced into an arrester during the assembly period has been recognized, and in the arresters discussed in our paper the assembly is carried out in an air-conditioned room in which the temperature and moisture content is controlled.

We agree with Mr. Pattison that this problem merits continuous study and we believe a good deal of good can be accomplished by co-operation between the user and the manufacturer, especially if this enables some co-ordination between laboratory tests and field results, leading to reliable and accepted methods of laboratory tests.

Mr. Langstaff has collected a considerable amount of significant data on discharge currents on his 132- and 25-kv systems. The indications again are that low discharge currents preponderate, as 75 per cent of his records show not more than 1,500 amperes. It is hoped that the fulchronograph installation mentioned by Mr. Langstaff will yield some significant data on wave shape to augment the records of crest current. The location appears to be a vulnerable one since 11 arresters have been lost in its vicinity.

Mr. Langstaff's records on the 132-kv system show no discharges in excess of 5,000 amperes in a total of 78 covering a period of five years. This, together with the data presented by Messrs. Gross and McMorris in a contemporary paper suggests that the performance of arresters at 5,000 amperes is a good point for co-ordinating insulation and arresters on high-voltage lines, at least.

Mr. Piepho has made some interesting observations on possible practical effects of surges of long duration. Since the Detroit Edison distribution system is one with a free neutral, arresters should be subjected to the full duration of the stroke currents, except for the effect of line flashovers. We understand that the arrester failure record in Detroit is very low, and this is of considerable interest as it indicates that some other factor may be operating in that locality perhaps to make the long-tailed discharge very exceptional. Further observation in this connection should be of value. The ground resistances or soil resistivity might be involved in this. On the other hand, Mr. Piepho cites a storm whose visible manifestations indicate long-duration strokes. Some further investigation of the blowing of customers' branch fuses would be desirable. We would suggest that Mr. Piepho make some surge tests on common house fuses and determine what it takes to blow them on surges.

Regarding Mr. Piepho's question about the type of failure experienced in the cases of 4 and 5 in figure 1 of the paper, the actual data on these particular arresters are not at hand, so the question cannot be answered specifically. On the type of arrester represented in this figure, the Autovalve arrester preceding the distribution arrester described in our paper, the prevalent type of block damage found in the arresters examined has been a partial flashover usually accompanied by small short punctures at the ends near the edge. There have been more cases of this kind than pure punctures. Parts 4 and 5 of figure 1 were probably such, although they might have been of either type. We have not found that the appearance of a damaged block is a guide to the duration of the discharge. The observations on damaged blocks led to the development of a new baked insulating coating for the block which, as far as our experience in the laboratory and the field goes, appears to eliminate the flashover, and thereby permits full use of the capabilities of the block itself. This finish is white in color as shown in figure 8 of the paper.

Mr. Gross, as well as Mr. Pattison has mentioned corrosion and other factors as possible causes of arrester failure. We have not intended to assert that long-tailed waves are the only cause of arrester failure, since other causes are recognized in the case of arresters of early construction more so than in those built within the last six or eight years. This was indicated at the beginning of the paper. It is our opinion, however, that the long-duration discharge, particularly on rural distribution systems, is an important factor in arrester performance and that greater immunity to this type of discharge should result in longer average arrester life. From our examination of a large number of distribution arresters that had been in service from one to eight years, we were impressed with the negligible evidence of moisture or deterioration.

As stated by Mr. Gross, the duty on arresters on rural lines increases with distance from a grounded-neutral source. This is shown by figure 5 of this discussion, which gives the result of some calculations on an actual distribution system, in comparative wave shapes of the arrester discharge currents, assuming a 1,000-ampere continuous current in the stroke.

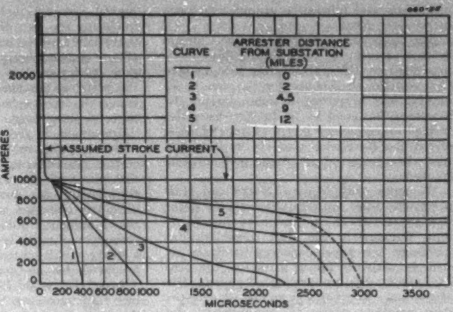

Figure 5. Current discharged through arresters; calculations on actual system

The selection of line-type or station arresters is largely influenced by economics, protected level, and discharge capacity. Line-type arresters cost less. Station arresters provide greater discharge capacity, and they also establish a lower protected level. From papers previously published, there is some indication that on some systems good results are achieved by line-type arresters. We do not believe Mr. Gross' question can be answered categorically with assurance until considerably more data are available.

We are glad that Mr. Smith raised the important question of ground resistance. In the explanation below figure 4 of the paper the following statement is made, "Variation of R_3 through a 10–50 ohm range does not change I_1 appreciably." This is based on the neutral wire forming a metallic path to the substation ground that is in parallel with the arrester grounds. Also, the neutral wire parallels many arrester grounds. Space limitations prevented our presenting the differential equations worked out for various values of R_3. The results for two typical cases are tabulated below:

Case 1. Time for I_1 to Reach 1,000 Amperes

R_3	5	10	50	100
Micro seconds	1,515	1,375	1,320	1,320

Case 2. Current I_1 Versus Time for Various Values of R_3

	Amperes		
R_3 (Ohms)	300 Micro-seconds	500 Micro-seconds	1,000 Micro-seconds
5	325	470	835
10	400	525	845
50	535	650	890
100	560	675	900

For a system where the only ground is at the substation so that there is no metallic connection between the arrester grounds and the substation ground, a higher R_3 will effectively force drainage current to the substation as Mr. Smith states. In this case, a low substation ground resistance R_3 is important because the voltage drop across it will keep I_1 from building up and relieving the arrester. For the connection in figure 4, R_3 is not such a factor because there is a low-time-constant metallic shunt path in parallel with the arrester through the line, substation transformer, and neutral wire in which E_a is acting to increase I_1 and unload the arrester. This question of ground resistance effects is so nebulous at present that it is an open field for much further work.

This rough analysis indicates that to be of value the statistical work must consider the type of system in evaluating the effect of arrester and substation ground resistance on arrester duty.

Mr. Halperin's experience on the Chicago system appears to corroborate the theory presented in the paper. We also believe that multiple strokes account for some cases of damaged arresters, in fact, among the arresters examined by us in the study described in the paper, the appearance of some of the gap electrodes aroused the suspicion that the arresters had discharged multiple strokes.

We agree with Messrs. North and Halperin who have both emphasized the point that protection of equipment against lightning damage is the first consideration. Although the paper concerns itself almost entirely with the life of arresters, the protection aspect is not considered closed. We agree that it is preferable to lose an arrester than another piece of equipment. In writing the paper, however, it appeared to us that with the arresters now available and with careful application, the protection problem is in quite satisfactory condition, and that at the moment the matter of freedom from damage to the arresters themselves was the more important, particularly in distribution systems to which the paper has confined itself.

A large number of laboratory calibrations of the surge marks left on gap electrodes have been made, of which figure 1*a* is typical only. Our calibrations are applicable only to the gap construction used in Autovalve arresters. Although we have not calibrated other types of gaps, we have found that the appearance of the marks is influenced by the material and form of the electrodes and will alter with significant changes in the gap spacing.

As remarked by Mr. North, figures 11 and 12 of our paper are tests made on the new arrester described in the paper. The discharge characteristics of the earlier type of Autovalve distribution arresters are of the same order.

Mr. Bellaschi's discussion lends further weight to the authors' suspicion of long-duration discharges, and we wish to acknowledge that Mr. Bellaschi's well-known researches in the laboratory and his coordination of observed natural phenomena with laboratory results gave us considerable assurance during the writing of our paper.

Enclosed Spark Gaps

Discussion and author's closure of paper 40-61 by Wm. E. Berkey, presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940, and published in AIEE TRANSACTIONS, 1940 (August section) pages 429–33.

L. J. Berberich and **M. E. Bell** (nonmember; both of Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): Mr. Berkey has pointed out a very interesting phenomenon in connection with lightning-arrester spark gaps. This was first observed when a rutile spacer was substituted for the usual porcelain spacer. The wide difference between the dielectric constants of rutile and of air leads to large stress concentrations at the edges of the spacer. Radiations are produced in these highly stressed air spaces which aid in initiating the gap discharge, resulting in a materially lowered impulse ratio. The same effects can be observed, but to a lesser degree, with porcelain spacers, particularly if the physical arrangement is such as to increase the stress concentrations at the metal-porcelain boundary.

Inasmuch as the behavior of a material under impulse voltage is determined to a certain degree by its high-frequency properties, the performance of the rutile gap as described by Mr. Berkey is due to the high dielectric constant at high frequency. As the information published on the dielectric properties of rutile is meager, we have made a study of this material. A paper has been prepared by us for publication in the *Journal of Applied Physics*. We will therefore limit ourselves to a brief discussion of the properties most pertinent here.

Rutile is one of three crystalline modifications of titanium dioxide. It has a body-centered tetragonal lattice, being the most dense of the three forms and the one stable at the highest temperature. Figure 1 of this discussion gives the dielectric constants and power factors over a range of frequency from 60 to 10^6 cycles for three specimens prepared from powdered crystals. Specimen 1 contained 98.2 per cent pure rutile and was fired at 1,675 degrees centigrade. Specimen 2 contained the same material with the addition of 5 per cent of a low-dielectric-constant ceramic binder and was fired at 1,330 degrees centigrade. Specimen 3 had the same composition as specimen 1, but was fired at 1,330 degrees centigrade. This shows that high-temperature firing is necessary for obtaining the highest dielectric constant and that a small admixture of low-dielectric-constant material can reduce the dielectric constant markedly. Specimens 2 and 3 are representative of material used by Mr. Berkey as gap spacers. Rutile is remarkable among dielectric materials in that it has a very high dielectric constant extending over a wide range of frequency accompanied by a low power factor. Infrared reflection data are available which show that the high dielectric constant persists to a frequency of about 10^{12} cycles (300 microns).

A qualitative explanation of the high dielectric constant can be made in the light of published work on weakly ionic crystals, assuming that the degree of ionic binding varies with the distance between titanium and oxygen atoms. This results in a disproportionately large transfer of electronic charge for a small shift in the positions of the titanium nuclei relative to those of the oxygen nuclei. This is in agreement with the evidence from infrared data which suggests an atomic polarization of an unusual type.

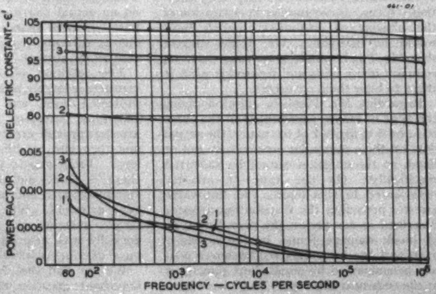

Figure 1. Power factor and dielectric constant versus frequency at 30 degrees centigrade for rutile specimens 1, 2, and 3

Theodore Brownlee (General Electric Company, Pittsfield, Mass.): Our laboratory experience confirms that of Mr. Berkey in that we find the same erratic impulse breakdown and high impulse ratio of gaps not subject to ionization, and much more consistency and lower impulse ratio of gaps in which the electrodes are exposed to ionization. Also we concur with his analysis of the reason for the good impulse performance of mica-spaced gaps and the rutile- or porcelain-spaced gaps of the designs he shows.

However, we disagree with the statement that this factor of ionization hitherto has been unrecognized. This factor has been recognized for many years and we have long used mica-spaced gaps to secure low and consistent impulse breakdown values in low-voltage protective devices which require the lowest possible impulse levels. It also has been recognized for a long time in Mr. Berkey's company. In 1926 an article ("Theory of the Autovalve Arrester," Joseph Slepian, AIEE TRANSACTIONS, volume 45, 1926, pages 169–74) concerning the mechanism of impulse discharge in the Autovalve arrester of that day, read in part as follows:

> "The mica, having a dielectric constant of six to seven, distorts the electrostatic field, very much as if it were conducting. Thus there is a concentration of electrostatic stress at the corners of the mica. . . Hence when a little more than 350 volts is applied, these highly stressed points break down and precipitate the discharge of the whole gap."

We have experimented with another method of reducing the impulse ratio. When porcelain spacers are replaced by similar-shaped spacers of high-resistance material, the impulse ratio is materially lowered. This improvement is attributed to minute ionizing sparks on the inner surface of the resistance gap spacers.

Still another method of securing low impulse ratio has been used in the Thyrite station arresters since 1933. This method operates on a series of gaps in close proximity, rather than on individual gaps discussed previously. The nine gaps in an 11.5-kv unit are resistance shunted. While the resistance values and gap settings are so chosen that none are overstressed at operating voltage, they are designed so that on impulse the gaps break down in a predetermined order starting at one end. The gaps are so arranged that the first gap to spark illuminates the remaining gaps, thereby effectively reducing their time lag.

In addition to this, a low over-all impulse ratio is attained, especially with several units in series, because the resistance shunts are selected to maintain a uniform voltage distribution at power frequency but a nonuniform voltage distribution at the rapid rates of voltage rise associated with impulse breakdowns.

There appear to be several inconsistencies in the data which Mr. Berkey presents. He states that leaded contacts improve the impulse ratio of porcelain-spaced gaps but do not affect rutile-spaced gaps. Comparing the results on rutile-spaced gaps in tables I and II we see that leaded contacts reduced the impulse ratio from 1.12 to 1.07. Also in table I we find leaded contacts improve the impulse ratio of porcelain-spaced gaps from 1.75 to 1.23 while the corresponding change in table II is from 1.72 to 1.36. In comparing average impulse ratios determined from several groups of breakdowns, we have usually found variations in the third significant figure and often the second. This very possibly explains the discrepancies mentioned above.

Edward Beck (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): Mr. Berkey's paper describes an important research on factors which influence the impulse breakdown of enclosed spark gaps such as are used in arresters. The work done on rutile and other materials and arrangements explains the better than expected performance of plain porcelain-insulated gaps used for some time in the past in arresters. The preionizing effect is apparently always present. If properly controlled it results in consistent and low impulse ratios. If not properly controlled, the impulse breakdowns may be variable. The understanding of the phenomena gained by this research work also shows ways of controlling and improving it, as described in the paper. These improved methods have been applied in Autovalve arresters. Mention has been made of a type of gap with good impulse ratio in reference 11 of the paper.

A combination of the quenching and the ionization gap illustrated by figures 9 and 10 of the Berkey paper are employed in the new distribution arrester which has been described in the contemporary Bergvall and Beck paper on "Lightning and Lightning Protection on Distribution Systems" (TRANSACTIONS pages 442–9) and illustrated by figure 8 of that paper. Some data on the impulse breakdown performance of these arresters is of interest as indicative of the consistency and low ratio of such gaps.

In these arresters the quenching gap and the ionization gap are used together in series, and the number of gaps of each kind increases with the arrester rating. Mr. Berkey's tests were made on single elements of these gaps. The performance of the combinations is not necessarily proportional to that of the single elements, hence the typical test data given in the following is of interest.

A three-kilovolt arrester tested for breakdown on the front of a test wave rising at the rate of 90 kv per microsecond gave with seven positive impulses applied a minimum breakdown of 20 and a maximum of 21; with seven negative impulses applied a minimum of $18^{1}/_{2}$ and a maximum of 20. The 60-cycle crest breakdown was 18 kv.

Tests on three different nine-kilovolt arresters with a wave of 148 kv per microsecond with six shots on each arrester, gave a minimum breakdown of 47 kv and a maximum of 53 kv. The 60-cycle crest breakdowns were 42 to 46 kv.

The 3,000-volt arrester which had been subjected to a direct stroke on the Cathedral of Learning, when checked for impulse breakdown afterward gave impulse breakdowns of 20 to 22 kv.

Another indication of the presence of preionization as a result of local discharges is the following. A very large number of tests for radio interference have been made under various conditions on distribution arresters incorporating this gap structure. This was an important item in the development program. The tests were made in a standardized test circuit, microvolts of "noise" being measured directly in the arrester circuit. It was found that low microvolt measurements (5–20) were obtained at voltages applied to the arrester which were below the breakdown of the gap.

This might increase as the voltage is raised farther to 60-cycle breakdown. The 60-cycle breakdown voltages are very consistent.

The voltage at which the ionizing current just becomes measurable is well above the rated voltage of the arresters, so that there are large factors of safety against interference with radio reception in the field.

W. E. Berkey: The discussion by Mr. Brownlee has brought up several points.

(1). Concerning the time of recognition of the importance of ionization on spark-gap behavior, the second sentence in the introduction states, "To obtain a low impulse ratio it has long been known that some form of ionizing radiation must be present."[1-4] More than 50 years ago Hertz[2] discovered the effect and importance of ionizing radiation on the breakdown of a spark gap.

(2). The low breakdown effected by the mica spacer in the early Autovalve arrester was discussed with Doctor Slepian. He agreed that the breakdown theory proposed then and the theory of operation given in the present paper are not comparable. In the early Autovalve, breakdown apparently took place over the edge of the mica-ring spacer and quickly spread over the electrodes. The initial breakdown was essentially a surface flashover of insulation. The present paper attributes the observed lowering of impulse breakdown voltage in enclosed spark gaps to ionizing radiation emitted from normally invisible discharges located in the insulator-electrode contact regions. These ionizing radiations are effective in lowering the breakdown of a spark gap at a *distance* away from their source.

(3). The use of resistance spacers greatly reduces the intensity of the effective radiation. This is due to the fact that the usual clay bond used in such resistance spacers has an effective low dielectric constant at equivalent impulse test frequencies. A single resistance-spacer gap without auxiliary surface sparking has a high impulse ratio. However, when many single gaps are stacked in series another important factor appears, namely, the voltage balance over the stack. Resistance spacers are used to give a high 60-cycle breakdown. The impulse breakdown with a stack of resistance-spacer gaps is not much different from that obtained with porcelain-spacer gaps. Thus the lower impulse ratio obtained with resistance spacers is due to an increased 60-cycle breakdown.

(4). The data in table I are the average values obtained with several gaps of the same type tested on many days. In table II are found values obtained with one typical test all made on the same day. In general the day-to-day and gap-to-gap variations are greater than repeated tests made on the same day. The third place in the impulse ratio is significant only when comparing gaps with low impulse ratios or "fast" gaps.

Berberich and Bell have described the extremely interesting and important physical properties of rutile with respect to its application as a spark-gap spacer.

Mr. Beck has given test data on arresters utilizing the self-generated ionizing radiations. Several design and control problems are mentioned. As the intensity of this ionizing radiation depends upon the displacement current in the insulator, one may ask how the impulse ratio varies with the rate of impulse-voltage rise. A rutile-spacer gap was tested for impulse breakdown at 100, 50, 25, and 1 kv per microsecond rate of voltage increase. The impulse ratio was low over the range indicating that while the radiation intensity may be lower at slow voltage rises, the time of overvoltage is relatively long and therefore little change in impulse ratio could be expected. Conversely on fast rises the ionizing radiation intensity is increased which insures the formation of an electron on the cathode surface at the right place and time to insure a short time lag of breakdown.

The CAA-MIT Microwave Instrument Landing System

Discussion of paper 40-44 by E. L. Bowles, W. L. Barrow, W. M. Hall, F. D. Lewis, and D. E. Kerr, presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940, and published in AIEE TRANSACTIONS, 1940, pages 859–65.

C. Francis Harding: See discussion, this page.

The Development of the Civil Aeronautics Authority Instrument Landing System at Indianapolis

Discussion of paper 40-43 by W. E. Jackson, A. Alford, P. F. Byrne, and H. B. Fischer, presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940, and published in AIEE TRANSACTIONS, 1940, pages 849–58.

Harry Diamond (National Bureau of Standards, Washington, D. C.): It may be of interest to compare the Civil Aeronautics Authority system at Indianapolis with the system set up by the National Bureau of Standards at Newark about seven years ago.* Many instrument landings were made on the Newark installation and the setup was considered by many pilots as suitable for airline experimental use. The achievements represented by the Indianapolis setup lie primarily in the provision of control of the individual elements of the system.

It is gratifying to note that every one of the modifications indicated to be desirable by the Newark tests have been incorporated in the Indianapolis system. Bends in the runway-beacon course are eliminated by control of the space-radiation pattern. The required course sharpness is obtained by sharper radiation patterns rather than in the course indicator, thereby providing increased course stability. The marker beacons, taken over from the Army system, have means for controlling the radiated patterns to conform with particular installation requirements. Finally, the glide path is made to have a shape desired by pilots and more easily applied to airports having long runways.

The authors of the paper are to be congratulated on the excellent progress made. The provision of means for controlling the shape of the glide path represents, perhaps, the outstanding achievement. By virtue of these means, the constant-intensity glide path becomes definitely superior to the equisignal type. Aside from the greater flexibility of path shape obtainable, there is considerable simplification and economy of equipment. Careful consideration of all of the factors involved will show that the stability of path is equivalent for the two types.

Since the demonstration at Indianapolis, Y. C. Houghton of the Department of Justice and I have devised, on paper, a second arrangement for controlling path shape which may afford some advantage over that employed at Indianapolis or may be used in conjunction with it to simplify the antenna required. It consists of progressively varying the reflecting coefficient of the ground along a strip in front of the radiating antenna system so that the interference between the direct and ground reflected waves produce paths of constant intensity having shapes which are practically linear. For example, the strip may be 30 feet wide and 150 feet long, extending from a point 100 feet in front of the antenna. The reflection coefficient along this strip is dependent upon the value of the factor

$$K' = K - \frac{2j\sigma c^2}{f},$$

where K is the dielectric constant (electrostatic units), σ is the conductivity (electromagnetic units), f is the frequency (cycles per second), and c is the velocity of light (3×10^{10} centimeters per second). To secure a progressive change in the reflection coefficient along the length of the reflecting strip such as to produce the shape of glide path specified as desirable by the Radio Technical Committee for Aeronautics, the factor K' must be made to vary from a value of about 360 at the point nearest to the antenna to a value of about 2 at the point farthest from the antenna. The desired distribution of the factor K' may be accomplished quite simply by a system of variably-spaced copper strips parallel to each other and perpendicular to the length of the reflecting surface combined with the use of a material of low dielectric constant (such as asphalt) for the surface of the reflecting strip. Note that the maximum conductivity required is of the order of 2×10^{-11} electromagnetic units, approximately that of sea water.

C. Francis Harding (Purdue University, Lafayette, Ind.): No presentation nor discussion of papers upon the application of the cathode-ray oscilloscope to the blind landing of airplanes would be complete without giving recognition to that developed by Professors R. H. George and H. J. Heim of the electrical division of the Purdue Research Foundation.

This system differs from those described in that the oscilloscope in the cockpit of the airplane shows, upon approach to the landing field, six distinct bright spots directed from six small short-wave radio transmitters located at the four corners and the midway side locations of the airport or along the runway. These radio impulses are transmitted on a single wavelength in sequence around the field in such rapid succession that the persistence of vision of the pilot provides the impression of a rectangular outline of lights of proper contour to indicate the shape of the airport and the direction of approach of the plane from any point not necessarily on a radio beacon. Such an indication is, of course, available whether the lights of the airport can be seen or not.

These transmitters, very small in size may be located on the borders of the airport in such a manner as to provide no interference with the landing operation, while the receivers in the plane may be made of sufficiently small size and weight as not to be objectionable. Indeed, the George-Heim system is capable of providing the pilot with more information than the glide-path system, although the Civil Aeronautics Authority-Massachusetts Institute of Technology system approaches most closely to the former. By properly locating the transmitters the system developed at Purdue University can be made to supply the three-light pattern for a glide path as described in the papers under discussion. In addition the outline of the runway or the entire airport would be outlined. It would, therefore, be unnecessary to have other supplementary equipment. If six, or even less, transmitters are used along the runway, the pilot should be able to choose his glide path from the perspective of the light spots.

Such a system has been under development for some time at Purdue University and promising results have been obtained with ground tests. Equipment has been constructed for flight tests which will be undertaken this spring.

The Cross-Air-Blast Circuit Breaker

Discussion and authors' closure of paper 40-19 by D. C. Prince, J. A. Henley, and W. K. Rankin, presented at the AIEE winter convention, New York, N. Y., January 22-26, 1940, and published in AIEE TRANSACTIONS, 1940 (September section) pages 510-17.

R. J. Wensley: See discussion, page 1127.

J. B. MacNeill: See discussion, page 1123.

H. W. Haberl: See discussion, page 1129.

C. M. Gilt: See discussion, page 1125.

C. G. Suits (nonmember; General Electric Company, Schenectady, N. Y.): When the great complexity of the physical phenomena in a breaker of this kind is considered, it must be agreed that the authors have done a very satisfactory job of interpreting their measurements. Their discovery that there are regions in the current and voltage range of the breaker where displacement phenomena and cooling phenomena may be identified represents a fundamental advance in our knowledge of the interrupting mechanism. Too often in the past it has been the effort of workers in this field to prove that a single mechanism was active to the exclusion of all others. In view of the findings of this paper it is not surprising that it has been possible to make out a very good case for both a displacement theory and a deionization theory in specific instances. In the present case both are found and their domains are defined. The discussion of this question in appendix *C* of the authors' paper is particularly good.

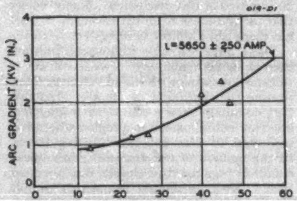

Figure 1. Gradient-pressure, cross-blast breaker

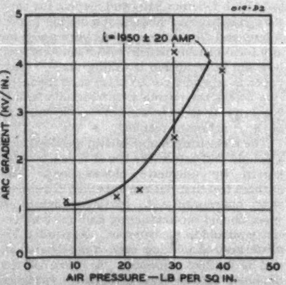

Figure 2. Gradient-pressure, cross-blast breaker

With regard to the question of the ranges of current and voltage in which displacement and cooling are important, it seems to me that the direct experimental evidence of the follow current as observed by the modification of the recovery oscillation provides much more convincing evidence than the physical argument based on the concept of Kesselring and Koppelmann. This concept has no experimental support and probably departs seriously from the detailed phenomena.

The use of impulse breakdown data of a rod gap as an index of the pressure improvement of interrupting ability as measured by the recovery strength characteristic is probably justified, but because the electrode shape factor may be very important in determining this pressure-breakdown curve (see, for example, I. Goldman and B. Wul, *Tech. Phys. U.S.S.R.*, volume 1, 1935, page 497; volume 3, 1936, page 16 and page 519), it would have been better to have taken the pressure-breakdown data on the same electrode structure used in the breaker.

Many questions may be raised concerning the physics of the breakdown between "ionized stumps" described by the authors as part of the displacement process. That the arc column does not cool uniformly, however, can be seen in the photographs, and in a very recent publication by Beams and Snoddy (*Phys. Rev.*, volume 57, 1940, page 63) a direct study of disruptive discharges between "ionized stumps" has been made. These authors used oxygen-gas flames as electrodes and observed a breakdown gradient of eight kv per centimeter over a ten-centimeter path, which is about one-fourth the value for sphere gaps, but is in excellent agreement with the impulse breakdown of the two-centimeter rod gap.

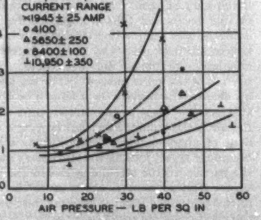

Figure 3. Gradient-pressure, cross-blast breaker

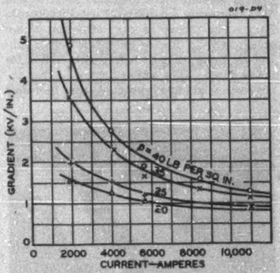

Figure 4. Gradient-current, cross-blast breaker (at indicated tank pressures)

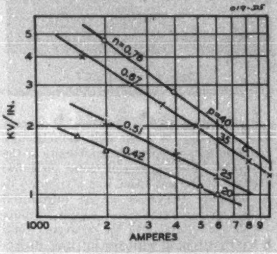

Figure 5. Log-log plots of gradient and current to determine n

It is stated in the paper that "there seems to be a purely random relation between arc drop just prior to clearing," by which I presume the authors meant to imply that the effect of cooling factors is not apparent in the magnitude of the arc drop. A close examination of table I, however, shows this effect very clearly. Figures 1 and 2 of this discussion show the gradient in kilovolts per inch as a function of air pressure in pounds per square inch for the case of the cross-blast breaker at 5,650 amperes and 1,950 amperes. These are the only two cases which have as many as six points for the curve, and unless the experimental error is ±50 per cent, there is definite evidence of an increase in gradient with air pressure. At the other values of current there are shown at most only four experimental points, and in most cases only three, so that for a necessarily large spread these few points do not make a very satisfactory curve. All points of table I, however, do fit in very well with a family of curves of gradient versus air pressure, as shown in figure 3 of this discussion. Considering the necessarily small deflections from which arc voltage was taken, the set of curves is quite convincing. This is just the type of variation in gradient with pressure that one would predict on theoretical grounds. From the set of curves of figure 3 one may plot the gradient-current characteristics as in figure 4 of this discussion, and determine the exponents of the gradient-current relation $E = \text{const } i^{-n}$ from log-log plots in figure 5 of this discussion. These exponents for pressures from 20 to 40 pounds per square inch are 0.42, 0.51, 0.67, and 0.76. In a paper on application of heat transfer data (*Phys. Rev.*, volume 55, 1939, page

1184) this exponent has been calculated for the case of forced convection leading to $n = 0.54$, which is satisfactory agreement when the spread in the experimental points and the assumptions of the theory are considered. That the arc gradient prior to the current zero depends upon the air pressure seems to be a necessary conclusion quite apart from the experimental data. Indeed, it seems difficult to imagine on what else the arc voltage could depend.

It may be argued that no failure tests are shown by table I. However, the curve of figure 5 shows the increase of interrupting ability with pressure, while the plot of figure 3 of this discussion shows the increase in gradient with pressure, so that there can be no doubt that a correlation exists between interrupting ability and arc gradient prior to interruption.

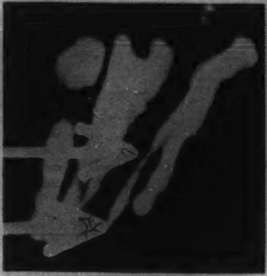

Figure 6. Picture 17

Joseph Slepian (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): The theory of the extinction of a-c arcs in rapidly flowing fluids has been a subject of lively debate before the AIEE for many years. The senior author of this paper some years ago presented what he called a displacement theory, in which, at current zero, a wedge of fresh and dielectrically sound fluid interrupted the continuity of the arc path. The recovering total dielectric strength of the arc space was attributed to the growing thickness of the introduced wedge, and an attractively simple formula was derived correlating the recovered total dielectric strength with the intrinsic dielectric strength of the normal fluid and its velocity. Much data was given to support this simple formula.

The present discusser disputed strongly the interpretation of the data offered, and gave many arguments why the simple displacement theory must be invalid. Since these arguments are all printed in past Transactions, it is unnecessary to repeat them here, except perhaps the one incontestable point, that careful examination shows that the pure streaming of a fluid according to accepted hydrodynamical or aerodynamical principles, can in no way lead to the introduction of a wedge into the arc path.

In the present paper, the displacement theory is again offered, with the accompanying attractively simple equation, but there now begins to appear a sign of uncertainty. The displacement theory is now thought perhaps not to be applicable at current zero, but the strong diffusive forces of thermal conduction and deionization are now permitted to account completely for the recovered dielectric strength for as much as ten microseconds. This is most encouraging.

The present discusser has contended that diffusive effects, must in the last analysis be responsible for the arc extinction. Streaming, alone, cannot interrupt the continuity of the arc path, or by itself, change in a large way the temperature or ion density in actual gas volumes in which the arc has been playing. Streaming, however, can make diffusion very much more effective by changing the configuration of the arc. Streaming can make the section of the arc small and its other dimension very long so that cooling and deionization take place very quickly. Particularly, if streaming is accompanied by turbulence, the diffusive effects will be very greatly enhanced.

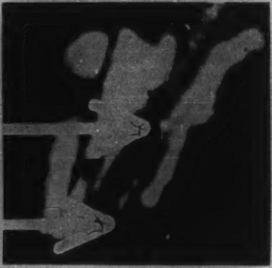

Figure 7. Picture 18

The high-speed pictures presented in this paper are most remarkable, and give just what theorists on arc extinction have been looking for. At last we may see directly what happens within the microseconds in which the arc space recovers its dielectric strength. The evidence which they show seems to me unmistakable. The gas flow places a considerable length of the arc in a position where diffusive effects are particularly strong. This considerable length, near current zero, recovers dielectric strength, apparently rather uniformly along its length.

I have enlarged pictures numbers 17, 18, and 19 of figure 4, of the paper so that more detail may be seen. In picture 17, figure 6 of this discussion, I have indicated by two white arrows the portion of the arc which I believe has been placed by the streaming in a position favorable for diffusive forces. This portion of the arc is pushed by the streaming up against the barrier for a length of about two inches. Next to the barrier, past which the air is streaming, there is, as every student of airplane-wing design knows, a thin boundary layer, joining the stationary gas at the barrier, to the streaming gas in the passage. Under some circumstances the flow in this boundary layer is laminar, but under the conditions obtained here, with the high mean air velocity, and with gas being rapidly evolved from the barrier material, there is no doubt that the boundary layer is quite thick and in an intensely turbulent state. It is precisely into this turbulent boundary layer that two inches of arc is placed.

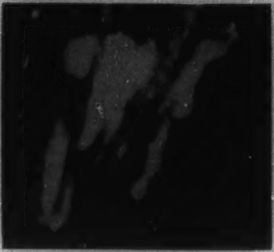

Figure 8. Picture 19

The apparent break in the continuity of the arc at the end of the barrier in picture 17 may be misleading. The lack of motion of this break indicates that it is not real, but the arc continues round the end of the barrier, back from the side of the chute, so that it is out of sight of the camera. Mr. Prince, with whom I discussed this point by letter, has kindly confirmed this statement.

In picture 18 (figure 7 of this discussion) we see that the favorably placed two inches of arc has hardly moved in space, but the intensity of its radiation has greatly decreased. The highly turbulent motion has so accelerated diffusive effects that the arc has been much cooled and deionized in the $16^{2}/_{3}$ microseconds between pictures. In picture 19 (figure 8 of this discussion), finally we see that the radiation from the two inches of arc has diminished almost to zero.

These most valuable high-speed pictures then show no evidence of a wedge of air, of thickness growing with sound velocity, interrupting the continuity of the arc. Instead, they definitely show a considerable length of arc, two inches, placed in a region where it is subjected to very intense diffusive forces. In the opinion of the discusser, they speak definitely against the simple displacement theory, with its related beguilingly simple equation.

D. C. Prince, W. K. Rankin, and J. A. Henley: The authors wish to thank particularly both Doctors Suits and Slepian for their very constructive discussions of this paper. A long and diligent search has been made for any form of tests which would show exactly how arc interruption is taking place. This paper is an endeavor to place such information before the engineering fraternity and it is gratifying to have a check on the validity of the conclusions reached.

The Kesselring-Koppelmann mechanism is a simple and attractive one if it can be supported by adequate observations. The authors feel that data in appendix *C* support that conception. A partially deionized space should be conducting and its conductivity should be measurable. Appendix *A* is a method of making such a measurement and is further evidence. A curve of arc diameter against time constitutes evidence along the same line by still another method. All point to the existence of a very brief time, less than 2 microseconds, during which deionization is taking place. If a sufficient potential is present during that time, some sort of discharge takes place which has been detected for 15 microseconds. In the absence of high rates of rise of recovery voltage, the discharge does not take place and the ionization may be swept away. Later application of voltage produces a disruptive breakdown if it produces any at all. Such a breakdown is characteristic of a clean dielectric.

In the matter of equivalent electrode shapes the wording of the paper must not be quite clear. The authors had a breakdown between "ionized stumps" in mind so that Doctor Suits' reference to Beams and Snoddy is directly confirmatory.

Again in the matter of effect of arc drop, the wording in the paper must not be entirely clear. No question has been raised concerning the interrelation between arc drop and cooling which is shown so beautifully in Doctor Suits' figure 3. The point is that the probability of clearing at any given current zero is not a function of arc drop. It seems that Doctor Slepian has not realized this same point. The authors found that by studying the high-speed photographs it was possible to relate the arc drop as measured by oscillograph with the observed arc length in the photographs. Such analyses add greatly to our knowledge of arcs, but the present investigation was carried only far enough to show that the arc drop which is a measure of intensity of deionization does not seem to be positively correlated with successful operation of the circuit breaker.

In the paper the attempt has been made to marshal all available evidence and the case should not be demolished without consideration of all of it. For instance, it is difficult to explain the 50 per cent increased capacity tests with carbon tetrachloride on any other basis than displacement.

Doctor Slepian feels that he has at last one "incontestable" point. If we understand the definition of incontestable, the authors have been contesting that point for years. They have been searching out all available evidence and trying to secure new and more direct evidence. At the moment, they feel that quite a good case can be made for the flow principle. Even if some readers do not agree with the conclusions of the paper, we hope they will agree that there are still two sides to the argument.

A New 15-Kv Pneumatic Circuit Interrupter

Discussion and authors' closure of paper 40-64 by L. R. Ludwig, H. L. Rawlins, and B. P. Baker, presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940, and published in AIEE TRANSACTIONS, 1940 (September section) pages 528–33.

R. J. Wensley: See discussion, page 1127.

H. W. Haberl: See discussion, page 1129.

R. C. Van Sickle (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): As an associate of the authors, I have been interested in the effect of various recovery voltage rates on the performance of the new pneumatic circuit breaker.

During the development, the breaker was tested with various rates of rise of recovery voltage. One range included circuit rates up to 2,200 volts per microsecond and represented service more severe than is imposed by most service locations. The tests made in this range resulted in arcing times averaging approximately one-half cycle. Inspection indicated that the arc was being extinguished in the first two passages of the chute and that the others were a reserve, not being used.

Because the arc was being extinguished at the first current zero after adequate contact separation was reached, there was no point in testing at lower, and easier, voltage recovery rates.

Consequently, the other range of circuit voltage recovery rates were higher and extended from 2,500 to 4,000 volts per microsecond. These rates were representative of extremely severe service. On part of the tests the arc restruck for an additional half-cycle, during which additional sections of the arc chute came into action, to bring about arc extinction at the next current zero.

Figure 1 of this discussion shows sections of cathode-ray oscillograms made during interruptions of currents having initial a-c components of 12,000 amperes at 13.2 kv. The oscillograms were made on a cathode-ray oscillograph having a film drum rotating at a speed of almost one revolution per cycle. The voltage across the breaker pole-unit was recorded. The heavy horizontal line is the zero line made before the contacts parted. The two curved lines represent parts of cycles of the 60-cycle restored voltage. The arc voltage immediately before current zero, and the recovery transient are recognized. The oscillogram on the left has a recovery voltage transient of 23,200 cycles per second corresponding to a circuit voltage recovery rate of 1,700 volts per microsecond. The oscillogram on the right has two frequencies, one 62,800 cycles per second and the other 32,200 cycles per second. The circuit voltage recovery rate was 4,000 volts per microsecond (2.35 times greater).

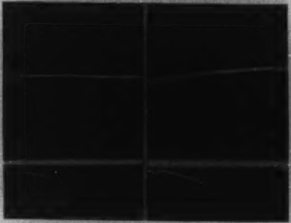

Figure 1

Figure 2 of this discussion shows two interruptions of current having initial a-c components of 20,000 amperes at 13.2 kv but having different recovery-voltage characteristics. The circuit used in obtaining the oscillogram on the left had a natural frequency of 26,500 cycles per second and a circuit recovery voltage rate of 1,920 volts per microsecond. On the right is an oscillogram of a similar circuit having natural frequencies of 32,100 and 85,000 cycles per second and a recovery voltage rate of 3,800 volts per microsecond (double the other).

Figure 2

Figure 3 of this discussion shows two sections of an oscillogram made on a circuit giving a 36,000-ampere a-c component at 13.2 kv. On the left is shown a current zero which occurred after about one quarter cycle of arcing. The arc restruck and cleared a half-cycle later as shown on the right. The transient has two frequencies 33,600 cycles and about 190,000 cycles per second. The restrike occurred after about a half cycle of the higher frequency during which time the recovery rate had averaged about 3,000 volts per microsecond.

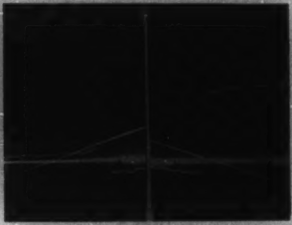

Figure 3

These oscillograms show the interruptions of heavy currents and demonstrate the ability of the breaker to interrupt the circuits with highest rates of rise of recovery voltage with little or no additional arcing.

J. B. MacNeill (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): Here we have for the first time in America a group of papers advocating the use of compressed gas for circuit interruption, with particular reference to high-power indoor equipments.

One naturally asks why have we in this country delayed the introduction of compressed gas and what are the factors which now make its use appear feasible.

In Europe where compressed air has been used for ten years, it is limited to approximately 750,000 to 800,000 kva for 15-kv service and below. This is not enough capacity to justify the introduction of the idea in America, since there are self-contained dry breakers requiring no storage facilities for the lower capacities. For the present we must have 1,500,000 kva and for the future we will need 2,000,000 or 2,500,000 kva at generator voltages. There are certain features of previous designs of compressed-gas interrupter which account for their limited rupturing capacity for indoor equipment. Briefly stated, the principal one is the tendency of the interrupter itself to choke up when subjected to high interrupting duty. To help this situation very high air pressures have been recommended and resistance shunts have been used. These devices, however, are not felt the most desirable solution for American practice.

As to the second question of what now makes compressed gas appear practical here, it is obvious from the group of papers presented that types of interrupter have been found which will handle large powers at those voltages used indoors with moderate gas pressures and with simple mechanical structures that are easily inspected and maintained, fit nicely into metal-clad housings and cell structures, of reasonable inherent cost, and which will provide necessary speed of operation both for synchronizing during closing and for switching speed on opening, and which is also adaptable for reclosing duty cycles certainly without greater derating than now afforded by oil breaker equipment.

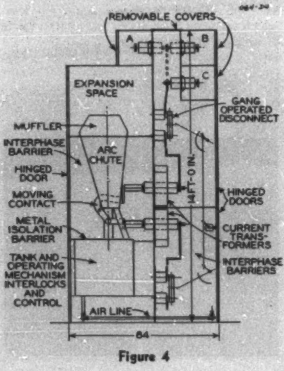

Figure 4

Figures 4 and 5 of this discussion show the device covered in the Ludwig-Rawlins-Baker paper arranged for metal-enclosed cubicle mounting with a capacity of 1,500,000 kva at 15 kv installed in a space no greater than required for many 500,000-kva oil circuit breakers. Several features of this design which make it commercially desirable are apparent from these figures:

1. The high-voltage leads and conductors are arranged well above the floor and make adequate arrangement for current-transformer mounting and provide space for potheads.

2. The moving contact is in full view when the cell door is removed and, when the breaker is open, the surfaces that have been subjected to arcing are visible without removal of parts.

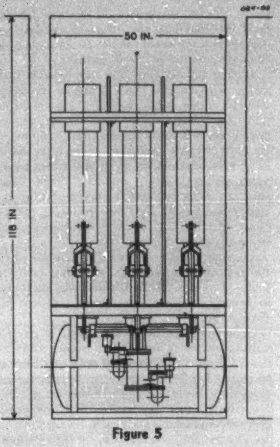

Figure 5

3. The relatively narrow arc chute provides adequate insulation space to intermediate and end walls so that a three-phase circuit can be arranged in 54 inches with 23-kv-class insulation test.

4. The air reservoir and all auxiliary equipment, including pistons, valves, interlocks, secondary control circuits, etc., are mounted in a lower compartment free from high-voltage connections and are readily accessible for inspection and repair.

5. The compressed gas proceeds in a straight-line direction from the tank through the feeder pipe to the arc chute and thence to the muffler without changing direction appreciably and thus giving minimum opportunity for eddy pockets of low dielectric strength during interruption.

6. The final air discharge is in a large grounded space where it can be handled without running up back pressure and is not objectionable to persons in the aisle.

The interrupter shown in the paper, figures 3 and 5, is of a type well adapted to handle high power. While it ordinarily opens the circuit at the end of the first half cycle of arcing, you will note that it has not at this time exhausted its ability, the space between stationary and moving contact being small. As the moving contact withdraws further from the stationary one there is introduced an added length of arc stream and added barriers, together with increased facility for gas disposal so that interrupting capacity is being continuously increased until the contact leaves the arc chute. These are the features which assure the high interrupting capacity necessary on large American systems.

Compressed gases such as those discussed here naturally have a flat arcing-time characteristic and in this way differ from previous conventional circuit breakers, both of the oil and air types. Figure 6, curve *A*, shows the arcing time versus current characteristic of a 15-kv oil circuit breaker. Note that the time required to handle light currents is considerably greater than to handle those heavier currents near rating, but that as the limit of the interrupting device is reached the arcing time again turns upward. Curve *B* shows the characteristic of a compressed-gas device which is flat up to the point where the interrupter becomes overloaded, where it in turn turns upward. For all types of device this final upturn of the curve should be beyond its rating.

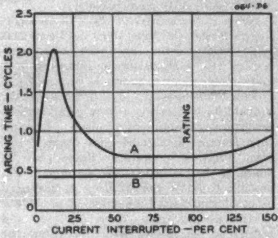

Figure 6

Considerable work has been done looking to standardized capacities for oilless interrupters and table I of this discussion shows the suggestion now being discussed between committees of manufacturers and users covering indoor equipment up to 34 kv. It will be noted that generally this suggestion lies within the framework of existing oil circuit breaker standards but there are fundamental differences which make some departures from existing standards desirable. The general reaction to date is that a standard at this time should be tentative in character. However, some of the more im-

Table I. A Suggested Schedule of Preferred Circuit-Breaker Ratings; Indoor Oilless Breakers

Nominal System Voltage	Circuit Breaker Rated Voltage	Rated Amperes	Interrupting Rating (Kva)	Interrupting Rating Total Amperes
2,300	2,500	600 to 2,000	100,000	23,000
	2,500	600	150,000	29,000
		1,200 to 2,000	150,000	35,000
5,000	5,000	600 to 2,000	100,000	11,500
	5,000	600 to 2,000	150,000	17,500
		3,000	250,000	30,000
13,200	15,000	600 to 2,000	250,000	10,000
	15,000	600 to 2,000	500,000	20,000
	15,000	1,200 to 3,000	1,000,000	40,000
	15,000	1,200 to 4,000	1,500,000	60,000
22,000	23,000	600 to 2,000	500,000	12,500
33,000	34,500	1,200 to 2,000	1,000,000	17,000
	34,500	1,200 to 3,000	1,500,000	25,000
	34,500	2,000 to 3,000	2,500,000	42,000

portant units which will go into general manufacture first appear well founded in station practice and standardization of their characteristics can be made with relatively little risk. As soon as practical such a standard should include desirable gas pressure both at the utilization device and in the main storage. At the present time it appears that 150 pounds utilization pressure will go a long way toward covering the indoor American switchgear field.

The authors of these papers and their associates are to be congratulated on the excellent development work done in the past year on this subject, which results in the practical assurance that compressed-gas interrupters can assume an important place in the American indoor switchgear field, and which makes possible the fine group of papers presented here.

C. M. Gilt (Consolidated Edison Company of New York, Inc., New York): To find extensive application, the various types of air breakers described must compete with oil breakers which, after many years of development and operating experience, may be relied upon with a high degree of confidence to perform successfully within their design limitations. The more recent addition of devices which, by controlling the oil and gas stream, control and shorten the arc, has given faster and more dependable arc interruption. This has been done so well that oil and its gases, while inflammable, have been the cause of extremely few fires and oil has been retained in breakers because of its excellent insulation qualities. However, the desirability of eliminating or at least reducing the amount of combustible material in stations is obvious, provided it can be done without too great a cost in other risks, or in dollars.

Laboratory tests and experience so far indicate that short-circuit arcs can be successfully extinguished by a properly controlled noninflammable gas with suitable arc chutes and cooling or deionizing devices. Experience and further investigations will undoubtedly modify the detailed mechanics of doing the job and, it is to be hoped with some simplification of the parts. It is unfortunate that some of the principles used in the self-contained equipment, such as the magnetic blast, do not offer promise of extension to the higher interrupting capacities and voltages.

The air blast obtained from a separate air tank appears to be very effective and tests which I have witnessed give very little outward or subsequent signs of any distress in opening short circuits of any magnitude within the breaker's rating. The high speed of operation is of course helpful, not only to the breaker but to the system. The separate air tanks and compressors are somewhat of a handicap, though not necessarily prohibitive. The proper operation requires an extremely close co-ordination and timing of the blast of air and the parting of the contacts. It is to be hoped that future development will arrive at a design in which this is co-ordinated in one mechanical operation rather than by mechanically or electrically interlocked valves and trips which, by a failure, may let the contacts part without an adequate blast at the time of parting. In at least one European design the operation of the mechanism produces its own blast of air by means of a piston, but it is reported that it is impractical to develop sufficient air volume and pressure by this means to be adequate for large interrupting ratings and high voltages. However, some design which combines these two operations in one mechanism is highly desirable.

The Consolidated Edison Company has installed two 15-kv 500,000-kva breakers of the air-blast type, one of which is carrying load and has opened one short-circuit of about 250,000 kva entirely satisfactorily. The company has on order some 5,000-volt 150,000-kva magnetic-blast breakers of two different manufacturers' design for generating-station auxiliary supply. However, it was decided to install oil breakers at individual motors in a boiler house using pulverized coal because of the dust problem. Experience with air-break switches of these designs in conditions of dust may confirm or disapprove the wisdom of this decision.

H. C. Louis (Consolidated Gas Electric Light and Power Company of Baltimore, Md.): The results shown in all of the papers presented justify the general conclusion that high as well as low-capacity circuit interruption can be successfully accomplished by various types of air circuit breakers. It is, however, desired to bring up certain questions of practical interest to operating men.

Normally, arcs in such switches are drawn internally without danger of external flashover or spreading to other apparatus. Abnormal conditions resulting from improper adjustments or defective materials are, however, possible. What consideration has been given in the design of such switches and related station layouts to guard against and minimize the hazardous effects of external arcing under the abnormal conditions mentioned?

L. R. Ludwig, H. L. Rawlins, and **B. P. Baker:** The authors were glad to receive the numerous discussions, indicating a considerable interest in air circuit breakers of relatively high interrupting capacity.

Mr. Wensley has brought out the importance of the blast valve in the design of breakers of this type. Positive operation of this element of the breaker is of paramount importance and for this reason we have utilized a mechanically operated blast valve which not only insures the supply of air for interruption because of the mechanical interconnection with the contact motion, but provides a high and positive force for actuating these valves.

Mr. Louis has raised the question of retaining the arc within the interrupting structure in case of faulty operation. Figure 7 of this discussion shows a $1^1/_2$ million-kva compressed-air breaker installed in a metal-clad housing. The provision of interphase barriers and the extension of the arc chambers to enclose partially the moving contact arm are design features incorporated with Mr. Louis' requirements for the purpose of keeping the arc enclosed within the phase structure in the event of faulty operation.

Mr. Gilt expressed the hope that a design will be arrived at in which there is close coordination between timing of the blast of air and parting of the contacts. The authors are in strong agreement and for this reason have described a compressed-air circuit breaker in which parting of the breaker contacts and opening of the blast valve are operated from the motion of the piston directly. With this construction, no mechanical or electrical interlocking is necessary.

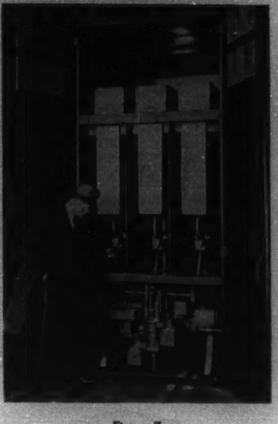

Figure 7

Magnetic "De-ion" Air Breaker for 2,500–5,000 Volts

Discussion and authors' closure of paper 40-65 by L. R. Ludwig and R. H. Nau, presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940, and published in AIEE TRANSACTIONS, 1940 (September section) pages 518–22.

H. C. Louis: See discussion, this page.

C. M. Gilt: See discussion, this page.

H. W. Haberl: See discussion, page 1129.

M. H. Hobbs (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): Messrs. Ludwig and Nau's paper on the magnetic De-ion breaker presents the most recent chapter in the contribution of the De-ion air circuit breaker principle to the art of circuit interruption. Its 150,000-kva rating at 2,500–5,000 volts covers a number of industrial, distribution, and station-auxiliary circuit applications.

One of the first questions asked about a new breaker is "How will it work out in metal-enclosed switchgear?" For this reason the development of the breaker and metal-clad structure were carried on in parallel to produce a co-ordinated design of assembled unit. The breaker design has been directed in such a way as to facilitate its metal-clad application. In the same way, in the switchgear development, there has always been kept in mind the fact that the primary duty of the assembly is the best possible arc interrupting performance of the breaker.

Figure 1 of this discussion shows the complete removable element which carries the circuit breaker, the primary and secondary disconnecting devices and levering mechanism for removing and inserting the element into the housing. The assembly is as compact and simple as convenient and reliable operation will permit. It will be noted that the withdrawal movement is horizontal for greater convenience, and to permit the location of the breaker arc chute in position to promote the greatest interrupting efficiency. This is not simply a matter of opinion, but is the result of tests actually made in various positions to determine the best arrangement.

After withdrawal of the breaker unit, removal of the barrier assembly for inspection and maintenance is both quick and easy as figure 2 shows. This is arranged to be done without bolt removal from the barrier assembly.

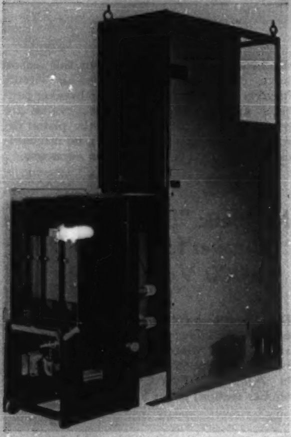

Figure 1

The housing which receives the removable element contains the stationary disconnecting contacts, safety shutters, busses, connections, instrument transformers, and such panel-mounted equipment as may be required. There are no exposed live parts in the compartments except potential transformer fuses, and each housing is isolated from its neighbor by a tight combination metal and Micarta barrier through which the busses pass.

Ventilation for temperature control and to carry off the products of arc interruption is provided at the top of the housing. The outside dimensions of the unit are width 26 inches, height 80 inches, depth 72 inches.

Proof of the breaker performance is incomplete unless it includes interrupting and momentary high current tests when in normal operating position in its metal-clad housing. This is also a check on the adequacy of the disconnecting contacts, insulating supports, and bus assembly design in the switchgear unit as well.

Figure 2

Supplementing the tests on the separate breaker, on which oscillographs were shown by Mr. Nau, the following were made on the breaker and the assembled metal-clad unit shown in figure 1:

57 at low currents of 9 to 1,000 amperes
66 at currents equivalent to 120,000 to 235,000 kva consisting of:
  28 opening only
  26 close-open
   6 standard duty cycles of two interruptions each, 15 seconds between the two
25 close-open with nine-second intervals on 1,500 amperes
25 close-open with nine-second intervals on 9.000 amperes

173 total

The series of tests at nine-second intervals was made to simulate the duty the breaker would have to perform if it were used for motor starting, although this is undoubtedly more severe than would be met with in usual practice except for "inching" a motor in steel-mill service.

The entire series of tests was made without maintenance work being done on the breaker or the disconnecting contacts in the housing, and the equipment was still in such condition that it showed only one degree higher temperature rise on the contacts carrying full rated current than before the tests.

Table I. Short-Time Tests

Five-second test—initial current	20,000 amperes
3 seconds	55,000 amperes
8 seconds	52,000 amperes
One-second test—initial current	20,000 amperes
2 seconds	55,300 amperes
2.7 seconds	73,500 amperes

At the end of the 1,500-ampere shots there was no evidence of gas accumulation when the breaker was withdrawn. After the series of tests at 9,000 amperes there was some smoke evident. However, this was insufficient to interfere in any way with successful interruption, and the structure withstood a one-minute potential test of over 30,000 volts without any cleaning of the insulation surfaces.

The five-second and momentary tests at the currents given showed no damage either to the circuit breaker contacts, the disconnecting contacts, or the bus structure. Normal ratings of this breaker are 50,000—five seconds and 60,000—one second so that these ratings have been adequately proved.

E. W. Boehne (General Electric Company, Philadelphia, Pa.): Messrs. Ludwig and Nau have presented a very interesting paper. With the more common use of the magnetic air breakers in the field of power interruption at the higher voltages, considerable importance should be placed upon the correct application of fundamental relations. The authors have implied that the energy dissipated in the arc increases with the arc voltage. Arc energy is the product of the arc voltage, arc current, and duration. Hence it would be just as correct, if it were correct, to imply that arc energy increases with arc current. The true relations of these quantities may be clarified from figure 3 of this discussion.

Here is shown a rheostat in place of a breaker in an inductive circuit. As the handle is turned inserting resistance to interrupt the current flow, three important changes take place. (1) The current is reduced, its locus following the circle diagram as indicated. (2) The phase angle of the circuit shifts from zero power toward unity power factor; and (3) the arc voltage builds up, its magnitude being shown by the circle at the top. Now watts is zero at maximum current and likewise zero at zero current. The wattage is maximum at 45 degrees phase angle when the arc resistance in ohms is equal to the external reactance of the circuit in ohms. Note at this point the current is reduced only 30 per cent or to 70 per cent of its maximum value.

This approach to the analysis of available oscillographic data in definable, measurable terms, familiar to the industry was the keynote of a paper "Magne-Blast Air Circuit Breaker for 5,000-Volt Service" presented at the 1939 summer convention (AIEE Transactions, volume 59, 1940, pages 202–08). Here it was shown that by magnetically controlling the arc resistance in a nonmetallic chamber that the current-limiting action would throw the current well over the wattage hump in a half cycle or less.

The distinct advantage of accomplishing this unique characteristic is the unity power factor, slow, sinusoidal recovery voltage as shown in figure 4 of this discussion of the interruption of 33,000 amperes at 3,600 volts, single phase. Note the low instantaneous voltage at interruption, the low current in the arc, the short arc duration, all of which result in quiet, easy performance. This test was repeated immediately as shown in figure 5, consistently producing arc-current crests far below the 70 per cent value. The arc chute employed to accomplish these desirable characteristics is shown in figures 9 and 10 of the above-mentioned paper.

The advantage of large phase-angle swing producing unity-power-factor interruptions lies in the fact that breakers are not affected by the severity of circuit to which they are applied. Figure 2 of the above-mentioned paper shows the three available recovery

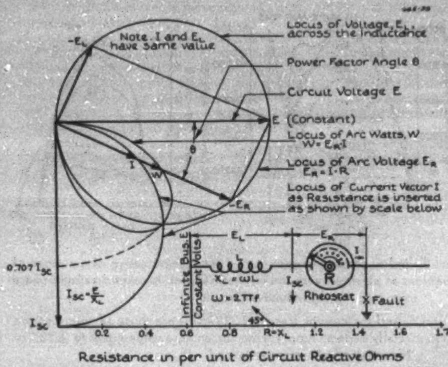

Figure 3. Circle diagram showing the inseparable relations between phase shifting, current reduction, watts, arc voltage, and initial recovery voltage as arc resistance is inserted into an inductive circuit

Note: (1) Maximum watts occurs at 45 degrees phase angle when the current is only 70 per cent of its zero power factor value; (2) the instantaneous value of recovery voltage will always be less than E_L because of the additional phase shift which takes place during the interval between current crest and current zero. Note that E_L and I are equal in magnitude although both do not exist simultaneously in the static diagram

rate characteristics of our high-power testing station in comparison with the low recovery rates obtained on Magne-Blast breakers, showing that Magne-Blast performance is independent of circuit severity. Such a characteristic eliminates all worry of applications to high-recovery-rate circuits. Throughout these tests thermocouples were imbedded in the chute and temperature rises of 2.5 degrees centigrade were recorded per each 100,000-kva interruption. These measurements confirm the many observations made by the well-known touch system. The Magne-Blast breaker was one of two breakers demonstrated to a notable audience last August 17, several months after the first field installations. Here, after a successful series of tests up to 40 per cent in excess of its rating, the breaker was opened for inspection. Its coolness was the subject of admiration.

Figure 4. Single-phase interruption of 33,000 amperes at 3,600 volts by one chute of 100,000 kva Magne-Blast breaker

Note the low arc current which is well below the 70 per cent value of maximum wattage indicated by figure 3 of this discussion. Also observe that the instantaneous value of recovery voltage in per cent is less than the maximum per cent of peak arc current as predicted by a study of figure 3

We conclude by stating that the authors' repeated reference to high arc energy must be founded upon their own experience. We have not encountered it—this being confirmed by simple calculations properly locating the decimal point.

Figure 5. This single-phase interruption of 32,000 amperes at 3,600 volts was taken immediately after the test of figure 4. Note the low arc current and the voltage recovering on a unity-power-factor basis

R. J. Wensley (I-T-E Circuit Breaker Company, Philadelphia, Pa.): The company which I represent has been in business for more than 50 years. During all of that time their slogan has been "air circuit breakers only."

We are very much gratified that the industry is showing signs of agreement with our policy.

Referring to the papers on air-blast circuit breakers, it is interesting to note that the authors have avoided the one feature that our experience has shown to be one of the most important in the design of air-blast circuit breakers. This is the blast valve. Our investigations convince us that an arc of any magnitude drawn in any sort of arc chute under practically any conditions can be extinguished if enough air is moved at a sufficiently high rate through the chute. The best form of chute for the most effective utilization of air will undoubtedly develop as the art progresses. Our own experience has indicated that the cross-blast breaker is better than the longitudinal blast. In our opinion, the blast valve should be made as simple as possible with no sliding parts which might stick at inopportune moments due to corrosion or dirt.

I would like to ask the authors of the paper on the magnetic De-ion circuit breaker as to the nature of the blast which they report as occurring in the arc chute of their breaker. They describe it as an electron bombardment of gas particles. Is this not a technical description of a very simple phenomena which could be illustrated by lighting a match? Our experience indicates that the large movement of gas is produced by the thermal expansion of gases in the arc chute coupled with the actual movement of the arc up through the barriers.

I would also like to ask the authors of the paper if the transverse barriers which they describe as being non-gas-forming are really of non-gas-forming material, or is the term relative? In other words, is it simply to distinguish from a free-gassing material such as boric acid, or is it actually a new material not hitherto available to the industry?

R. H. Nau: The lively discussions show that both the manufacturers and operating engineers are keenly interested in the development and possibilities of air circuit breakers of relatively high interrupting capacity.

R. J. Wensley, of the I-T-E Circuit Breaker Company, suggests "thermal expansion of gases in the arc chute coupled with (or associated with) the actual movement of the arc up through the barriers (that is, arc-shield and arc-chamber sides)" as an explanation for the gas-blast characteristic in arc interruption by the magnetic De-ion circuit breaker. It has been demonstrated through testing that the thermal-expansion theory does not hold by simply cutting the magnet coil out of the circuit, yet leaving the panel-end horn (see figure 1 of the paper) connected to the upper stud. Further consideration points to the fact that there should be no reason for suspecting thermal expansion as the cause of the characteristic gas blast. In less than 100 microseconds after the arc is drawn (position 1, figure 1 of the paper) it has looped to the region as indicated by position 4. In this region the effect of the current loop to produce movement is relatively small. Here the effect of thermal expansion is to blow highly ionized gases back down upon the contacts and permit the arc to play unimpelled in the space enclosed by the arc shield and arc chamber sides.

However, it might be pointed out that an interrupter can be designed to give quite effective operation wherein thermal expansion does become a factor in aiding an interrupting blast.[1]

Mr. Wensley asks further concerning the gas-forming properties of the spaced insulation plates of the arc chamber. As compared to free-gassing materials such as boric acid or fiber, the plates are truly nongas forming. The material is of a high-grade refractory ceramic which has been specially developed by the Westinghouse company. Even when subjected to temperatures of the magnitude found in a 60,000-ampere rms arc, only minute quantities of gases are evolved from this refractory ceramic.

M. H. Hobbs, of the Westinghouse company, commends the magnetic De-ion circuit breaker for its desirability in modern metal-clad switchgear applications. Particular reference is given to the 173 (total) tests made on the breaker as an assembled metal-clad unit shown in figure 1 of Mr. Hobbs' discussion. These tests demonstrate the high efficacy of the magnetic De-ion circuit breaker to function at and above 150,000 kva.

H. C. Louis, Consolidated Gas Electric Light and Power Company of Baltimore, raises a question also asked by many of the operating engineers—"What consideration has been given in the design of such switches and related station layouts to guard against and minimize the hazardous effects of external arcing under abnormal conditions (failure to interrupt circuit)?" During the early development period the magnetic De-ion breaker, without an enclosure, was tested to destruction. The laboratory back-up breakers were blocked closed, permitting the arcing to go rampant for more than a minute before the excitation was removed from the generator supplying the circuit. Although the contact parts and stud blocks were left in a devastated condition, the arc was kept enclosed within the arc chamber. If the breaker had been enclosed in a cubicle such as was discussed by Mr. Hobbs, the breaker would have been completely isolated by the structure for a considerable period of time.

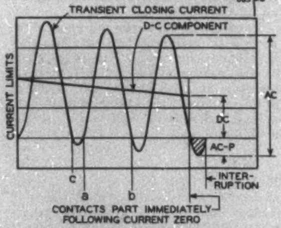

Figure 6. Oscillogram of an asymmetrical current wave interrupted on the small current loop

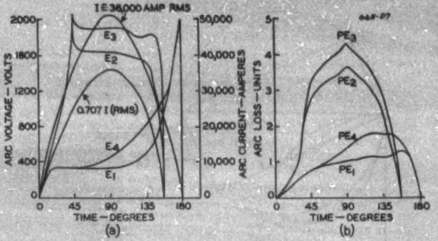
AC—Symmetrical a-c component of current interrupted, 36,000 amperes rms

DC—D-c component of current interrupted, 34,800 amperes rms

AC-P—Current value during arcing period, 11,200 amperes rms (unsuppressed)

The rms value of *AC* and *DC* is 50,300 amperes

Figure 7. Oscillograms of current interrupted and corresponding arc-loss curves



(a)—The arc voltage traces E_1 and E_4 and the current trace *I* are representative of a number of 36,000-ampere rms interruptions as obtained with the magnetic De-ion breaker on single-phase tests, interrupting inductive circuits

The arc voltage traces E_3 and E_2 and the current trace 0.707*I*(RMS) are those of interruptions wherein the arc voltage was specially made to suppress the current to a value equal to 0.707 of the unimpeded current as trace *I*

(b)—Arc-loss curves for corresponding currents and arc voltages of figure 7*a*

Mr. Boehne and his associates have prepared an elaborate treatise[2] on the theory of interruption of 2,500 to 5,000-volt circuits capable of producing fault currents equivalent to 150,000 kva. The central theme of Mr. Boehne's discussion follows that of his paper, and there are certain fundamental factors or relationships to which he should give further consideration. In fact, practicing electrical engineers would be greatly perturbed to find now that their beautiful tools—Heaviside's operational calculus, symmetrical components, tensor analysis, differential equations, complex functions, and other operational means—for analyzing circuit phenomena in transient states were to be supplanted by such elementary steady-state relations of an a-c circuit as expressed by the circle diagram (figure 3 of Mr. Boehne's discussion). The circle diagram, of course, does express notable relationships within a circuit under steady-state conditions.

Fundamental expressions for instantaneous and transient circuit conditions were used to check the oscillographic data given in the following paragraphs. The actual data demonstrate that arc energies of at least two to three times the values obtained with a low-arc-voltage device are encountered when the arc voltage characteristic is of such nature and magnitude as to suppress the arc current of the circuit to 70 per cent or less of the rms value of a practically sinusoidal half-wave of current.

When the current of a given circuit is not noticeably suppressed by the arc during current interruption, the value of the current interrupted is usually obtained by measuring the first cycle of arc current from the current-wave envelope. However, in the event of half-cycle arcing under asymmetrical conditions, the last half-cycle of current may be either of much smaller or much larger value than the average. Accordingly, particularly difficult or unusually easy interruptions may be obtained with asymmetrical currents. These conditions are clearly illustrated in figure 6 of this closure. The a-c symmetrical current measures 36,000 amperes rms, and the d-c component 34,800 amperes rms. The rms value of the asymmetrical current interrupted is then 50,300 amperes rms, in accordance with AIEE Standards No. 19—appendix. Practically, the current interrupted is the rms value of the shaded half-cycle of current *AC-P*, which measures only 11,200 amperes rms. Had the breaker contacts parted immediately following the current zero at *a*, figure 6, and the interruption been completed at *b* the current interrupted would within reasonable accuracy be that of the half-cycle *a-b*. The relative areas under the wave *a* to *c* and under the wave *a* to *b* give an indication of the accuracy of using one instead of two half-cycles in calculating the arc current.

In the paper and in this discussion the AIEE standards have been used to measure interrupted currents. However, relatively easy tests as given by a small last half-cycle of arcing have been excluded from all data. Note has been taken of the fact that by means of rather simple test circuits synchronous closing may be utilized so as to obtain repeatedly easy asymmetrical current interruptions by the test breaker.

Several sets of oscillographic data have been superimposed on one co-ordinate axis as shown in figure 7*a* of this discussion. The arc voltage traces E_1 and E_4 and the current trace *I* are representative of a number of 36,000-ampere-rms single-phase interruptions obtained with the magnetic De-ion breaker on an inductive circuit. The arc voltage traces E_3 and E_2 and the current trace 0.707*I* are those of interruptions where the arc voltage was specifically made to suppress the current to a value equal to 0.707 times the unsuppressed current of *I* amperes rms. The corresponding traces of instantaneous arc power loss are shown in figure 7*b*, being obtained by multiplying the arc voltage and arc current point-by-point. The areas beneath these curves are directly proportional to the respective arc energies dissipated. Thus, it is shown that to suppress current by increasing the arc voltage actually does cause a considerable increase in energy dissipation.

Mr. Boehne assumes in his analysis an rms voltage drop across a resistor through which an rms current is flowing, and calculates the wattage loss as the product of these factors. The arc energy is then presumably equal to this rate of loss multiplied by the arcing time. However, since the arc voltage is far from sinusoidal, it appears that the only reasonable method of obtaining the actual arc energy for the purpose of comparing interrupting devices is to integrate the product of the instantaneous voltage and current over the arcing period. This procedure fully confirms the claims made in the paper regarding the advantage of low arc voltage in interrupting devices.

Inasmuch as Mr. Boehne's discussion is a résumé of the paper, "Magne-Blast Air Circuit Breaker for 5,000-Volt Service",[2] I refer the reader to a discussion submitted by R. C. Dickinson of the Westinghouse company, on that paper [AIEE TRANSACTIONS, volume 59, 1940 (April section) page 210].

Circuit Interruption by Air Blast

Discussion and authors' closure of paper 40-66 by W. S. Edsall and S. R. Stubbs, presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940, and published in AIEE TRANSACTIONS, 1940 (September section) pages 503–09.

D. C. Prince (General Electric Company, Philadelphia, Pa.): The very interesting paper which Messrs. Edsall and Stubbs have presented should provide an opportunity for comparing the practice and performance of Continental-type air-blast circuit breakers with the practice and performance of those being developed in this country.

For instance, it should be possible to compare figure 9 of the Edsall paper with figure 2*A* of the paper, "The Cross-Air-Blast Circuit Breaker" by Messrs. Prince, Henley, and Rankin (TRANSACTIONS pages 510–17). Also it should be possible to compare figure 8 of the Edsall paper with figure 2*B* of the Prince paper. Such comparison should show whether in the cross-air-blast paper a fair comparison has been made between the axial-blast and the cross-blast designs. Unfortunately this cannot be done because of the lack of specific information in connection with the foregoing figures 8 and 9 of the Edsall paper. In figure 8, port diameter and recovery rate are absent, while in figure 9, pressure and recovery rates are both absent.

The data in the cross-blast paper, which might easily be considered as biased and giving an unfair comparison between the American and European developments, could be quickly evaluated were the additional information available.

H. W. Haberl (Montreal Light, Heat, and Power Consolidated, Montreal, Canada): The subject of arc interruption by air blast has always been of great interest to operating companies in Canada, where temperature changes are in excess of those experienced in the south, and where extreme cold has a tendency to congeal oil circuit breakers and perhaps slow their operation or decrease their interrupting rating.

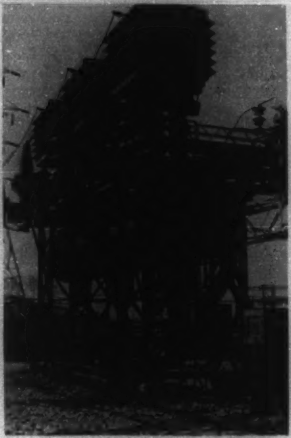

Figure 1

Our company has been interested and doing experimental work on air blast breakers since 1926. Our first commercial installation was made in 1934. This breaker was installed at a new hydroelectric power house, the switch yard of which is adjacent to the tail race, where during very cold weather a mist deposits frost, etc., on the switch-yard apparatus.

Figure 1 of this discussion shows this breaker installed at the power house, and figure 2 shows a general view of the switch yard with the three breakers installed.

Figures 3 and 4 show a general outline of the 1936 breaker, and at the present time a fourth breaker is in the process of installation; the outline of this new switch is similar to those of 1936.

The power-house superintendent, in a paper given before the Canadian Electrical Association, in June 1938, gave data on the operation of these breakers. He brought out the necessity of drying the air before storage in the breaker tank (the original installation only included one drying mechanism). At the present time there are twin dryers installed, one dryer is being re-activated while the second dryer is in service. The other points reported by the operating superintendent were the necessity for having the moving parts free-operating without packing glands in this outdoor installation. This was remedied by the removal of all nonmetallic packing in the operating cylinder and the use of annular rings in their stead.

The report also covered the fact that there was no maintenance work required or done on any of the current-carrying parts, and the contacts have neither been cleaned nor filed in any way, although these breakers have interrupted numerous short circuits on the transmission lines protected.

The newer breakers in service have a clearing time of 3 cycles, which includes relay time. The breakers themselves operate in from 2 to $2^1/_2$ cycles. Our company is quite satisfied that air-blast circuit breakers have decided advantages over other means of circuit interruption, which points have been covered so well by the papers presented on the subject.

W. S. Edsall and **S. R. Stubbs:** D. C. Prince has stated that the data presented in the Edsall and Stubbs paper should provide an opportunity for comparison between the practice and performance of Continental-

Figure 2

type air-blast circuit breakers with that of air-blast circuit breakers being developed in this country. It should be borne in mind in this discussion, that the device described in the Edsall paper is not a Continental design, but an American development, based on a particular Continental design, in which certain factors have been introduced which have so increased the interrupting efficiency as to make it quite acceptable to American power users.

Mr. Prince refers to the possibility of comparison between figure 2*A* of the paper "The Cross-Air-Blast Circuit Breaker" and figure 9 of the paper "Circuit Interruption by Air Blast." In this connection, it should be noted, in plotting figure 9 of the Edsall paper, any operation having more than one-half cycle of arcing was regarded as inefficient. The resultant nozzle area-kilovolt-ampere characteristic, drawn through the points of maximum kilovolt-ampere interrupted with an arcing time of one-half cycle or less, approximated a straight line. If this procedure is followed in the case of the points plotted on figure 2*A* of the Prince, Rankin, and Henley paper, an exponential curve is obtained (for nozzle diameter versus kilovolt-ampere). It is interesting to note that if these data are plotted on the same nozzle area—kilovolt-ampere bases as for figure 9 of the Edsall paper, the three points obtained, for areas equivalent to diameters of $^5/_8$, $^7/_8$, and $1^1/_4$ inches, are substantially in a straight line.

Figure 2*C* of the Prince paper shows a maximum a-c component of arc current of 28,000 amperes for the radial-type nozzle at zero rate of rise of recovery voltage. As stated in Mr. Nye's discussion, this figure was presumably prepared from data obtained from tests made on a European breaker whose design differs greatly from the American design described in the Edsall paper. In the way of emphasis on this point, it is interesting to note that the breaker described in the Edsall paper has interrupted an a-c component of arc current of 36,500 amperes with the arc-paralleling resistors disconnected and with an arcing time of less than one-half cycle. The rate of rise of recovery voltage was 306 volts per microsecond; nozzle diameter $1^3/_8$ inches; and air pressure 200 pounds per square inch. The equivalent value for the breaker, upon which figure 2*C* of the Prince paper is based, would apparently be of the order of 16,000 amperes.

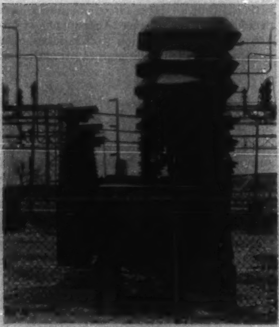

Figure 3

Figure 4

With further reference to the comparison between the European radial-nozzle type breaker and the American cross-blast design, it is noted that Mr. Prince, in transferring the characteristic from his figure 2*C* to his figure 9, seeks to compare a European breaker characteristic, based on half cycle maximum arcing time, with an American breaker characteristic based on one cycle maximum arcing time; a comparison which does not appear to be strictly relevant.

J. B. MacNeill has made reference to the interrupting-capacity limitations of some European designs of air-blast circuit breakers and to the use of high air pressures and resistance shunts. The 500,000-kva 15-kv circuit breaker, with a $1^3/_8$-inch diameter nozzle, described in the Edsall paper, has successfully interrupted as high as 60,000 rms amperes approximately with an arcing time not exceeding one-half cycle.

We see no particular reason why air pressures higher than 150 pounds per square inch should not be used, if by so doing greater interrupting efficiency can be obtained. It is interesting to recall that a decade or so ago, boiler pressures of 200 or 300 pounds per square inch were considered to be a safe maximum, whereas today, in the interests of greater efficiency, boiler pressures of 1,000 pounds per square inch and higher are used.

The advantages accruing from the use of resistors automatically inserted into the circuit by the action of the arc during interrupting have been described in the original paper, and their use as an aid to the interrupting process has been amply verified on test. As the breaker consistently operates with not more than one-half cycle of arc, and as the resistor is only connected into the circuit momentarily, toward the end of the arcing period, failure of the resistor is extremely unlikely. During high-current tests, made on a breaker equipped with resistors, there was no appreciable heating of the resistors; proving that the resistors used have ample factors of safety. The use of resistors for the control of the rate of rise of recovery voltage is not new, but this particular design of air-blast circuit breaker lends itself so aptly to the use of this device that it has been considered advisable to take advantage of the possibilities of recovery voltage control thus rendered available, in the interests of greater interrupting efficiency and improved system stability.

H. C. Louis has referred to the danger of external flashover resulting from improper adjustment or defective material. The axial-air-blast circuit breaker described in the Edsall paper has been proved to have adequate operating and insulation factors of safety. Positive sequential timing, inherent in the breaker design, minimizes the possibility of incorrect adjustment. In common with all air-blast circuit breakers, incorrect adjustment or operation beyond rating may result in external flashover, but on the breaker described, such a flashover will not amount to more than an ordinary insulator flashover, since no explosive gases or vapors are present.

Reference has been made by C. M. Gilt to the necessity for co-ordinating the timing of the blast of air and the parting of the contacts. As, in the axial blast design described, the arcing contacts cannot be parted until sufficient air pressure for arc interruption is present in the contact chamber, possibility of the arcing contacts parting at a time when an adequate air blast is not available is eliminated.

Mr. Nye has referred to the use of the terms "cross blast" and "axial blast", and if Mr. Nye's interpretation of the term "axial blast" is expanded to read "The air blast leaves the point of contact separation in a direction parallel to the axis of the moving contact part and is parallel to a substantial portion of the arc path", it will be readily understood that the action of the air blast on the arc in the cross-blast types of breakers described in the Prince, Rankin, and Henley, and in the Ludwig, Rawlins, and Baker papers, is generally quite similar in principle to that obtaining in the circuit breaker described in the Edsall paper, since in both these cross-blast designs a substantial portion of the arc is subjected, during interruption, to a blast of air which is parallel to the sides of the arc chutes and is, therefore, parallel to those considerable portions of the arc which are adjacent to the arc chutes.

The main advantage of the axial-blast design described in the original paper so far as the interrupting process is concerned, is that it enables full use to be made of the three air-pressure characteristics which influence arc interruption, namely dynamic effect, cooling effect, and dielectric effect. It is the efficient use of these three characteristics which is responsible for the maximum arcing time of one-half cycle consistently obtained with the axial-blast design. As a further indication of the high efficiency of air blast obtained in the axial-blast design, it is interesting to note that the actual amount of air used in a 500,000-kva three-phase breaker for arc interruption, is less than one cubic foot of free air.

Design and Construction of High-Capacity Air-Blast Circuit Breakers

Discussion of paper 40-63 by H. E. Strang and A. C. Boisseau, presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940, and published in AIEE TRANSACTIONS, 1940 (September section) pages 522–7.

Compressed Powdered Molybdenum Permalloy for High-Quality Inductance Coils

Discussion of paper 40-20 by V. E. Legg and F. J. Given, presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940, and published in AIEE TRANSACTIONS, 1940, pages 865–72.

William Fondiller (Bell Telephone Laboratories, Inc., New York, N. Y.): The paper by Messrs. Legg and Given, adds another interesting chapter in the development of new magnetic materials. In the past 25 years we have seen the cores of loading coils change successively from hard-drawn four-mil iron wire to compressed powdered electrolytic iron; then to powdered Permalloy, and finally to molybdenum Permalloy. As a result of these developments, the effective permeability of the magnetic cores has been raised from approximately 35 to 125. We are dealing here with the initial permeability, that is, the permeability at very low magnetizing forces, and with flux densities of the order of ten gausses. In this same period developments in connection with sheet Permalloy have made available material having an initial permeability of about 2,000. Looking at the matter superficially one might question whether it was worth 25 years' effort to raise the permeability of compressed powdered cores to 125, with this high permeability sheet material ready at hand. I think that a study of the curves of core loss and stability with superposed magnetization just shown by Mr. Given will demonstrate that no continuous sheet-metal core, no matter how thinly rolled the metal, could be made to meet all of the requirements as satisfactorily, considering cost and quality.

Another matter which is of interest in connection with the coil developments described concerns the testing problems involved. The energy losses, due to eddy currents and hysteresis, are by design made extremely low. In order to secure the exceedingly uniform characteristics needed in these coils, it has been necessary to develop refinements in testing technique, particularly for making measurements of modulation characteristics and temperature stability of this core material. Since the modulation can be predicted from the hysteresis factor, equipment has been developed for accurately evaluating this characteristic. For this purpose carefully shielded bridges using amplifier detectors, and precisely calibrated standards have been devised. As a result, absolute accuracies in the measurement of losses in the coil of the order of ±0.2 per cent or ±0.02 ohm are realized. In the evaluation of the core-loss factors, involving the measurement of incremental resistance changes in test coils due to successive changes in current and frequency, an accuracy about ten times this, that is, ±0.002 ohm is realized. The testing of cores for temperature stability involves inductance changes which are measured to an accuracy of ±0.005 per cent. This involves measurements of a fraction of a microhenry in a coil of six millihenries.

In order to attain these relative precisions it is necessary not only to calibrate accurately the bridges along with their meters and power sources, but it is essential that all the equipment be maintained under constant conditions of temperature and humidity. In addition to these precautions, the test samples are specially designed to minimize the effects of stray capacitance, as well as wire and dielectric losses. It is also essential that the coil under test be well dried and that it be kept at constant temperature during measurement. In order to eliminate small errors, due to contact resistance and other effects incident to moving the coil under test, d-c resistance measurements are made in the same circuit as employed for a-c testing. In making the temperature-stability observations means are provided for heating and cooling the test samples which are hermetically sealed in containers to keep them dry.

It should be noted that while these tests were originally developed as laboratory tools, it has been necessary for the Western Electric Company in manufacturing a product having as refined requirements as loading coils and filter coils, to install and operate similar testing equipment for control purposes in its manufacturing operations.

No discussion of loading coils is complete, I feel without a mention of the contributions of the late Professor Pupin. To those of us whose good fortune it was to know him well, he evoked in us feelings of affection and admiration. In this connection, I want to refer to the winter convention of 1926, at which a paper on loading was presented by Thomas Shaw and myself. Professor Pupin, who was then president of the Institute, gave a rather lively discussion of this paper. In the course of his remarks, referring to his invention of the toroidal loading coil, he said, in his own inimitable way, "An invention that cannot stand the companionship of other inventions is probably a poor invention. The loaded-conductor invention takes the repeater invention into its arms, and they hug each other, and make a beautiful pair of congenial companions".

It is quite apparent from the present paper that, using Professor Pupin's criterion of the goodness of an invention, the loading art has also contributed materially to advancing the design of filters which form so vital a part of multiplex telephony using carrier frequencies.

J. W. Campbell (American Telephone and Telegraph Company, New York, N. Y.): The installation of loading coils within the splice sleeve, which is made possible by the reduction in coil size which Mr. Given mentioned in his paper, has a number of important advantages. In new installations a large part of the program loading on cable pairs used for broadcasting services is being done in this way. The arrangement avoids the cost of the cases and of assembling the coils in them and it eliminates the chance of mechanical trouble such as that due to sheath breaks in the stub cables of the loading coil cases, as well as troubles associated with the cases themselves. The use of the individual coils also affords greater latitude in the location of the coils from a spacing standpoint on aerial cables and helps to minimize congestion in manholes.

In the exchange plant, the use of these individual coils provides an economical means of loading small complements of pairs in cables that are not otherwise loaded, and permits the installation of coils in line manholes where space might not be available for placing standard cases. Also the individual exchange loading coils can be employed effectively in loading small submarine cables such as those used to serve islands off shore or small communities separated from the rest of the exchange by a bay or other body of water. In this instance the coils can be placed in the splice between adjacent lengths of cable by using a lead sleeve slightly larger and longer than normal. A steel splice case of essentially the same type as would otherwise be used to cover the splice is applied to provide adequate mechanical protection. This method of loading avoids the use of a separate submarine loading case which is heavy and costly and requires two splices to connect it to the cable. It has the further advantage of greatly facilitating the underrunning of the cable in connection with maintenance operations.

The availability of the relatively compact lead-sleeve cases containing exchange coils is likewise advantageous since it permits loading in line manholes without encroaching unduly on the space designed for splicing and racking cables. In aerial cables, the lead-sleeve cases can be suspended from the strand in most instances, thereby minimizing the likelihood of troubles in the stub cable which may occur when the case is fastened to the pole and the stub is carried up the pole and bent to follow the main cable to enter the splice. The same type of lead-sleeve case is suitable for installation in both aerial and underground plant whereas the normal steel case requires a different outside finish depending upon whether it is to be used underground or aerially.

Taking a look at the effect of these reductions in unit size on the present-day requirements for manholes to house the larger loading coil cases, a comparison with the requirements of 15 years ago is rather striking. For example, to load eight 300-pair 19-gauge cables with coils of the iron-wire or iron-dust type, which were in use up to about 15 years ago, 24 large loading-coil cases were required necessitating a manhole of something over 1,500 feet cubage. Today, using the new molybdenum-Permalloy coils, these cables could be loaded with 8 cases of smaller dimensions, the required manhole having a cubage of some 270 feet, a reduction of about 80 per cent. Incidentally, the number of splices required to connect the loading coils would be reduced by half, thus reducing splicing costs and the troubles to which wiped joints are subject.

In addition to the reduction in plant investment offered by the opportunity to employ smaller loading manholes a no less important advantage is gained from the improvement in subsurface conditions. The smaller manholes naturally take up considerably less space in the street, which is of advantage during initial construction particularly in the congested subsurface conditions of metropolitan areas, and also, occupying less space in a direction paralleling the curb, access by other services to adjoining property is facilitated materially.

High-Speed Voice-Frequency Carrier Telegraph System

Discussion and author's closure of paper 40-51 by F. B. Bramhall, presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940, and published in AIEE TRANSACTIONS, 1940, pages 873–9.

C. M. Brentlinger (The Western Union Telegraph Company, New York, N. Y.): The introduction of carriers into the Western Union Telegraph system is a comparatively recent development, and has brought with it some interesting operating problems. Prior to 1929 practically all circuits were operated on physical conductors, utilizing ground-return circuits. With circuits of this type, transpositions in outside wire construction are not necessary, and the wire plant was therefore largely made up of nontransposed conductors and, except for short sections in congested areas, was and is practically all open-wire construction. With the introduction of carrier systems it was, of course, necessary first to do a considerable amount of outside plant work in transposing pairs, eliminating excess resistance, and loading cable sections to obtain suitable pairs for the carrier system. In order to keep the expense for this work at a reasonable minimum, the outside plant work was limited to those pairs actually needed for the carrier systems, so that the carrier leads now contain two or more transposed and balanced pairs for carrier operation, in addition to many wires not transposed and carrying ground-return telegraph circuits of various classifications. In this connection it is interesting to note that while the use of nontransposed wires is generally unsatisfactory in carrier operation, we have in emergencies successfully bridged breaks in carrier pairs by patching with nontransposed conductors of the same ohmic resistance in lengths up to 50 miles.

Perhaps the most significant new problem has been the increased seriousness of wire failures, involving carrier pairs. Assuming that all ten channels of a carrier system of this type are multiplexed for four-printer operation, the carrier group totals 40 duplex printer channels, and a failure of any one of the four wires supporting this system will interrupt all 40 of these channels, as well as the circuit assigned to the physical conductor. While carrier groups are not ordinarily assigned to full capacity, the New York-Chicago carrier, for example, has 28 duplex printer and Morse circuits normally assigned on the ten carrier channels, and the loss of such a considerable group of facilities is indeed serious.

As protection against such failures, each carrier system is provided with an alternate route, in addition to the regular route over which service is normally maintained. The two routes are usually over different pole lines with repeater stations in different cities. In the case of the New York-Chicago ten-channel system the regular route is from New York through repeaters at Binghamton, Jamestown, Akron, Marion, and Hammond to Chicago, while the alternate route is from New York through repeaters at Bound Brook, Harrisburg, Bedford, Pittsburgh, Wheeling, Columbus, Cincinnati, Indianapolis, and Hammond to Chicago. It is interesting to note that while the wire mileages of the two routes are practically equal the alternate route has twice as many repeaters as the regular route. This difference is largely due to a greater amount of cable in the alternate route. Over-all attenuation of the two routes compares approximately in the ratio of nine to five.

Alternate routes are lined up daily and maintained intact from terminal to terminal, ready for instantaneous use in case of trouble on the regular routes. Changes to the alternate routes are made by prearrangement between terminals, with practically no interruption to the carrier system. Individual multiplex circuits that lose synchronism because of the change are back in service within one to five minutes after the change in a carrier route is initiated. In addition to the terminal-to-terminal alternate routes, repeater stations on different routes are in some cases provided with connecting carrier pairs to permit rerouting promptly in the extreme cases of failure of both routes on opposite sides of the connecting pairs. As a matter of fact, the necessity for such changes is of infrequent occurrence, and it is not uncommon for a carrier system to operate over its regular route without change to an alternate route for a period of a week or more. With fall-back facilities of this character it can be safely said that circuits assigned to carrier channels are at least as reliable as those assigned to physical conductors.

In addition to the daily line-ups of all carrier routes, regular and alternate, as mentioned above, which include the adjustments of repeater gains at all terminals and repeater stations, frequent checks are made of the balances within pairs, and of the cross fire between pairs. While all of the repeaters on carrier systems now in operation are in regularly maintained repeater stations, a few of these stations are closed during certain hours of the night. Unattended operation of the repeaters during these hours has been entirely satisfactory.

Experience in the operation of the four carrier systems that radiate from New York north to Buffalo, west to Chicago, and south to Washington and Atlanta has amply demonstrated the adaptability of this type of carrier to our particular needs. Additions to the system are planned as the need for additional facilities arises, with the expectation that carriers of this general type will eventually be in operation over most of the principal trunk routes.

R. B. Shanck (Bell Telephone Laboratories, Inc., New York, N. Y.): It is interesting to compare the voice-frequency telegraph system, designed for multiplex printer operation, described in this paper with other systems intended primarily for single-channel start-stop printer operation. The ratio of spectrum efficiencies of at least two to one in favor of multiplex working mentioned in the paper seems high. The 170-cycle spacing used by the Bell System was made liberal in order to allow for possible speed increases and to promote transmission stability of complicated circuit networks. In private-line service, such as that furnished to the press, the government, and others, it is required to operate many sections in tandem and, in the case of teletypewriter exchange service, transmission must be satisfactory over a number of sections switched together in tandem without line-up. It is believed that satisfactory transmission at the usual speed of 23 dots per second could be obtained with a spacing of about 100 cycles without excessive cost for selecting circuits, if it were not required to operate a comparatively large number of sections in tandem. The present standard 170-cycle channels have in a number of cases been used successfully for three-channel multiplex operation at speeds of 40 dot cycles per second and upwards, on a one- or two-section basis. As regards usage abroad, it is understood that a speed of 33 dots per second with 120-cycle spacing is common practice. From the foregoing it appears that for practical purposes the advantage of the multiplex is little more than the 40 per cent advantage of the five-unit code with respect to the seven-unit. It is obvious that for certain classes of service, particularly private-line service with many drops and switched message service, the start-stop method has very important advantages as regards flexibility.

Concerning the effect of changes in level of received signal current, it has been found of great advantage in Bell System service to build into the amplifier-detector circuit of each channel a correcting feature known as a "level compensator". This has practically eliminated the necessity for manual adjustment of the sensitivity of the receiving apparatus. A description of this device will be published in the near future.

It is stated in the paper that it has been found desirable to furnish individual monitoring equipment in conjunction with each channel terminal. In Bell System service it has been found sufficient to provide generally about one monitoring set for each 12 channels. This contrast can doubtless be accounted for by differences in character of the services.

Mention was made of the effect of exact phasing of the various carrier currents at the sending end and it was stated that experience indicated that little is to be gained from exact phasing. A study of this question has indicated that with a number of carriers, such as ten or more, provided in fixed phase relation it is probable that a random arrangement will not be objectionable from the standpoint of excessive peaks. If, however, the various frequencies are furnished by independent sources it will happen at times that substantially all the various currents will add directly to produce peaks which will cause serious modulation effects in vacuum-tube repeaters unless the latter are designed to have considerable excess power capacity.

I should like to ask Mr. Bramhall whether the figure of 12 minutes per day average lost time for a 1,000-mile multiplex carrier circuit includes periods of storm break, and also what type of tuned circuit is used in the carrier system.

F. B. Bramhall: C. M. Brentlinger, in clarifying the broader picture of one or more carrier systems operating on a heavy lead alongside a large number of grounded telegraph circuits, may have raised a question concerning the interference from the latter. All polar-operated grounded physical circuits are, and have for many years, been equipped with a noise-suppressing filter for the suppression of interference to paralleling telephone circuits. These are quite adequate for the protection of the carrier system.

It was not my thought to intimate that the 170-cycle spacing as used in the Bell System voice-frequency telegraph carrier was excessive or wasteful. I can well appreciate the rigidity of the transmission requirements for a system where a number of links are tied together in tandem.

System level changes are the bugaboo of all long-distance carrier circuits. Numerous solutions have been offered and some are highly effective but all add somewhat to the cost and to the complexity of the equipment. I shall be anxious to learn of the "level compensator" mentioned by Mr. Shanck.

The desirability of having individual monitor sets for each channel is, as Mr. Shanck suggests, accounted for by the class of service. Failure of the duplexed multiplex circuit on the individual channel interrupts the work of 16 operators. Any reasonable expense for facilities which will minimize the duration of the interruption is easily justified.

In our experiments with optimum phasing of carriers it was found that good could be accomplished by such phasing as long as the lines and repeaters were a fixed quantity. However, if the generator was lined up for best results on one route and then the system was swapped to another route of greater length and more repeaters an entirely different phasing was required for best results. Our answer has therefore been to build repeaters with ample overload capacity.

The lost time of 12 minutes per day on the multiplex circuit operated on the carrier channel includes all interruptions not directly chargeable to multiplex apparatus failures or to grounded polar-operated extensions beyond the carrier terminals. It does include storm breaks which interrupt, simultaneously, two routes not separated by an average distance of perhaps 125 miles. The question on tuned circuits is a bit out of my domain but I can say that our tuners comprise a series of tuned-circuit elements coupled together by transformers which may or may not contribute to the frequency-discriminating properties. This general type of tuners, I am told, is described in a paper by E. K. Sandeman "Transformers as Band Pass Filters", published in *Electrical Communication*, April 1929.

Calculation and Design of Resistance-Coupled Amplifiers Using Pentode Tubes

Discussion and authors' closure of paper 40-52 by F. E. Terman, W. R. Hewlett, C. W. Palmer, and Wen-Yuan Pan, presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940, and published in AIEE TRANSACTIONS, 1940, pages 879–84.

True McLean (Cornell University, Ithaca, N. Y.): This paper should be of considerable value to engineers charged with the duty of designing practical amplifiers, since it assembles for the first time almost all of the important factors involved in the particular type of circuit discussed.

Beginning with the well-known relation of equation 1 of the paper, first given by Hull and Williams in 1926, the authors add the three factors α, β, and γ of equation 2. The factor α is treated at length elsewhere by Doctor Terman, so the vital contribution of the paper is the rational derivations and uses of the factors β and γ. There appears to be no handy means of control over these factors that would tend to make them compensating, or reduce undesirable variations in α. The most desirable condition would therefore appear to be realized by making β and γ each equal to unity for all frequencies. This can be done in the circuit of figure 1 only by making the capacity of capacitors C_f and C_{sg} infinite. The practical difficulties are greatly aggravated if several stages are cascaded for the amplification of very small voltages. In this case a very small mutual impedance in the power supply will cause low-frequency oscillation (motorboating), and piling up capacitors on C_f and C_{sg} does not cure the trouble, but merely reduces the frequency of oscillation.

Several years ago (1931) the writer was led to a solution of this difficulty that has recently become rather common. It consists in arranging a circuit that actually takes advantage of the voltage drops in R_s and R_f to improve the general performance, so that capacitors C_f and C_{sg} are not only superfluous, but actually detrimental. The result is accomplished by adding a second tube and interstage coupling network to form a push-pull or balanced circuit. The important thing is that a single common resistor R_f is used for both cathodes connected together, and another common resistor R_s is used for the two paralleled screens. Capacitors C_f and C_{sg} are omitted entirely.

Briefly, an oversimplified description of the circuit action is as follows: The alternating components of the cathode currents of the two tubes are in phase opposition, and tend to cancel each other as far as the production of a-c potential drop in R_f is concerned. Exactly the same relations exist for the two screen currents, while correct direct-potential conditions are maintained by merely using resistors of half the size that would be used in the circuit of figure 1*a*. This arrangement has been criticized on the theory that it depends on balance and accurate matching of all elements on the two sides of the circuit; the tube elements being notoriously bad in this respect.

A thorough analysis of the push-pull circuit with common screen and cathode impedances under unbalanced conditions is quite lengthy and obviously cannot be given here. It is hoped that this may be made the subject of a separate paper in the near future. One result of the complete analysis pertinent to the present discussion is that the circuit works just about as well under severe unbalance as it does balanced. The reason is that the common cathode and screen resistors constitute a differential feedback circuit which always works in the direction to improve the balance. By proper circuit design this "balance forcing" action may be made very powerful, and results in an over-all response curve for the amplifier the same as curves 1 of figures 7 and 8 of the paper. The complete removal of phase shifts due to factors β and γ is a powerful advantage when stabilized feedback is attempted on the amplifier. In addition, a high-gain amplifier made of several stages displays a remarkable lack of sensitivity to common impedance and a-c ripple in the power supply.

Frederick Emmons Terman: The use of push-pull circuits throughout an amplifier as advocated by Professor McLean is a very effective means of making the factors β and γ unity. Such arrangements are to be recommended where the amplification must be maintained down to very low frequencies.

At the same time it is to be kept in mind that in many cases one does not desire uniform amplification at very low frequencies but prefers some form of low-frequency cutoff. Under these conditions the screen-grid and bias impedances can be so proportioned as to aid in achieving the desired results as pointed out in our paper.

Control of Inductive Interference to Telegraph Systems

Discussion and author's closure of paper 40-50 by J. W. Milnor, presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940, and published in AIEE TRANSACTIONS, 1940 (August section) pages 469–74.

F. A. Cowan (American Telephone and Telegraph Company, New York, N. Y.): Mr. Milnor's paper is indeed interesting and should prove a worthwhile reference for those concerned with the problems of mitigating interference on telegraph systems.

Although in the Bell System most of the telegraph services are handled over carrier or metallic systems, there are still several hundred thousand miles of grounded d-c telegraph circuits on which it is necessary to employ suitable means to reduce interference to tolerable values.

In the past we have used various circuit arrangements, some of which were similar to those discussed in the paper. For some types of circuits, use is made of an arrangement similar to the multiwire neutralizing-transformer arrangement discussed. It has been our experience that other forms of interference, such as 25-cycle inductive interference, cross fire, lightning and forms of static, ground potential, both that due to magnetic disturbances and that due to local conditions such as d-c transportation systems coupled with high ground resistivity may frequently be as important as 60-cycle interference.

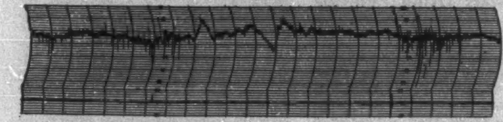

Figure 1. Bias in telegraph signals received simultaneously over two telegraph circuits on the same line, one equipped with balancing wire and other without

Neutralizing or balancing wires have the advantage over selective filter arrangements in that such wires tend to reduce interference in all forms. For this reason balancing wires are the most extensively used mitigative measure in the Bell System. In order to secure full benefit from the balancing wire it is customary to have it extend over the full length of the telegraph repeater section. The usual practice is to employ a balancing wire similar in make-up to the wire to be balanced and to connect this wire to an extra winding on the receiving telegraph relay. The poling of the operating and balancing windings is such as to reduce the interference. An example of the effectiveness of such arrangements is shown in figure 1 of this discussion. This is a record of the bias in telegraph signals received simultaneously over two telegraph circuits on the same line, one equipped with a balancing wire and the other without. The variations in bias on the circuit without a balancing wire originate from two sources, the slow swings being associated with ground potential differences and the sudden momentary changes being associated with a local lightning storm.

J. O'R. Coleman (Edison Electric Institute, New York, N. Y.): The paper by Mr. Milnor presents excellent and much needed information on measures which can be applied to telegraph systems for co-ordination with power circuits. Previously papers pointing out measures applicable to power and telephone circuits have been presented before the AIEE, but this is the first presentation of measures specifically applicable to the telegraph system.

Mr. Milnor points out certain specific applications of many of the devices which he describes, but not their full range of application of their limitations.

It appears to me that the developments in rural power supply will result in many more problems involving co-ordination of power circuits and telegraph circuits. The telegraph circuits in general follow railway rights-of-way and the demand for rural power service will frequently necessitate a distribution line on an adjacent highway. Such conditions largely eliminate the possibility of separation and means must be found economically to co-ordinate the two systems under such conditions.

Work has been contemplated jointly between the Edison Electric Institute and the Western Union Telegraph Company to study these factors for some time, and it appears that we will shortly have an opportunity to actively start this work.

R. K. Honaman (Bell Telephone Laboratories, Inc., New York, N. Y.): Mr. Milnor's paper draws attention to the use of the neutralizing-transformer principle in telegraph circuits. This same principle, of course, has applications in other fields of communication protection

The neutralizing-transformer idea has had a very considerable appeal for mitigating the effects of induced voltages since it first appeared on the scene a number of years ago. It is simple and uses only coils with no moving parts or contacts to involve high maintenance.

The principle embodies merely a wire to pick up a voltage from an induction field and a transformer by means of which the voltage thus picked up may be inserted serially in any one or more working conductors which experience the same induction. By proper poling, the voltage thus applied to the working lines may be made substantially to counteract the voltage which they experience by induction, thereby preventing the flow of any induced currents of appreciable magnitude in the working circuits and the effects resulting from such currents.

From the beginning, however, it has been appreciated that while the device was very simple, its design would have to be carefully made because of the fact that it is inserted directly in working conductors and the presence of the transformer windings has a potentiality of interfering with the normal transmission of signal currents.

Mr. Milnor has pointed out the effect of the added impedance in each telegraph wire and where a multisecondary transformer is used, the more important effect of cross fire between the various circuits arising because each necessarily operates through a winding which must be coupled to windings connected to the other circuits. When used on telephone circuits, these difficulties take the form of transmission loss due to the insertion of the impedance, reflections because of the lumped character of these impedances, longitudinal unbalances which may react upon noise, and in the case of a multisecondary transformer cross talk between circuits.

The refinements involving the addition of amplifiers in Mr. Milnor's arrangements are largely brought about by the necessity for avoiding these adverse reactions on the telegraph circuits plus the fact that he is primarily interested in the relatively low continuous (so-called normal) induced voltages. Under the latter conditions, the self-impedances of the coils are relatively low which makes it desirable to tune the primary circuits so as to minimize the effect of the impedance of the primary pilot wire itself.

It may be of interest to point out a different set of conditions under which the neutralizing-transformer principle is being used without these additional refinements. The application I have in mind has to do with the protection of telephone circuits operating into power stations; protection against abnormal rise of ground potential due to the flow of short-circuit current through the station ground. The application of this device is particularly appropriate under these conditions because, in addition to the ordinary telephone communication, wires into power stations frequently carry pilot-wire relaying, remote control, remote indicating, and similar circuits, many of which cannot tolerate even the brief interruption of service that would accompany the temporary discharge of protector gaps. In these cases the voltage to be neutralized is considerably higher, ranging up to 4,000 volts and not infrequently even higher. The problem is somewhat simplified by the fact that the voltage is concentrated at one point and it can be completely picked up in a relatively short pilot circuit. The voltage is picked up between the power station ground itself and either the sheath of an aerial cable from the central office, if it is available, or some point substantially outside the field of the station ground. In many cases such a point would be not more than 2,000 feet away.

A transformer to neutralize several thousand volts under these conditions has a primary winding impedance which is quite high compared to the impedances which would be used on telegraph circuits, and therefore substantially all of the voltage of the pilot circuit appears across the primary winding without any additional tuning. It is practicable to neutralize all but about 100 volts out of 4,000 (60 cycles) with a primary circuit whose impedance does not exceed about 35 ohms. For this use it has been found most convenient to install the transformers on the basis of one transformer for each circuit so that the cross-talk problem does not become involved.

The Joint Subcommittee on Development and Research of the Edison Electric Institute and the Bell System made an investigation some years ago of the use of the neutralizing-transformer principle for mitigating induction under abnormal conditions in a 24-wire toll line. The transformers, of which there were 12, each contained 24 secondary windings connected to wires over which physical and phantom telephone circuits and d-c telegraph were operated. The design of these transformers was made with special care to minimize transmission loss through the windings and to reduce reflections and unbalances. They were designed to neutralize only 250 volts per transformer in contrast to the much higher voltages used for the power-station service and the primary wires required to pick up these voltages in each section were considerably longer. Under those conditions, it was necessary to use a capacitor to tune the primary winding at the interfering frequency to prevent too large a part of the induced voltage appearing as drop in the external primary circuit. This arrangement very effectively neutralized the induced voltages, leaving only about five to ten per cent of the applied voltage as a remanent voltage under steady-state conditions. It was found, however, that at the beginning of a transient disturbance, the initial charging of the capacitor delayed the initiation of action of the transformer, thereby permitting a transient remanent voltage in the telephone circuits which rose to values of 30 per cent or more of the applied voltage. While this persisted only for a brief interval, it was sufficient to cause breakdown of the telephone protectors.

No further application of the neutralizing transformer to the mitigation of transient induced voltages in toll telephone lines has been made and up to the present time it appears that, all things considered, it is less desirable for this type of service than other measures which are available.

J. W. Milnor: The discussion by Mr. Honaman supplements the paper in illustrating the broad field of usefulness of the relatively simple neutralizing transformer. He indicates a difficulty in correcting transient disturbances due to the shunting effect of the tuning capacitor which parallels the transformer primary. In our work we have met this, at least in part, by placing a reactor in series with the capacitor. Such an arrangement with two capacitors each in series with a reactor, for mitigating transient voltages is described in the paper.

The neutralizing amplifier also is finding a broad field of usefulness, and with further experience the synchronous selective system is likely to be of much value where the induced voltages are not subject to rapid changes.

Problems of inductive co-ordination of power and telegraph systems are the natural result of the desire of each utility to expand, and the desire of each to use its plant at a maximum of capacity and efficiency. The responsibility for co-ordination, to the extent that it is justified, is recognized as joint. As Mr. Coleman indicates, the growth of rural power distribution lines is lending increased seriousness to the problem. Their co-ordination may be especially expensive because the exposures tend to be distributed. In some such cases it may be practicable to reduce the inductive influence of the power systems; in others reliance must be placed upon devices such as those herein described.

The Design Characteristics of Amplidyne Generators

Discussion and author's closure of paper 40-10 by Alec Fisher, presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940, and published in AIEE TRANSACTIONS, 1940, pages 939–44.

C. R. Hanna (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): This paper on the design of the familiar metadyne is very interesting. Where regulation accuracy requirements are not too great, this device may be used, but as the author points out, a nice balance between the compensating field and the armature ampere turns due to load current is required for high amplification, and this balance, of course, is subject to definite practical limitations.

It may be interesting to compare the power amplification of the metadyne with that of a simple standard exciter generator with an electromechanical rheostatic voltage regulator such as the Silverstat[*] or any similar device preceding the exciter. Such regulators cover the full range of resistance variation for changes in applied voltage of less than four per cent and in the middle of the range the flatness is equivalent to less than two per cent. The change in power of the input circuit of the Silverstat represented by two per cent change in voltage is about 0.4 watt. Taking the exciter output as 4,000 watts, to correspond to the size of machine mentioned in Mr. Fisher's paper, the power amplification is 10,000. This is somewhat better than that of the best reported value of a four-kw metadyne at full load. The Silverstat, however, can control much larger exciters with the same low input power. For example, the largest size may regulate a 100-kw exciter with 0.5 watt input, giving an amplification of 200,000.

Such a combination of regulator and exciter has the advantage of being less fussy to design and manufacture. It is inevitable that machines designed to perform several functions are subject to a greater number of limitations and compromises.

A further advantage of the electromechanical regulator is that it uses the force of a spring as a reference and this is much more stable than any conveniently available electrical reference current such as required in the metadyne circuits.

K. K. Bowman (nonmember; General Electric Company, Schenectady, N. Y.): Mr. Fisher has pointed out that the shunt quadrature field reduces the armature heating during steady-state conditions. However I believe a few remarks are in order regarding the effect of the shunt quadrature field during transient conditions. In circuits using control field forcing the armature short-circuit current may be instantaneously larger when the shunt quadrature field is used than when it is omitted. This is due to the close coupling between the shunt quadrature field and the short-circuit axis of the armature. Hence in certain applications omitting the use of the shunt quadrature field may reduce the armature heating as well as increasing transient stability and response.

Mr. Fisher's figure 4 shows the effect of the shunt quadrature field upon amplification. When we consider that there is a wide variety of fields that may be used all of which affect amplidyne characteristics, some idea of the flexibility of the amplidyne for special and difficult control jobs can be realized.

Another very important practical characteristic of the amplidyne, other than its very high volt-ampere amplification, is that this amplification increases rapidly as the size of the machine increases. That is, assuming the same general design in accordance with good mechanical and electrical practice, the volt-ampere input to the control field will tend to remain constant regardless of the size of the amplidyne. This means that one size of control apparatus, such as a high-vacuum tube amplifier may be standardized to control jobs requiring power from a few watts to many kilowatts. This means a real simplification and will be extremely important with the increasing use of automatic control.

K. M. Sparrow and **E. C. Watson** (nonmember; both of Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): We have been using a rotating regulator similar to the amplidyne described in the paper since 1928. There have been some problems arising out of its use. In some cases this amplidyne has been designed without interpoles, reliance being put on the brush drop to commutate the currents involved. In applications where close regulation is required and where the control voltage must reverse, the brush drop is objectionable for it causes an error in the response. This regulator has two sets of brushes and so it appears that this error will be amplified. Would the authors please give their experience with the brush drop?

It has been our experience that in this type of regulator the residual voltage must be kept at a minimum. In Mr. Fisher's paper he mentions that it is desirable to keep the iron loss at a minimum. We would like to have the author's experience on the effect of the residual voltage on the accuracy of response.

The author is to be complimented on the work. The trend in industry is toward a greater use of regulating devices and this type of machine doubtless will find a number of applications.

Alec Fisher: See discussion, page 1137.

Dynamoelectric Amplifier for Power Control

Discussion and authors' closure of paper 40-7 by E. F. W. Alexanderson, M. A. Edwards, and K. K. Bowman, presented at the AIEE winter convention, New York, N. Y. January 22–26, 1940, and published in AIEE TRANSACTIONS, 1940, pages 937–9.

P. L. Alger (General Electric Company, Schenectady, N. Y.): The advance of engineering in recent years has been especially marked by the joint use of widely different branches of engineering knowledge in a single structure, as, for example, the combined electrical, mechanical, and thermal theories underlying such developments as the Magne-Blast breaker and the hydrogen-cooled machine.

Heretofore, the experts in the communication and electronic fields have seemed to live almost in a world apart from their fellow engineers who have dealt in industrial types of power equipment, very few of either branch being interested in the work of the other. Now, however, it has been shown that the circuits and concepts of the electronic art can be built into power equipment; and that in fact there is a remarkable similarity between amplification and stability problems throughout these fields.

These papers on amplidynes, therefore, seem to me to be of historic importance. They mark for the first time the union of the talents of the electronic and industrial motor engineers, resulting in the creation of power amplification systems of the greatest variety and potential value to industry. Hereafter designers of d-c machines will take a real interest in negative-feedback power amplifiers, and communication engineers will think of d-c machines as possessing far more than the prosaic character with which they have generally been endowed in the past.

K. M. Sparrow and **E. C. Watson** (nonmember; both of Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): The amplidyne described is very interesting. Since 1928 our company has been manufacturing a rotating regulator and are using it extensively on variable-voltage elevator and planer sets.

In Mr. Alexanderson's paper he mentions the difficulty caused by back coupling and he states that it required a rather delicate adjustment. In most industrial plants we have found it is best to avoid delicate adjustments. The paper also states that the tendency toward regenerative oscillation is present when the amplifier is used to feed highly inductive loads such as field windings on large machines. He comments that they have always been able to obtain stable operation in "one way or another". It appears that this would tend to complicate the application as compared with a simple easy-to-maintain regulator.

Mr. Alexanderson's paper mentions that the electromechanical resonance is apt to be a real problem in certain applications of this amplifier. Does this mean that it cannot be applied to an existing drive unless new motors and generators are also supplied? There are many applications where it is desired to add a regulator without having to change the present drive.

The regulator as described in the papers should find its place in industry where there is a growing demand for all types of regulators.

E. F. W. Alexanderson: The question asked by K. M. Sparrow and E. C. Watson is very appropriate, and I am glad to have an opportunity to make the situation clear.

The delicate state of balance of forces which make possible a high ratio of amplification is a problem for the designer, but if the machine is once correctly designed this does not involve any complication or difficulty in operation. Quite the contrary, the better the design the less will the operator be aware that there ever was a problem. In most cases, it is only necessary to have a specially designed generator, whereas existing motors can be used. It is also usually possible to use an amplidyne generator as an exciter for an existing generator, which in its turn controls a motor or performs whatever function is desired.

Now we have endowed the dynamoelectric machine with a new property, that of an amplifier, and the implications of this new requirement must be understood if the principle is to be successfully applied. We have also hoped that our analysis of the problem will convince those who wish to become interested in the practical use but find it hard to believe that a ten-kw dynamo can be controlled directly by a small radio tube.

Industrial Applications of Amplidyne Generators

Discussion and authors' closure of paper 40-23 by D. R. Shoults, M. A. Edwards, and F. E. Crever, presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940, and published in AIEE TRANSACTIONS, 1940, pages 944–9.

K. M. Sparrow and **E. C. Watson** (nonmember; both of Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): Since 1928 our company has been applying a rotating regulator to certain applications. We have had many problems arising out of its application.

In many industrial plants where they have their own power station we have found that the frequency is allowed to vary. This variation in frequency is objectionable on this type of regulator especially in cases where it is used against a matching voltage supposedly supplied by a constant-potential exciter such as in the paper-mill drive. Would the authors please give their experience with the effects of variation of frequency? It appears that the amplidyne would amplify the changes in frequency.

In some cases this amplidyne has been designed without interpoles, reliance being put on the brush drop to commutate the currents involved. In applications where close regulation is required and where the control voltage must reverse, the brush drop is objectionable for it causes an error in the linear response. This regulator has two sets of brushes and so it appears that this error will be amplified. Would the authors please give their experience with the brush drop?

The paper states that in the simple circuit, figure 1, the accuracy obtained is within a few per cent. From further discussions and diagrams it appears that to get better accuracy it is necessary to use a "composing amplifier". Nothing is said in the paper about the "composing amplifier". Is the simple amplidyne accurate only within a few per cent? Our experience has been that most applications requiring a regulator must have greater accuracy.

Can this regulator be applied to a constant-voltage circuit such as an adjustable speed motor or must it always be used on variable or modified variable voltage?

The authors are to be complimented on their work. The trend in industry is toward a greater use of regulating devices and this type of machine doubtless will find a number of applications.

R. W. Porter (General Electric Company, Schenectady, N. Y.): Messrs. Shoults, Edwards, and Crever have pointed out the fact that the amplidyne generator, because of its low control-power requirement, can often be used as a regulator or closed-cycle controller without any additional amplifiers. Although the amplidyne characteristics differ from those of an ordinary machine only in order of magnitude, this difference opens up an entire new field of applications which previously have been impractical.

For example, in the scheme shown by the authors in figure 1, there are two opposing control fields. The magnetomotive force which controls the amplidyne is the difference in magnetomotive force of these two fields. If the per cent regulation of the controlled quantity is to be R, the reference field must produce $(1/R)$(A.T.) and the control field must go from $1/R$ to $(1/R)(1+R)$(A.T.), where (A.T.) is the number of ampere turns required to control the amplidyne over the necessary output range when only the one control field is excited. Since the watts dissipated in a field winding containing a fixed amount of copper varies as the square of the ampere turns, the total dissipation in the two bucking fields will be approximately $2/R^2$ times the power required for one field alone, or $4/R^2$ times the power required if the copper space in both fields were used in a single large control field.

An ordinary generator requires about one per cent of its rated output for excitation. If it were to be used in a differential-field scheme such as this, designed for ten per cent regulation, it would have to dissipate 400×0.01 or four times its rated output in the form of field heating. The amplidyne, however, needs only one $^1/_{100}$ as much power for excitation and therefore will dissipate only four per cent, instead of four times its rating in the two opposing fields.

In the differential-voltage scheme, shown by the authors in figure 2, field heating is no longer a problem, but still an amount of power approximately equal to $1/R$ times that required for excitation must be transferred either from the primary source B into the load, or in the reverse direction. Furthermore, if the range of control is great, the potentiometer across B must be of low resistance, and will absorb at least as much power as this, possibly several times as much. For the ordinary generator in a design for ten per cent regulation, B would have to be capable of supplying at least 20 to 30 per cent of the generator rating with exceptionally good voltage regulation, and the potentiometer would be large and expensive. On the other hand, if an amplidyne generator is used, B will need to be good for only a fraction of a per cent of the amplidyne output, and the potentiometer will be small.

Thus it is evident that with the amplidyne a variety of simple control circuits are brought within the range of practicability.

The truth of the authors' statement regarding stability is illustrated by the following criterion for the stability of a closed-circuit system having three time constants, T_1, T_2, T_3, and a total amplification around the circuit of A. Such a system will be unstable unless

$$1+A<(T_1+T_2+T_3)\left(\frac{1}{T_1}+\frac{1}{T_2}+\frac{1}{T_3}\right)$$

This same criterion holds whether the system is composed of three generators, or an amplidyne and a standard generator, connected to regulate voltage, in which case the time constants are all of the form L/R, or a motor with an exciter which is connected to regulate speed, in which case one of the time constants is determined by the inertia and armature resistance of the motor. The worst situation is obviously when all three time constants are equal, for then the amplification is limited to eight. If one of the time constants is $^1/_{20}$ of the largest one, then the amplification can be a large as 44. Similar but more complicated expressions hold when the number of time constants is more than three. The short time constant of the amplidyne, therefore, makes possible definite improvement in the stability of a regulating system.

A. Fisher, D. R. Shoults, M. A. Edwards, and F. E. Crever: The comments by Messrs. Bowman and Porter in connection with these papers are particularly appreciated because of the wealth of experience which they have had with these machines and with their application. Mr. Bowman touches upon one point which might well be discussed further and that is, that the trend in design of the amplidyne generators has been such as to result in a practically constant control-field input even though the size of the machine is materially increased. Several 50-kw machines have been built and tests on these machines have shown that full control of output could be obtained with a control-field input expenditure of considerably less than one-quarter of a watt. The amplification factor of these machines then is materially greater than 200,000:1, which is the figure mentioned by Mr. Hanna as being representative of the performance of a 100-kw exciter with field control by means of a rheostatic-type regulator.

A mere statement of amplification factor is, however, not a complete statement of the utility of such an amplifier. Mr. Porter has given a criterion as to the relationship of the stability factor of a closed control system as determined by the over-all amplification and the number and magnitude of the independent time lags of the various devices in the system. As the number of time lags is increased, the stability problem becomes more difficult even though the time constants may be short in each case. It is particularly necessary to have as short a time lag as possible in most amplifiers for industrial purposes as there are usually at least two other components in the system which necessarily involve time delays and if the time delay of the amplifier itself can be made very small in proportion to the others, then the amplification may be correspondingly large with less difficulty in obtaining stability. It is realized, of course, that stability can be obtained with high degrees of amplification by means of various types of circuits feeding back into the input of the amplifier. The problem of design of such feedback units is made easier however, with high amplification and with low time lag of the amplifier.

The comments by Mr. Hanna and also Messrs. Sparrow and Watson refer generally to regulators and regulating devices. The authors wish to stress that the amplidyne generator as such is not a regulator and is instead, as stated in the paper, an amplifier. A regulator must contain within itself the standard of comparison and differential operating means for producing the required control function. The amplidyne generator is adaptable however, to use with other regulators and comparison circuits as is any power amplifier. The essential requirements of an amplifier are that it must be capable of covering its required output characteristic range within a certain limit of input control power. As applied, the regulating circuits or devices should be capable of providing this amount of input control power within the permissible deviation of the final output characteristics from the specified ideal. Thus, in using the amplidyne generator, the comparison circuits or supplementary devices must be engineered with this point in view. It was not intended that these papers should cover a complete description of such circuits or such amplifiers, as many such devices are generally known and available.

As Mr. Porter has ably pointed out, if the amplidyne generator is used in comparison circuits, the required amount of excitation loss in the machine is insignificantly small as compared with the excitation which would be required for a conventional d-c machine operated in the same type of circuit with opposed fields and also that the required power output of a differential voltage circuit with a conventional machine would be prohibitively large as compared with the same circuit used with an amplidyne generator. It is perhaps for this reason that such factors as brush drop have not been of detrimental influence in the operation of amplidyne generators as these factors are of themselves small as compared with the resistance of circuits and saturation in the magnetic paths, all of these factors being lumped together in the complete control power requirements.

The name "amplidyne" is intended to distinguish between this new development of a variable current, controllable constant-voltage generator, and the "familiar metadyne" as mentioned by Mr. Hanna. The metadyne machine is usually thought of as being a constant-current machine and as such contains within itself the regulatory or comparison characteristics. The constant-current machine has, of course, a vastly different volt-ampere characteristic than the relatively flat one of the amplidyne generator. The restoring effect or tendency to bring about any particular output is internal in the usual metadyne arrangement and must be supplied by external means or circuits with the amplidyne generator.

Messrs. Watson and Sparrow have questioned the effect of frequency variations on such applications as the paper-mill drive described. In this particular application the standard of performance with which the operation of the machine is compared by use of the tachometer generator, is set up in the composing amplifier as a voltage standard and as such is independent of frequency or similar variations. Hence the only effect of a frequency variation would be to change slightly the amplification factor of the amplidyne by varying its rotational speed. The effect of this change is negligible as far as causing any disturbance of speed of the main drive.

The amplidyne generator is not limited in its application to any particular type of speed-control system, but is adaptable to any system requiring power amplification of a high degree and with time limit requirements considerably more severe than those usually met by conventional d-c machinery.

Analysis of Bushing-Current-Transformer Performance

Discussion and authors' closure of paper 40-69 by J. P. Gebelein and J. A. Elzi, presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940, and published in AIEE TRANSACTIONS, 1940 (September section) pages 541–6.

C. O. Werres (General Electric Company, Schenectady, N. Y.): One point which has been mentioned by Messrs. Gebelein and Elzi should be given more consideration sooner or later. I refer to the saturation that occurs in relays when they are subjected to overcurrents. This, of course, changes their impedance so that characteristics determined by either test or calculation which are usually made on the basis of nonsaturating burdens are not correct. Fortunately, the actual burden is less than the supposed burden and hence the transformer is better than indicated by the test or calculation. Offhand this does not sound too serious and it is not, if, for example, the errors in all transformers involved in a given setup using a percentage differential relay are kept below the relay setting. However, if this should not be done, it is conceivable that the effect of saturation of the burden might effect one transformer more than another to such an extent as to cause trouble.

P. O. Langguth (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): The authors have aptly described the problems besetting the application engineer in the analysis of relay problems involving

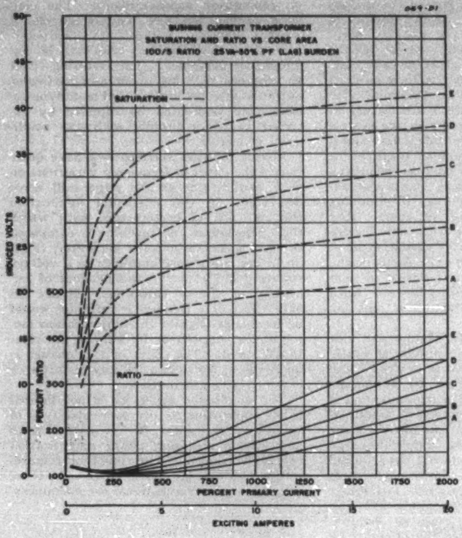

Figure 1

the use of bushing current transformers. They are to be congratulated on the extent and exactness of their investigation to obtain data that is a real value to the operating engineer.

It is important to note that the use of transformer excitation characteristics is more generally applicable in the solution of their problems than the usual ratio curves. The authors' discussion on burdens is indicative of the variety of loading conditions such as saturating burdens, introduced which render the use of ratio curves none too satisfactory. If the burden impedance varies with the value of secondary current, a ratio curve taken on some constant impedance burden is not suitable over the entire current range of the curve.

Relating to the variation in transformer characteristics with core volume, it is interesting to note the data shown in figure 1 of this discussion. Five transformers are represented here having the same internal and external diameters with the area ranging from normal to twice normal by changing the axial dimension. Steps represented are 20 (*B*), 40 (*C*), 80 (*D*), and 100 (*E*) per cent increases in core area. Similar data were taken by changing the external diameter only which gave approximately the same results. The improvements obtained are negligible under low-current conditions but easily apparent under high-current or high-flux conditions. This type of information is very important in the analysis of applications involving transients. The saturation characteristic is an index to the limit of operation with transients.

In commenting on the effect of wave form, it seems desirable to bring out the fact that the methods of measurement and the types of instruments used in making transformer tests have considerable bearing on the results obtained. In taking saturation characteristics for instance, we have found that the presence of harmonics in either the voltage or current waves or both, does not materially affect the results obtained if a Rectox voltmeter is used. However, ratio and phase-angle data in the saturated region will be affected somewhat by harmonics as pointed out by the authors. Since null methods ordinarily involve the fundamental only it may be desirable to suggest that a common level be approached for this type of testing.

The application of transformers involving circuits such as presented by the authors in their figure 6 is apparently simplified by using the transformer equivalent impedance. Ratio and phase-angle curves can be ignored when making analysis on this basis. The authors have nicely demonstrated a method of using the saturation characteristic in solving relay problems and have verified the over-all procedure by test measurements.

J. P. Gebelein and J. A. Elzi: The discussions which have accompanied the presentation of the group of papers on bushing-type current transformers indicate a widespread interest in this subject and bring out many valuable points.

The data presented by Mr. Langguth in his figure 1 is appreciated because it supplies information showing the effect on transformer performance for various values of core area. Since transformers were not available for test, data such as these were not included in the paper. It appears that the data presented in this figure could be considered as giving a true indication of the results which could be expected in any transformer of similar construction.

We feel that the points brought out by Mr. Langguth regarding the care which must be exercised in making measurements for saturation curves and the type of instruments to be used cannot be overemphasized inasmuch as experience has shown that considerable error can be introduced if these precautions are not taken.

Messrs. Werres and Langguth discussed the importance of taking account of the saturation characteristics of burdens from the standpoint of the harmonics which they introduce into the circuits and the change in burden resulting from saturation. We agree with Mr. Werres in that in many cases the effect of burden saturation is not of sufficient consequence to affect seriously the results obtained, but due judgment must be exercised in taking the effect of burden saturation into consideration.

A Proposed Method for the Determination of Current-Transformer Errors

Discussion and authors' closure of paper 40-68 by G. Camilli and R. L. Ten Broeck, presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940, and published in AIEE TRANSACTIONS, 1940 (September section) pages 547–50.

C. A. Woods, Jr. (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): This paper, like the Gebelein-Elzi (TRANSACTIONS pages 541–6) and Woods - Bottonari (TRANSACTIONS pages 554–60) papers, proposes a method of calculating the steady-state performance of current transformers from their fundamental data; consisting of the excitation characteristics, and the values of secondary resistance and leakage reactance. It differs from these other papers in that it is not restricted to bushing-type current transformers, in which the leakage reactance has usually been found sufficiently small that it may be neglected for most relay applications.

The calculation or measurement of leakage reactances in current transformers has been recognized as a problem, and is often quite serious in wound-type current transformers. Methods for reducing its effects such as equalizing windings as employed by the Westinghouse Company have been in use for many years. Hence, the treatment of this subject is important due to the ease and simplicity of performance calculations when adequate information on the leakage reactance is available. For the range covered, the material and methods presented seem very practical and worthy.

The authors state that the secondary leakage reactance is not necessarily constant, but varies with the secondary current and distribution of the winding. By test they have found the changes are quite limited, and from a practical standpoint may be assumed constant. I believe at high primary-current values additional factors should be considered. These include the magnitude of primary current, location of the primary conductors, the relative size of the core with respect to these spacings and currents, and the mutual or working flux in the core.

It would be interesting to know the spacings and locations of the primary conductors for the conditions under which the particular transformers were tested. It is realized that the method of measuring the leakage as given is subject to limitations in currents, but additional data at current values considerably above the 600 amperes primary and 10 amperes secondary, covered by the paper, would be quite valuable.

If the characteristics of the current transformers, including the secondary leakage, are known, then the use of the equivalent circuits and excitation characteristics gives an excellent method of calculating the overall relay and transformer performance. Perhaps additional work and data on the determination of secondary leakage reactances at the higher values of operating currents would accelerate the acceptance of such a method for applying current transformers in the relay field.

C. O. Werres (General Electric Company, Schenectady, N. Y.): The fact that we have five papers on this general subject shows clearly (1) a growing realization of its importance, and (2) definite progress in providing means for analyzing current-transformer-relay problems. The introduction of calculation methods carries three implications: (1) ordinary ratio and phase-angle data are inadequate for certain analyses, (2) because of the difficulties and expense involved in making such tests only a few central laboratories have been able to do this work, and (3) sufficient ratio and phase-angle data have not been available until recently to satisfy those who prefer it for those cases in which it is useful. I would, therefore, like to review the subject of direct testing because (1) some still prefer test data as is evidenced by the demand for it, and (2) it is valuable as pointed out by Messrs. Wentz and Sonneman in verifying predictions obtained by calculation.

For over 20 years the overcurrent ratio characteristics of General Electric bushing-type current transformers have been obtained by a simple comparison test which is fairly fast and economical. Another simple ratio test that may appeal to those who have to do less of this work than the manufacturer is described in our literature on bushing-type current transformers (*GEH*-229).

A few years ago the demand was extended to cover phase angle as well as ratio. As a result of this, the test equipment described by the writer in the August 1937 *General Electric Review* was built up around the shunt method apparatus used for high-precision normal-current tests. This was higher grade equipment than was necessary for overcurrent testing, but it was applied because it was so readily adaptable.

More recently, equipment which is much simpler and at the same time faster has been installed. Readings are taken on portable instruments, hence only one application of current is necessary for each point taken, whereas by the old method five to ten applications were sometimes necessary. The advantage from the standpoint of heating, hence time and expense, will be quite evident.

This new method has been a very good improvement as far as small current transformers are concerned. However, some of the high-voltage transformers have so much insulation that their thermal characteristics make testing rather tedious, even by the improved method. The difficulty is not in preventing the windings from reaching a dangerous temperature, but it is rather the time involved in waiting for them to cool down to a suitable temperature before taking the next point. Direct tests on such transformers are a real problem so for these cases an indirect method should be especially useful.

However, I would like to emphasize one point brought out in these papers, namely, that the calculation of a current transformer is simpler and results are more reliable if secondary leakage reactance can be neglected. However, this is not always possible and when this factor exists it should be recognized that the accuracy cannot be as good as otherwise, particularly if saturation occurs. Because of this fact, the method of determining reactance as proposed by Messrs. Camilli and TenBroeck promises to be helpful.

E. C. Wentz (Westinghouse Electric and Manufacturing Company, Sharon, Pa.): The authors assume the existence of a constant secondary leakage reactance, which is equivalent to a transformer with no leakage, but with a constant reactance in series with the burden. This is the same as assuming an equivalent leakage flux which flows around the whole magnetic circuit. A study of the actual flux paths in the transformer core will lead one to doubt the existence of such an equivalent constant reactance, or equivalent leakage flux. Figure 4 of the Wentz-Sonnemann paper (TRANSACTIONS pages 481–8) shows that the leakage flux flows through only a part of the core, and it is well known that the flux density in the core varies from point to point around the core. Any equivalent flux cannot possibly be the same as the real leakage flux which flows in only part of the core.

As long as the real density is not near the saturation value, the assumption that an equivalent flux in the whole core will cause the same ratio and phase-angle error as the real flux in part of the core is not very much in error. If the burden is high the leakage flux is small relative to the working flux, and errors in assuming the equivalent value of leakage flux will be less important.

However, if the burden is relatively low so that the working flux to induce the burden voltage is low, and the leakage flux, therefore, relatively high, and the flux density is near the saturation value in part of the core, it is no longer even approximately correct to say that a certain flux flowing in the whole core is equivalent to a greater flux flowing in only part of the core.

However, even though the assumption may not be exact, the resulting errors in calculation can probably be made to be always on the conservative or pessimistic side. The errors in calculation will be greatest when the burden is low. If the authors can show that at the lowest usual burden and highest possible current the measured ratio error will always be less than the test ratio so that results are always conservative, the method of calculation may have a real value to the industry.

The tests in the paper do not show this, as they are at high burdens.

For precision calculation a π circuit instead of a T circuit has been used in our work for a considerable number of years. This has the advantage of being more accurate—the disadvantage of requiring more numerical work.

C. T. Weller (General Electric Company, Schenectady, N. Y.): The operation of differential relays for generator protection on through short-circuits some 20 years ago led to overcurrent tests on the current transformers involved. These were of the bar type with rectangular cores and were rated at 2,000 amperes for 15-kv circuits. Tests were made up to about 25 times normal current at various values of matched and unmatched burdens. Two general recommendations were based upon the results: First, to adopt a short time delay for the relays in order to by-pass the larger part of the transient differences between the current transformers and second, to limit the differences between the burdens supplied by each pair of transformers in order to reduce both their transient and permanent differences at high overcurrents. The adoption of these recommendations has resulted in fairly satisfactory performance. However, the desirability of instantaneous operation on true internal faults has stimulated further investigations. Current transformers, as well as burdens, have been matched and special designs of transformers have been applied.

In matching current transformers, their secondary leakage reactance must be considered and in this connection, I should like to quote from a discussion presented in 1925: "For current transformers of the ring-core type with evenly distributed windings, the secondary leakage reactance may be taken to be zero. For current transformers of moderate voltage ratings and of low ratios of the square-core type, the leakage reactance may be taken to be approximately one-quarter of the total leakage reactance obtained from the short-circuit impedance test. This value applies over the range of rated current. For moderate overloads, the value may reach over one-half of the total leakage reactance. At heavy overloads, the saturation of the core greatly complicates the results. These results were obtained by calculation from the ratio and phase angle and exciting-current results and were referred to the results of the short-circuit impedance tests." The current transformers tested were of 1:1 ratio and were for use on 4.5-, 7.5-, and 15-kv circuits, respectively. Although the method used was far from exact, a considerable range of leakage reactance overcurrent ranges ordinarily encountered was indicated. From the standpoint of leakage reactance alone, ring-core type current transformers offer an advantage over rectangular-core types.

In conclusion, it appears that all of the work done on this general problem of overcurrent characteristics of current transformers, with particular emphasis on the papers here presented, has created a much better understanding of the difficulties involved and of the possibilities inherent in special treatment of individual cases.

R. L. TenBroeck: In regard to the secondary leakage reactance, which seems to be the main topic under discussion, our tests have indicated that in bushing-type current transformers with concentrated winding, the total secondary leakage reactance is constant up to the complete saturation of the core.

In wound-type current transformers the method of determining the secondary leakage reactance outlined by the authors, seems to be of particular value in all these cases in which the primary winding is so located that it does not saturate a portion of the core much in advance of the remaining portions of the core.

The use of fundamental values for the exciting current, instead of effective values, seems to result in better agreement between the calculated and test results.

Overcurrent Performance of Bushing-Type Current Transformers

Discussion and authors' closure of paper 40-67 by C. A. Woods, Jr., and S. A. Bottonari, presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940, and published in AIEE TRANSACTIONS, 1940 (September section) pages 554–60.

G. B. Dodds (Duquesne Light Company, Pittsburgh, Pa.): Aside from the calculation of ratio curves and determination of leakage currents, there are other uses of excitation curves. One of the most useful and easiest to use is a quick method of determining the approximate range over which the current transformer will perform without any great deviation from normal ratio for any given combination of burden and secondary currents. This is covered in appendix III, item *c* (linear performance range). For example, in figure 1 of this discussion are shown excitation curves of various types of current transformers, including both wound primary and through type. Ratio curves of the same current transformer at burdens of four ohms and two ohms respectively are shown on figures 2 and 3. It can be observed that overcurrent ratio performance of various types of current transformers is in the same order as the excitation curves shown in figure 1; that is, the current transformers having the lowest voltage excitation curves perform the poorest during heavy overcurrents.

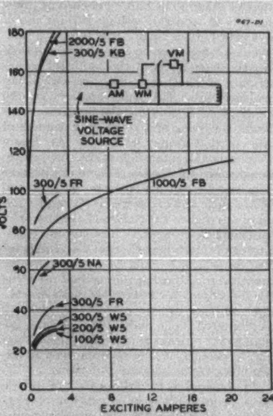

Figure 1. Excitation curves

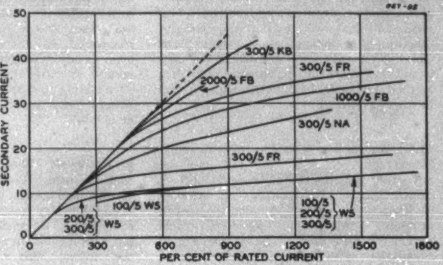
It has been agreed among current-transformer designers that the ratio curves could be rather accurately computed from excitation curves of ring-type current transformers. This same accuracy has not been obtained in other than ring-type current transformers. However, it is felt that, even in wound primary and bus-bar types of current transformers, the excitation curves are of some value in roughly determining performance at overcurrents.

Figure 2. 100-volt-ampere burden, 50-per-cent power factor



In figures 1, 2, and 3, the *W-5*, *NA*, and *KB* are wound-primary-type current transformers, the *FR* is ring type, and the *FB* is the rectangular bus-bar type with two coils. It can be seen that, at the voltage corresponding to one ampere excitation current, considerable departure from straight-line voltage characteristics has already occurred. Considering the *NA* current transformer, 60 volts is required to produce one ampere excitation current. Considering the ratio curve of this current transformer with a burden of 50 volt-amperes at 5 amperes, which is two ohms, it is seen that at 30 secondary amperes, which, with a two-ohm burden, required 60 volts to produce, the current transformer has broken off in ratio roughly 16 per cent. Similar rough ideas of the performance of the other current transformers from their excitation curves can be obtained.

Figure 4 shows the excitation and ratio curves of an oil-filled wound primary type of current transformer and a rectangular bus-bar through type with four coils. In these cases, ratio curves were made with extremely high burdens in order to obtain breakdown without necessity of using large primary currents. Again, it can be determined that there is a rough relationship between the excitation curves and the ratio curves.

It is hoped that the investigation of uses of excitation curves in connection with overcurrent performance of current transformers and relaying will be continued. Usefulness with ring-type current transformers has been definitely established. It is believed that further investigation may enable us to apply them similarly to rectangular bus-bar types and wound primary types with an accuracy approaching that of the ring-type current transformer.

C. C. Cole (nonmember; Duquesne Light Company, Pittsburgh, Pa.): The authors have given us a method of calculating the performance of current transformers from data obtained from a secondary excitation test; these data being taken by impressing sine-wave voltage on the secondary and reading the effective value of the exciting current with an rms ammeter and the iron losses by means of a wattmeter. This method appears to give quite satisfactory results on the ring-type transformers of the kind considered in this paper. The authors have also called attention to the similarity of the saturation curves obtained by using sine-wave exciting voltage and by using sine-wave exciting current when the readings of excitation voltage are obtained with a voltmeter which gives a deflection proportional to the average value of voltage. We believe that this point is worthy of special emphasis because of the wide variety of conditions encountered in field and laboratory tests. In many cases, even when these tests are performed in the laboratory, the supply voltage may be sufficiently distorted so that it could not be considered as a sine-wave voltage. Under field conditions this is even more likely to be the case. It has been our practice when conducting secondary saturation tests to use a rectifier type of voltmeter which is calibrated to read in rms terms. In case there is any doubt as to the distortion of the supply voltage, it is probably advisable to use two voltmeters, one reading average values and the other reading rms values. If there appears to be a considerable discrepancy between the readings of these two meters, it might be desirable to consider making a correction of the iron loss data obtained from the wattmeter.

It appears that the type of ratio curve which the authors are calculating will represent the ratio between the primary current (assumed sine wave) and the rms value of the secondary current. This would be the type of ratio characteristic ordinarily required for determining the operation of overcurrent relays. However, there might be cases where we were interested only in the fundamental components of secondary current. In this case it would probably be more accurate if the secondary saturation data were obtained by reading the inphase and quadrature components of exciting current

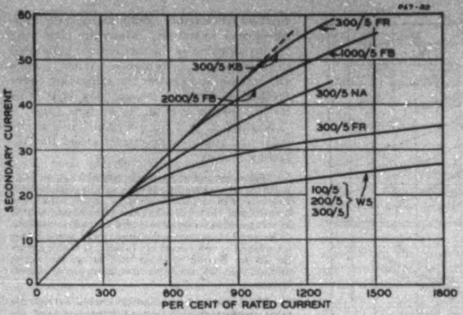


Figure 3. 50-volt-ampere burden, 50-per-cent powerfactor

with a wattmeter having a constant potential obtained from a phase shifter. This method would, of course, give only the fundamental components of exciting current, and when a ratio calculation was made with these data, we would expect to obtain the fundamental component of the secondary current. This is the type of ratio curve which might be desired when investigating the performance of directional relay elements in other similar devices.

There is a third kind of ratio characteristic that might be desired in some cases. When current transformers are used on differential circuits, there may arise cases where the equivalence of the secondary currents in rms value or of their fundamental components is not sufficient to insure a satisfactory balance. We are pointing out this possibility with the idea that in some cases it might be desirable to obtain both types of saturation curves for all the current transformers involved in the differential circuits, so that by comparing the various pairs of curves at least some qualitative idea could be formed regarding the performance of the transformers when used for differential protection.

The ideas which have been offered in this discussion are not intended to imply that more accurate methods of calculating performance than those suggested by the authors are generally necessary, but only with the thought that when more extended application is made of this method of calculation to all sizes of through-type transformers, some of which might have different core materials, there might occur cases where greater refinement would be required. One possibility that immediately suggests itself would be to apply the authors' method to wound-type current transformers. It has been our experience, which we believe has been borne out by the results of others, that the calculation of the overcurrent performance for wound-type transformers is not nearly so satisfactory as for the ring type. In the wound-type transformer it is probably not permissible to neglect the secondary leakage reactance either in calculating the ratio curve or in determining the secondary saturation curve. When secondary saturation curves are run on this type of transformer, even if the supply voltage is sine wave, the excitation on the core would still be distorted due to the voltage drop caused when the exciting current flows through the secondary impedance of the transformer.

H. A. P. Langstaff (West Penn Power Company, Pittsburgh, Pa.): The authors of this interesting paper on the overcurrent performance of bushing-type current transformers have plainly demonstrated the value of the saturation and loss curves as a means of analyzing and predicting the operation of bushing-type current transformers under normal and overload conditions. The usual ratio and phase-angle curves furnished with bushing-type current transformers are lacking in ability to supply information required in the application of high-speed relays. It has been difficult to obtain such curves extended into short-circuit-current ranges. The information concerning method of calculation given in the appendix of the paper should prove very valuable to the engineer who must investigate the action of current transformers under short-circuit conditions for high-speed relaying. The publishing of saturation and loss curves for bushing-type current transformers would be very helpful and along with the ratio and phase-angle curves which are satisfactory for usual relay considerations will give the relay engineer valuable tools with which to work.

We wonder to what extent manufacturers are prepared to supply saturation and loss curves for current transformers already installed in breakers and built over a period of the last 10 or 15 years. Are such curves on file in the design engineers' historical data? We suspect that they are not available and that in most cases it would be necessary to obtain characteristic data in the field at considerable expense. The physical position of the transformers and of their primary lead will have some effect on the curves thus obtained as compared to laboratory-obtained data. However, this possible variation due to secondary leakage reactance may, according to the authors, be neglected for currents up to 25,000 or 30,000 amperes.

As a result of reading this paper we are more than ever of the opinion that more information should be given operating engineers concerning the characteristics of bushing-type current transformers and we recommend that manufacturers supply that data in the form of voltage-saturation and watt-loss curves.

P. O. Langguth (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): The several papers in this session are strongly indicative of the interest and possible trend in the use of saturation characteristics to determine bushing-current-transformer performance. Transient and steady-state performance of transformers in combination with relay systems can be more completely analyzed by the use of these basic data.

The performance of power transformers is determined by the use of excitation and impedance characteristics. Likewise, at this time it is apropos to consider a standardized method of evaluating the output of current transformers. Normally, the ratio characteristic only is available to the user and a rough calculation from this is made to determine the overall transformer and relay performance. This information is usually satisfactory where normal speed relays and simple overcurrent protection schemes are involved. However, where differential, high-speed, or ground relays are used, ratio curves do not normally provide sufficient information for determination of relay settings.

Since this paper indicates methods by which the excitation characteristics of bushing transformers may be used in the solution of application problems, it would seem that standardization of their performance could be made on a similar basis. Modern relay practice is requiring an increasing amount of current-transformer data. The present method of supplying ratio curves and in rare cases phase-angle curves is an outgrowth of wound-type current-transformer and metering practices. Such procedure is relatively simple for this type of transformer in the metering range, because one set of curves will suffice for an entire line of transformers of a given general type. Due to space limitations, however, the performance of bushing transformers will vary with each breaker size, ratio, etc., requiring numerous curves for each ratio and voltage class. An attendant problem is the extension of these curves to 10 and 20 times normal current using special nonsaturating burdens as compared to the practical burden which may be saturating.

Therefore, this seems to be the proper time

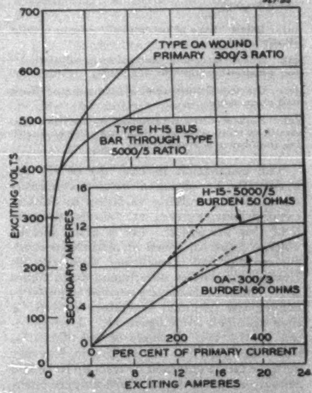

Figure 4. Ratio and excitation curves of current transformers

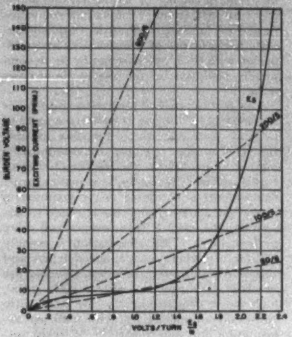

Figure 5a

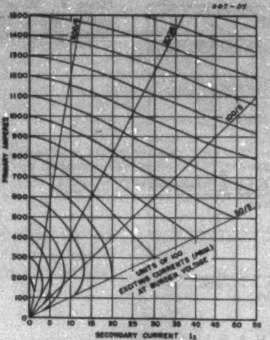

Figure 5b

to review our bushing-current-transformer practice from the standpoint of testing and publication of performance data. A single saturation characteristic for a transformer of each design is suggested as standardized procedure. This characteristic, including the watt and wattless components of the exciting current, could be drawn in one of several forms and extended well beyond the "knee of saturation". This thought can be carried further to obtain a measured standard of performance for each transformer size. A point selected beyond the saturation point would be well suited for this purpose.

The various papers indicate methods of using the saturation-curve data. However, in view of the proposed elimination of published ratio curves further reference is made to the methods given in this paper for calculating ratio, phase angle, and related relay problems. The extent of calculation depends on the accuracy required and the complexity of the relay scheme. The methods are listed in the order of their accuracy and complexity,

(*a*). Below "knee of saturation"—use turn ratio. (Ratio only)

(*b*). Above saturation approximate calculation—use simplified method in this paper. (Ratio only)

(*c*). Use complete method in this paper. (Ratio and phase angle)

(*d*). Represent the transformer in the equivalent circuit of relay scheme. (Use turn ratio and exciting impedance of transformer)

The calculation in case (*b*) or (*c*) can eventually be obtained from a composite curve chart involving variation in burden, ratio, primary current, etc., similar to figure 5 of this discussion. For a given burden voltage (case *a*), based on assumed secondary current and transformer ratio, the excitation current is determined from figure 5*a*. The actual primary current required to deliver the assumed secondary current is then obtained from figure 5*b*. A comparison of the two methods of calculation is shown in figure 6 of this discussion, together with the curve obtained by tests up to 70,000 primary amperes on a 3,000/5-ampere bushing current transformer.

Summarizing, the industry would be benefited by the adoption of a standard for circuit-breaker-bushing current-transformer performance which would provide:

1. Saturation characteristic for each transformer design, that is, for a given circuit breaker rating and voltage class.

2. Standardizing by means of a given voltage at a definite value of excitation current.

3. Ratio and phase-angle curves to 100 per cent normal current for the occasional transformer used in metering applications.

E. L. Harder (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): The paper by Woods and Bottonari shows that, for bushing-type current transformers at least, the performance may be specified by three data.

1. The saturation curve giving exciting current or error current, versus voltage being induced by the transformer.

2. The exciting-loss curve, similar to a saturation curve but giving the loss component versus the voltage induced. This, together with the saturation curve fixes the power factor or phase angle of the error current.

3. The secondary leakage impedance, which added to the other burden of leads and relays determines the voltage the transformer must induce.

These three data comprise a complete description equivalent to the statement of ratio and phase angle. The expression and use of part or all of the data in this form for specifications or application work is usually referred to as the *saturation curve method*. Frequently only the saturation curve itself is needed. For many cases the secondary leakage impedance is also required. Only for the most exact work are the loss data also required. That these three data are equivalent to ratio and phase-angle curves, for the bushing-type transformers over a wide range of conditions has been shown in the paper by calculating the one from the other, with entirely adequate accuracy for overcurrent performance.

The paper by Camilli and TenBroeck (Transactions pages 547–50) shows equally good results for other than bushing types. However, there is still a question of the equivalence in certain types where primary leakage fluxes cause severe saturation of parts of the iron circuit.

The directness of the saturation-curve method has already swung many relay engineers over to its use. Many are clamoring for its adoption as the medium for standards of overcurrent performance. What, then is the case for and against the saturation-curve method in general, recognizing that it is much superior over-all for bushing types.

Against it, and for continued use of the ratio and phase-angle curves stand the following factors:

1. The ratio and phase-angle curves leave no loopholes for any misleading results with special designs. Regardless of the mechanism of action within the transformer they tell what the transformer will do as measured at its terminals under steady-state conditions and at the particular burden and power factor for which the test curves are taken. It is still a matter to be proved whether the saturation curve method will be adequate for all types of transformers.

2. The ratio and phase-angle curves extend the same method of performance expression used for metering at normal currents, into the relay field involving overcurrents. Since the same personnel is frequently involved in both problems this has its advantages.

On the other hand, *for* the saturation curve, stand the following prominent factors:

1. For a single current transformer feeding a burden of overcurrent relays or a trip coil, the error current and resulting secondary current may be determined readily. This can be done without the necessity of interpolating or estimating based on ratio curves taken possibly at a different power factor from the actual burden.

2. For transformers connected differentially the steady-state current in the differential connection is the vector difference between the error currents (given by the saturation curves) of the two transformers. The limiting case is generally when one transformer saturates and the others do not. The saturation curve gives directly the error current of the transformer which saturates and this is the false differential current. Ratio curves would not show this value unless the burden current happens to be in phase with the exciting current.

3. The saturation curve and secondary leakage impedance provide the necessary data to determine the performance when subjected to an asymmetrical primary current. This is of prime importance in differential protection of busses, generators, and transformers.

Instead of viewing saturation as reaching a certain flux density, it may be viewed directly as reaching a certain error current. A voltage may be determined from the a-c saturation curve corresponding to the particular exciting or error current which defines saturation in the particular problem. In my discussion of the Wentz-Sonnemann paper (Transactions pages 481–8) it will be shown that this voltage may be substituted for the quantities, flux density, iron area, and secondary turns in the formulas which determine whether or not saturation will occur and if so, when.

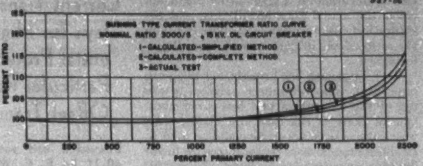
In conclusion, the advantages of the saturation-curve method are so great as to recommend its general use in preference to ratio and phase-angle curves. This has been shown to be feasible for bushing-type transformers over a wide range, and for many other types, although some test data seem to indicate that it may not be universal to all types. Further tests are desirable to show whether it may be sufficiently universal for standardization purposes for all types of current transformers. In any case its clarity and directness recommend its use quite generally for relay application work.

Roy M. Smith (Westinghouse Electric and Manufacturing Company, Newark, N. J.): This paper should be a real contribution to protection engineers, for it forms the basis of securing more accurate relay settings. In the past, considerable stress has been placed by relay men on obtaining precise overcurrent or distance settings, but many of the settings obtained were in error due to incorrect data, that is, incorrect short-circuit current values. Although the system of symmetrical components for the calculation of short-circuit currents has been available for some time, and is now familiar to most of us, and the d-c and a-c network analyzers can be used to simplify the calculations, the results have been merely approximate, since the real ratio of the current transformer has not often been used. This has resulted from the fact that the correction factors have not always covered the actual conditions met with. Now that a method of calculating the correct ratio for any condition is available, faster relay action should be possible. This is because any type of relay selection except definite time, automatically slows down the fault-clearing time when nominal current-transformer ratios are used in determining the secondary currents. Since the ratio always falls off at higher currents and sometimes quite badly, as indicated in figure 9*a*, slower relay times are bound to result unless the corrected ratio is used.

It is not meant that the correct ratio must be calculated for every relay setting, but where there is an effort to get the most from the relay in the form of high-speed protection, then the correct current-transformer ratio should be used.

Probably the greatest use of the procedure outlined in this paper will be the calculation of the "leakage" current through "dead" current transformers. This subject has been much discussed by relay engineers but my experience has shown that few people actually know the magnitude of the leakage for any single case. This factor is important in differential schemes and also in calculating the setting of an inverse-time overcurrent ground relay. Particularly is this latter true for a sensitive relay (and hence high burden) using a low-ratio bushing current transformer. Many operating men have found to their surprise that upon actual test a ground relay operated on less primary amperes when connected several taps above the minimum.

Figure 6



C. A. Woods, Jr., and S. A. Bottonari: The comments submitted on this paper by various members of the Institute indicate that the open-circuit saturation and loss characteristics of current transformers will become an exceedingly useful tool in the hands of the application engineer. These discussions call specific attention to the many points worthy of note in evaluating the material presented.

G. B. Dodds has stressed the usefulness of the saturation curve in determining the approximate linear performance of the current transformer, or in other terms, the burden capacity of the transformer, as indicated by the correlation of the data shown on the various curves given in his discussion. These data cover not only bushing-type current transformers, but also and to a greater extent, the wound and the bus-bar two-coil types. Even on these types, when neglecting the vector relationship between the burden and exciting currents, and the winding resistance, rough calculations indicate a fair correlation between the ratio performance and the data given on the saturation curves for all of these transformers. It is worth while to mention that the ratio curves in figure 4 were made by using extremely heavy resistance burdens, and a rather good approximation of performance may be calculated from the saturation curves if the vector relationship of the exciting and burden currents are taken into account.

A very timely question has been asked by H. A. P. Langstaff, relative to the possibility of furnishing saturation and loss data on bushing-type current transformers already in service. In a good many instances, the data are quite likely to be on file in the manufacturer's records, but where they are not available, they are quite readily obtained by field test. With the proper selection of instruments as outlined, saturation data, practically independent of wave form, may be easily obtained in the field without disturbing the transformer installation. The loss measurements, of course, require additional equipment, and the accuracy of field tests will probably not be as good as that made in the laboratory. However, extreme accuracy in the watt-loss measurements is not necessary. The effect of the secondary leakage reactance will be negligible when obtaining saturation characteristics.

The supplementary information contained in the discussion by C. C. Cole emphasizes the care which must be taken in measuring the excitation characteristics of the transformer with regard to wave shape, unless proper attention is paid to the type of meters used in making these measurements. Any appreciable error in the watt-loss measurements due to wave form would occur only in the region of high flux density, and yet, in this region, the relative magnitude of watt loss to exciting volt-amperes is such that correction for wave form is probably unnecessary.

As indicated in the paper, the authors have neglected the effect of harmonics in their calculations, and have assumed that the exciting current obtained by test is all fundamental. Based on data given in the paper, it is evident that unless the excitation current is held to sine wave, there will be some harmonics in this current. By adding the exciting current as all fundamental to the assumed secondary current, a primary current is calculated in excess of that which would be obtained if only the fundamental component of exciting current is used. Mr. Cole has pointed out the possible need of further analysis of the excitation characteristics by measuring both fundamental and rms values. The purpose of this would be to obtain some qualitative measure of the secondary current wave shape. It appears that any such procedure would require a similar analysis of the characteristics of the secondary burden. For example, with given value of primary current and burden impedance, a transformer will be operating at approximately the same flux density either when energizing a 100 per cent power factor burden or when energizing 50 per cent power factor nonsaturating burden. Oscillograms taken with these two burdens on a transformer operating at a high flux density show a marked difference in wave shape and crest values of secondary currents even though the rms values are approximately equal. Usually the excitation current with sine-wave impressed voltage will contain 80 to 85 per cent fundamental, and never less than 50 per cent. In a typical case, where the excitation current is 10 per cent of the assumed secondary current and contains 80 per cent fundamental, there is approximately 0.2 per cent difference between the fundamental and rms value of total primary current. Likewise, the error in calculation of primary current would be less than 2 per cent when assuming that all the rms exciting current is fundamental. Thus, only under conditions of severe saturation would the neglect of harmonics cause any appreciable error. In those relay applications, particularly differential protection, where harmonics might adversely affect the relays it would probably be desirable to use transformers of a design which would prevent a-c saturation. In this connection, the ratio curves which have been used in the past for the determination of current-transformer performance do not give any indication of the magnitude or character of the harmonics in the secondary current.

The viewpoint of an engineer actively engaged in the design and application of protective relays, as given by R. M. Smith is quite constructive. The effect of "dead" current transformers is forcibly brought to our attention by these comments, and it is evident that information for calculations of this type is not readily available from any other source of data.

E. L. Harder has very concisely reviewed the methods presented by the authors, and shown the superiority of the saturation and loss data over the ratio data for use in predicting the current-transformer performance. It is quite true that ratio and phase-angle data will continue to be the standard by which metering performance of all types of current transformers should be measured. The methods given in the paper cannot be applied, at present, equally well to the wound-type current transformers, but it is hoped additional work in the future will permit the use of the same methods to determine the overcurrent performance of these types of transformers. Quite often laboratory ratio tests do not fully portray the field performance due to the character of the secondary burdens, wave shape of the primary current, and the method of test. In addition, the design schedule of large installations and changing operating conditions may be such that definite test requirements are not available when the current transformers are available for laboratory tests. Hence, ratio curves made for a specific application on a given order might not cover the actual final installation, and the saturation curve would be of more use than the ratio curves in determining over-all performance.

P. O. Langguth has brought out two very important items of interest relative to the use of the saturation and loss-curve data. One of these is the ease and clarity with which the saturation curve could be used to establish standards of performance for bushing-type current transformers. As stated, due to the many variations and restrictions in the design of bushing-type current transformers as applied to circuit breakers, standardization for the various voltage classes and ratings of breakers becomes quite burdensome. This is particularly true when it is necessary to use some form of the ratio curve for such standardization. It appears that a material simplification would result by taking a definite value of excitation, such as ten-ampere, on a predetermined ratio. Such a point will always give a voltage over the so-called "knee" of the saturation curve, which, with the secondary resistance, would establish a standard level of design. Second, the possibility of adapting the formulas as given in the paper to various forms of compound curves has been well illustrated. The curves in figures 5*a* and 5*b*, illustrate one form which such compound curves could take, and with additional effort, the more accurate method for determining ratio could be similarly illustrated.

Figure 6 of this discussion illustrates the correlation between the calculated values by the simplified and the complete method as compared to actual tests for currents up to 75,000 amperes primary current. This illustrates the conservative viewpoint taken by the authors in limiting their statement on accuracy of the methods to 25,000 or 30,000 amperes primary current. Undoubtedly, with the accumulation of additional data, the method can be substantiated for all bushing-type current transformers in commercial use.

It will be noted throughout the paper and discussions that more attention has been paid to the saturation characteristics than to the loss characteristics of the transformer. The reasons are more or less obvious, but it might be of interest to point out that the excitation angle, θ_1 shown in figure 7 of the paper, is usually between 45 and 90 degrees. As the transformer core becomes saturated, its excitation angle rapidly approaches 87 or 88 degrees. Under these conditions, the watt-loss current is practically negligible compared to the magnetizing current, and hence it can often be neglected in making the various calculations.

The methods outlined in the paper are particularly applicable to the solution of relay problems. Since the majority of bushing-type current transformers are used in conjunction with protective relays, it is our hope that the saturation-curve method will become familiar to all engineers making such applications. Likewise, the solution of problems involving the transformer performance when subjected to offset transient currents (reference 3 of the paper) requires the use of the open-circuit saturation characteristics. Hence, it seems logical that the open-circuit saturation and watt-loss curves should supersede the ratio curves for defining the overcurrent characteristics of bushing-type current transformers.

Current Transformers and Relays for High-Speed Differential Protection, With Particular Reference to Offset Transient Currents

Discussion and authors' closure of paper 40-71 by E. C. Wentz and W. K. Sonnemann, presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940, and published in AIEE TRANSACTIONS, 1940 (August section) pages 481–8.

T. R. Halman (The Detroit Edison Company, Detroit, Mich.): The methods described in the paper by Messrs. Wentz and Sonnemann for determining the performance of current transformers under high values of primary current involving fully offset waves should be of great value to those interested in applying instantaneous bus differential protection. The problem is particularly important where it is desired to use existing current transformers having relatively low ratios and moderate-sized cores.

A practical example of such a problem arose on the system of The Detroit Edison Company in 1933. A large number of 120-kv busses was to be protected with instantaneous differential relays using 400-to-5 current transformers which were already installed in the breakers.

Before starting on the installation a trial setup was made using three current transformers, similar to those in the breakers, connected differentially to reproduce the actual service application as closely as possible. Current was applied unequally through the primaries in a manner corresponding to conditions existing during faults external to the protected zone and up to the maximum magnitude expected on the system which was 7,500 amperes. This should give no current through the differential relays but actually on some trials as much as 100 amperes flowed for a brief period.

This would, of course, cause incorrect operation as was demonstrated by observation of a test relay.

The problem was solved by taking advantage of a principle which is mentioned in the paper under discussion. That is, an increase in the impedance in series with the differential relays will reduce the transient current through them. An equally important corollary is that this impedance does not affect the steady-state current nearly so much as the transient and so does not prevent the current transformers from performing their desired functions satisfactorily within certain limits to be mentioned later. Resistance was found more effective than reactance, also as mentioned in the paper.

It was decided, accordingly, to insert 12 ohms of resistance in series with the differential-relay operating coils. Tests showed that this would eliminate the trouble and give at least a two-to-one factor of safety.

Of course, this high differential burden would cause the current transformers to saturate badly when forcing current through the relays in case of a high-current fault within the zone of differential protection. Tests showed, however, that they would still furnish enough current to permit proper operation of the differential protection when required except under system conditions giving minimum values of fault current. To take care of this case, an additional relay was connected to short out the resistor after one-half second. This delay permits the transient to subside and the differential may then safely be made more sensitive. This method results in instantaneous tripping for all severe faults with a slight time delay for minimum faults. A total of 126 bus years of operation have been experienced with this scheme. There have been two correct operations and no failures nor unnecessary tripouts.

A. R. Miller (Lehigh University, Bethlehem Pa.): The following method of analysis for current transformers operating under saturated-core conditions is based upon standard circuit theory and may offer a more readily understood method than those suggested or referred to in the papers relating to this topic. In order to conserve space the procedure is presented in the simplest fashion but can be carried out to any degree of accuracy under a given set of assumptions.

In order to solve equations pertaining to circuit theory in a practical way it is required that the circuit parameters be held fixed (there are certain exceptions to this statement), that is, the values of resistance, inductance, and capacitance are fixed quantities. However, when saturation occurs, the inductance of the circuit changes, or as we commonly say, the ratio of flux to exciting current is not fixed, as is indicated by a saturation curve. However, as the authors of these papers have assumed, this nonlinear characteristic can be approximated by two or more linear relationships as is indicated in figure 1 of this discussion, where two straight lines are used to approximate the magnetization curve. For values of exciting current less than i_1 the inductance is proportional to the slope of the first straight line *A*; when greater than i_1, it is proportional to the second straight line *B*, assuming the saturation curve to be approximated by two straight lines. This would usually be sufficient, but closer approximation would be

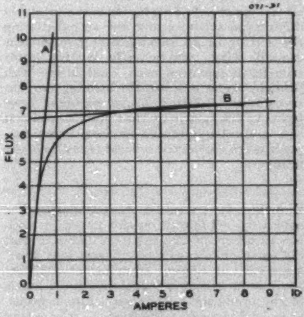


Figure 1

obtained by using a greater number of straight lines.

In calculating the current in the circuit, it may be assumed that the inductance is changed from a value of L_1 to L_2 when the current passes through the value i_1. In a magnetic circuit, the point i_1 at which this fictitious switching occurs, would depend upon the initial state of magnetization and whether the flux is increasing or decreasing in value. That is, in general, the hysteresis characteristics of the core would have to be known. But no matter what type of solution is used, as long as the current phenomena is dependent upon the hysteresis characteristics of the core material, this would be the case.

The calculations are outlined on the basis of the diagram in figure 2 of this discussion, which corresponds with the equivalent circuits used by the several authors in their papers. As the current in the exciting coil goes through increasingly larger values, and when a value of i_1 (figure 1) is reached, the switch S is assumed to be closed. Mathematically this is done by superimposing a current on the circuit which, together with the initial current that is assumed to flow through this part of the circuit, produces zero voltage across that portion of the circuit shunted by the switch S circuit. This satisfies the condition of the circuit and the circuital equations and is therefore a complete solution. With the above explanation it is believed the following analysis is self-explanatory.

Let

$$i = I_1\epsilon^{-at} + I_2\epsilon^{-bt}\epsilon^{j\omega t}$$

then

$$i_2 = \frac{Z'}{Z'+Z}\,i = \frac{L'p}{L'p+Lp}\,(I_1\epsilon^{-at} + I_2\epsilon^{-bt}\epsilon^{j\omega t})$$

where

$$Z' = Z_1 + Z_2,\ p = d/dt$$

and the resistances are assumed to be zero throughout the circuit. Under these assumptions the operational terms drop out and

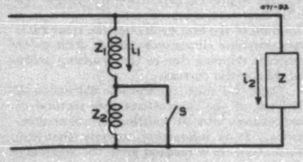

Figure 2

$$i_2 = \frac{L'}{L'+L}\,(I_1\epsilon^{-at} + I_2\epsilon^{-bt}\epsilon^{j\omega t})$$

The voltage across the switch S produced by the initial current is

$$e_s = i_1 L_2 p = L_2 p \frac{L}{L'+L}\,(I_1\epsilon^{-at} + I_2\epsilon^{-bt}\epsilon^{j\omega t})$$

Therefore, at saturation a new current Δi_2 is added to i_2, and

$$\Delta i_2 = e_s/Z_1 + Z$$

since it may be assumed that the impedance of the source is high with respect to Z_2. This gives, as the increase in the current in the secondary circuit of the current transformer

$$\Delta i_2 = \frac{L_2 L}{(L'+L)(L_1+L)}\,(I_1\epsilon^{-at} + I_2\epsilon^{-bt}\epsilon^{j\omega t})$$

and, after the current passes the value i_1, and until the instant when the saturation is assumed to change again

$$i_2 + \Delta i_2 = \left(\frac{L'}{L'+L_2} + \frac{L_2 L}{(L'+L)(L_1+L)}\right)\times (I_1\epsilon^{-at} + I_2\epsilon^{-bt}\epsilon^{j\omega t})$$

Taking the following to be relative values for a current transformer,

$$L_1 = 0.1L';\ L = 0.01L';\ L_2 = 0.9L'$$

$$i_2 + \Delta i_2 = 0.91(I_1\epsilon^{-at} + I_2\epsilon^{-bt}\epsilon^{j\omega t})$$

approximately during this interval of saturation.

The differential current between a perfect current transformer and a saturated transformer with the characteristics assumed would be approximately ten per cent of the primary current.

The inclusion of resistance in the secondary circuit would somewhat complicate the analysis but does not make it impossible. The relative value of resistance and reactance would ordinarily be such as to make the effect of secondary resistance quite negligible.

H. P. Sleeper (Public Service Electric and Gas Company, Newark, N. J.): This paper discusses a phase of the current-transformer problem in connection with relay protection which has but recently been recognized. Heretofore, ratio curves were considered to provide sufficient data for analyzing protective relay performance under conditions of known volt-ampere load and primary current. This picture has been entirely changed within the last two years, and the paper by these authors is one of the very first to discuss the problems incurred by offset transient currents. Since differential protection is coming into popular use in generating stations where such conditions may readily be present, it is most important that protection engineers be familiar with the problems presented to such relays.

This very situation was recently the subject of considerable study in connection with proposed differential protection on the 13.8-kv busses of a generating station on the system with which this writer is connected. The maximum value of short-circuit current was calculated to be approximately 60,000 amperes rms, and the system time constant by calculation was 0.21 second. Generating capacity of approximately 150,000 kva would be connected to the busses, and all elements of the problem described in the authors' paper would be present.

In order to ensure correct relay operation there appeared to be the following methods of solution:

1. Use of standard current transformers and differential relays, and application of a time delay of from 0.5 to 1.0 second to provide sufficient delay to permit the offset transient to recover. This would allow the relays on the unaffected busses to operate incorrectly, but the time delay would prevent the occurrence of false tripping, during which period the d-c effect would disappear and the relays would reset. By standard current transformers is meant those which have six to eight square inches of iron core.

2. Use of standard current transformers which, it should be understood, would not saturate on maximum alternating currents but would saturate when offset transients occur, and the use of two sets of Westinghouse type *CA-6* differential relays with multiple restraint coils. This scheme was described in a paper by Smith, Sonnemann, and Dodds, which is published on page 243 of the 1939 AIEE TRANSACTIONS.

Six relays are employed and the contacts of the two relays on the same phase are connected in series. Incorrect operation is theoretically prevented by the proper grouping of current transformers so as always to maintain restraint on at least one relay per phase during conditions when the offset transient tends to saturate the current transformers receiving the maximum currents.

3. Installation of current transformers with sufficient iron so that saturation does not occur due to the offset transient currents. This theoretically enables any standard differential relay to be applied.

An analysis of all factors led us to the following conclusions:

The number 1 scheme was not considered good operating practice because of the amount of damage at the point of fault and the shock to the system which would result from hanging on to faults of the magnitude and durations indicated. It was deemed inadvisable to use two relays in series (scheme 2) instead of one due to the expense involved, the difficulties of phasing, and the hazards of contacts in series. Therefore, the conclusion was to use the oversize current transformers (scheme 3). These transformers had approximately 20.5 square inches of iron in the core and were approximately 19.5 inches square and 11.5 inches long measured lengthwise of the conductor. The aperture for the conductor bushing was 8 inches in diameter. The completed unit weighed approximately 600 pounds.

It is recognized that the expense of such an installation cannot always be justified, and in some cases it is impossible to install current transformers with this amount of iron. The latter situation, of course, applies particularly to current transformers used in connection with existing outdoor circuit breakers. It appears, therefore, from the viewpoint of the operating engineer that the practical and economical solution of the problem has not yet been obtained.

Viewed abstractly there seem to be several possible avenues of attack to solve the problem. Suggestions are:

1. Development of an iron of such characteristics that, with a standard cross section of six to eight square inches, would not saturate under conditions presented by offset transient currents.

2. Use of secondary corrective devices which would eliminate the effects of d-c saturation.

3. Provision of wells on outdoor circuit breakers sufficiently large to receive oversize current transformers if the latter are dictated.

Still another problem is present in such differential relay protection which even the oversize current transformer does not solve. This occurs when ground differential relays are used and faults occur between two phases which leave the third phase with only load current. D-c transients will appear in the two phases and not in the third, and hence a resultant current will enter the ground relay which will have no compensating restraint. This will cause incorrect operation unless this relay has a suitable time delay, or is interlocked with another relay which responds to neutral current only. It is important that provisions be made to cope with this situation, which is inevitable under the conditions described.

R. L. Harder (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): This paper is important in that it supplies to relay engineers, for the first time, a really practical method for predetermining current-transformer performance under transient conditions. It also gives an associated method for utilizing this information in predetermining relay performance. Both steps are simple, well grounded in fundamentals, adequately supported by test, and have proved an invaluable aid in making with assurance numerous bus protective applications since the method has been available.

I wish to give a graphic picture of the current-transformer flux during the transient interval, and preceding saturation, to clarify some physical aspects of this problem.

Figure 3 of this discussion shows for the simplest case of a perfect transformer and pure resistance burden, the various current, voltage, and flux waves. The fully offset current wave is broken up into symmetrical and transient components. These, in flowing through the resistance burden (which includes leads and transformer secondary winding resistance), create voltages as shown, which must be generated by flux change in the transformer. The flux variations required to generate the symmetrical and transient voltage waves are shown in the next two traces and then combined to show the total flux variation required in the transformer.

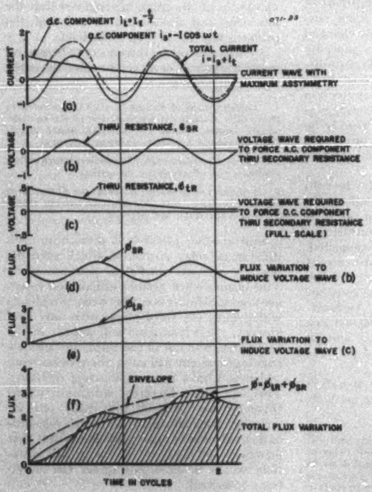

Figure 3. Current-transformer flux during assymetrical short circuit, one-cycle time constant

The resulting flux wave, figure 3*f*, has been shown for a one cycle time constant. Figure 4 gives the corresponding flux wave for a ten-cycle time constant.

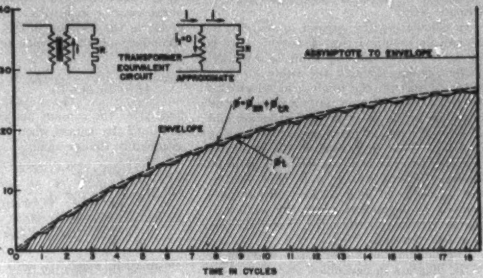

Figure 4. Current-transformer flux during assymetrical short circuit, ten-cycle time constant

The transformer saturates whenever this combined flux wave reaches saturation value. To be on the safe side the authors have used the upper envelope of the flux wave, their equation 10 giving the time for this envelope to reach the saturation value B_sA, or for the flux density to reach the saturation value B_s.

With but slight approximation when the time constant is longer than three cycles the term $1/\omega T$ can be omitted and a curve plotted, figure 5, giving the time to saturate as a function of the quantity NA/IRT for a particular assumed saturation density. The time may then be read as a fraction of the time constant. For example, with $(NA \div IRT) = 3$ the time to saturate is 0.26 "time constants", or 2.6 cycles for a 10-cycle time constant, 5.2 cycles for a 20-cycle time constant, etc.

The approximation of omitting the term $1/2\pi T$ amounts to neglecting the a-c flux density altogether. Hence figure 5 actually gives the time for the transient flux component to reach saturation density. The ratio of maximum a-c density to final transient density, is, for pure resistance burden, simply $1/2\pi T$, for time constant T expressed in cycles. In other words if T is three or more, the a-c density is not over $^1/_{19}$th of the maximum density which would be reached by the transient component alone, assuming no saturation. For $T = 10$ cycles the maximum transient density is 62.8 times the maximum a-c density. Obviously then, if the time to saturate being computed is longer than a time constant the error of the approximation could be offset by an assumed saturation density but few per cent different. If the time to saturate being calculated is a fraction of a time constant, the difference in time between passage of the transient component through a particular density, figure 5, or passage of the envelope through the same density, equation 10, is but a small fraction of a cycle, and hence does not affect the calculations in which the results are used.

The value of $(NA/IRT) = 13$ corresponding to infinite time to saturate is of particular significance in that it describes the conditions required to prevent saturation in the transformer. Satisfactory relaying can generally be secured if saturation would not occur due to the a-c component alone. With a ten-cycle time constant and allowing an a-c density of 10,000 gausses, this means that satisfactory relaying can be secured when NA/IRT calculates but $^1/_{30}$th of enough to prevent saturation altogether. In this case saturation occurs, of course, in a fraction of the first cycle, but the relay ratio and impulse characteristics are such as to prevent tripping due to the resulting peaks of differential current.

There has been considerable discussion of the use of the saturation-curve method of expressing current-transformer characteristics. It is interesting to note that the saturation-curve method gives the necessary data to determine transient performance also; that is, time to saturate, and differential current peaks following saturation. In a differential relay problem the worst case is usually when one transformer saturates and the others do not. The false differential current is then the error current or exciting current of the transformer which saturates. Saturation may be defined, then, as reaching a particular exciting current. For example, if a differential relay has minimum trip value of one ampere, an exciting current of 0.1 or 0.25 ampere might be chosen as the threshold of saturation since exciting currents below these values are unimportant. Use 0.1 ampere for example.

When a d-c transient current flows, the exciting current reaches a value of approxi-

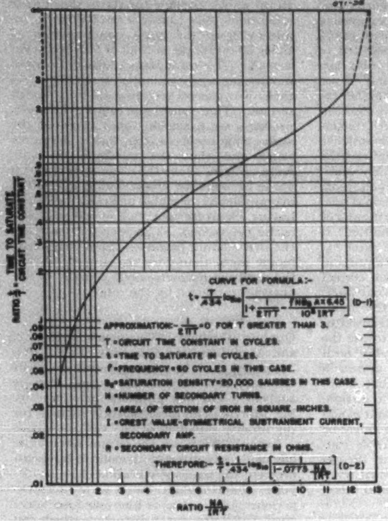

Figure 5. Current-transformer time to saturate

mately $0.1\times\sqrt{2}$* ampere instantaneous value, when the flux reaches the value associated with 0.1-ampere a-c exciting current under steady-state conditions.

Suppose then that from the saturation curve is read the voltage, E_s, which the transformer induces with the a-c exciting current, I_s, equal to 0.1 ampere in this case. The value of NB_sA to substitute in the equation of figure 5, is given from the relation of induced voltage to NB_sA, which is

$$E_s = 4.44 fNB_sA6.45\times 10^{-8} \tag{3}$$

or

$$\frac{fNB_sA6.45}{10^8}=\frac{E_s}{4.44} \tag{4}$$

Making this substitution in the equation of figure 5

$$t=\frac{T}{0.434}\log_{10}\left[\frac{1}{1+\frac{1}{2\pi T}-\frac{E_s}{4.44\,IRT}}\right] \tag{5}$$

which is obviously simpler than the original expression.

Also a curve similar to figure 5 can then be plotted against E_s/IRT as an abscissa, see figure 6 of this discussion. It has the advantage of always involving a saturation density corresponding to an exciting current I_s selected for the particular relay problem rather than using an arbitrary density.

Recapitulating:

1. From the a-c saturation curve may be chosen a saturation voltage E_s corresponding to an error current I_s.

2. Let the transformer be subjected to a fully offset primary current wave of time constant, T.

If E_s is substituted in equation 5 it gives the time for the transformer exciting current to reach a magnitude equal to the crest value of I_s. Or figure 6 may be used to determine whether saturation will occur and if so, when.

The remainder of the relay application method is of course unchanged.

Thus the saturation curve method of presenting the transformer characteristics lends itself especially well to the analysis of transient conditions.

E. C. Wentz and W. K. Sonnemann: Mr. Halman has presented an interesting picture of the experience of his company with reference to the use of a simple overcurrent differential relay. It is of interest to note that it is often practical to insert a great deal more resistance in the differential circuit than could be tolerated connected directly in series with the current-transformer secondary.

Mr. Harder has presented a valuable discussion and has furnished useful curves for the utilization of the authors' formulas. Mr. Harder's figure 5 should be used with caution, we believe, because of the saturation density of the 20,000 gausses quoted. This value is likely to be too high for the lower-ratio current transformers. However, the curve and formula of figure 6 are more useful in that the corresponding formula of the paper is interpreted directly in terms of the saturation curve. This formula represents a real simplification of equation 10 of the paper with regard to practical application.

Mr. Miller has presented an interesting discourse attacking the same problem with the benefit of operational calculus. However, it is not obvious from Mr. Miller's mathematics just how he arrives at the conclusions he does in the closing part of the discussion. For an example, any values of inductance may be chosen within reason, as Mr. Miller has done, but the authors have found that in most cases the differential current between a perfect current transformer and a saturated current transformer will run much higher than ten per cent. More important than this, however, is the erroneous conclusion that the secondary resistance is

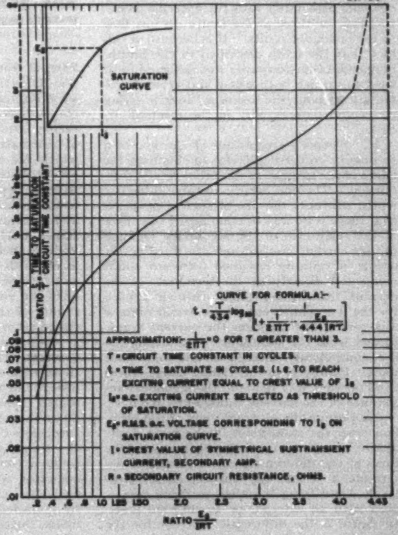

Figure 6. Current-transformer time to saturate

---

* Form factor or ratio of crest forms is somewhat greater than $\sqrt{2}$, probably between $\sqrt{2}$ and 2.

quite negligible. Perhaps we have misunderstood Mr. Miller's statement, but there is no question of doubt, both from the theoretical standpoint and from test results, that the secondary resistance is by far the most important factor in determining current transformer performance on asymmetrical currents.

Mr. Sleeper's discussion is interesting through its presentation of the problems involved in choosing the proper relays and by his abstract view of possibilities for the future. With reference to existing possible relay schemes, we feel that Mr. Sleeper overemphasizes the difficulties of the use of two relays per phase as brought out in the Smith-Sonnemann-Dodds paper referred to. With particular reference to the use of contacts in series for the important function of tripping a bus, there is ample precedent for this in past relay practice. For example, directional overcurrent relays have been utilized for years in which two contacts in series must close to perform the tripping function. The principal difference is that in the case of the directional overcurrent relay the two contacts are in the same relay case, whereas in this case the contacts are in separate relays.

Mr. Sleeper also brings out that there is a possible false differential current involved for ground relays in the event of external phase-to-phase faults. This would be caused by unequal saturation of the current transformers in the two phases because of dissimilarities, even between nominally duplicate current transformers. More important than this, however, is the case of an external three-phase fault. In this case it is immediately obvious that not all of the three phases can have the same magnitude of d-c transient. Hence, for the external three-phase fault, there is even more possibility of a ground differential relay being subject to incorrect operation because of insufficient restraint. This is explained by the fact that the heavy currents associated with the external phase-to-phase or three-phase faults do not flow in the residual circuits. It is because of this fact that the relay described in the Smith-Sonnemann-Dodds paper was designed to be used to furnish both phase and ground protection without the use of a "fourth" relay connected differentially in the residual circuit.

Mr. Sleeper's suggestion of the use of a secondary correcting device to eliminate the effect of d-c saturation has often received attention. The one insurmountable difficulty which prevents the use of such a device is that there is no way of eliminating the effect of the resistance of the secondary winding of the current transformer itself. For example, a suitably designed transient shunt connected directly at the terminals of the current transformer might furnish a path for the d-c component which would materially reduce the duty on the current transformer from the standpoint of shunting the d-c component through a low resistance path. However, as mentioned above, there is no possible way to avoid the secondary resistance of the current transformer itself.

Continuing the abstract view of the problem from the standpoint of the most desirable relay, it is interesting to consider the form of the differential current itself to determine if it has any characteristics positively identifying it either as being associated with an external or an internal fault. In figure 7, the differential current for the cycle between the two highest peaks was analyzed and it was found that expressing the fundamental 60-cycle component as 100 per cent, the d-c component amounted to 329 per cent while the second and third harmonics amounted to 9.9 per cent and 3.6 per cent, respectively. Harmonics of higher order were 1 per cent or less. If it is assumed that the total harmonic components amount to 15 per cent, then it is seen that in order to adequately restrain a high-speed differential relay, the relay must be particularly sensitive to harmonics. For the above condition, it would appear that the relay should adequately restrain on 10 per cent harmonics or less to furnish sufficient safety factor. If such sensitivity were secured, the same exceedingly small percentage of harmonics in the differential current would block correct tripping of the relay for an internal fault. This would immediately involve the necessity for very high-quality current transformers. A second thought would be to use the d-c component to restrain the relay until such time as the harmonics finally appear in significant quantities. It is immediately obvious, however, that the same d-c component in the event of an internal fault would delay the relay so that it would no longer be a high-speed relay. The inescapable conclusion to be reached is that, so far, the use of fault current itself forms the most reliable means of restraining a differential relay.

Harmonic Theory of Noise in Induction Motors

Discussion and author's closure of paper 40-13 by Wayne J. Morrill, presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940, and published in AIEE TRANSACTIONS, 1940 (August section) pages 474–80.

Samuel Noodleman (Delco Products, Dayton, Ohio): The author has presented a very interesting attack on the problem of magnetic noise in single-phase motors. The theory is unique in that it develops a method of calculating the actual harmonic forces which act on the stator. There are, however, conditions which do not seem to agree with the results of this paper. For example, from the assumption of a uniform air gap and constant permeance it would be assumed that the magnetic noise of motors with tunnel-slot rotors would check very nicely with this theory. Actually the magnetic frequency spectra of motors with open-slot rotors agree much closer with the results of this paper than do those having closed rotor slots.

Motors with tunnel-slot rotors have predominating frequencies which are lower than those with similar open-slot rotors and thus lower than would be predicted from the presented theory. For example, in a four-pole 60-cycle motor having 32 stator slots and 48 rotor slots the magnetic noise at no load with the tunnel-slot rotor has a predominating frequency of 480 cycles per second, while the open-slot rotor has a frequency of 1,440 cycles per second. This may be explained by considering the frequency of the harmonic fluxes generated by the stator slots. In the above example the stator slots create a harmonic flux having a predominant frequency from the noise standpoant of 32 times 30 cycles per second or 960 cycles per second. The rotor slots similarly create a flux having a predominating frequency of 48 times 30 cycles per second or 1,440 cycles per second. The tunnel-slot rotor, however, produces its harmonic tones at about the same magnitude as the stator harmonic tones and thus the resultant magnetic noise contains a tone the magnitude of which varies between the sum and difference of the magnitudes of the stator and rotor tones and having a beat frequency of, in this case, 480 cycles per second. The open-slot rotor, on the other hand, produces much larger harmonic notes than does the stator and thus the resulting magnetic noise consists of frequencies produced by the rotor.

Quentin Graham (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): This paper gives an excellent summary of a very useful method of noise analysis. The new notation introduced by Mr. Morrill in his force charts is valuable for the orderly handling of the various waves.

I should like to ask the author whether he has made any attempt to confirm by measurement the mode of vibration of the stator yoke. I feel certain, based on my own experience, that a two- or four-pole force wave gives a definite stator distortion which can be measured. However, when the number of force poles becomes 16, 24, or 32 on a fractional-horsepower motor it would appear that the stiffness of the yoke would be very great for the same mode of vibration. I admit that the noise frequencies are usually in agreement with the theory as outlined but I have often wondered if perhaps the teeth were not vibrating circumferentially more than the stator yoke in cases involving a high number of force poles. It would be useful to know just where the surfaces are that set the air waves in motion. Has the author explored the possibilities of any other types of vibration?

C. G. Veinott (Westinghouse Electric and Manufacturing Company, Lima, Ohio): Mr. Morrill's paper presents a method for predicting the frequencies of some of the noise components in a single-phase induction motor. His general method of approach is to set up equations for the flux waves due to the principal harmonics in the magnetomotive-force waves of both stator and rotor and to compute the forces due to the interaction of these various harmonic flux waves, and their frequencies. Such an approach necessarily leads to mathematics sufficiently involved that the author introduces a new notation. It is interesting to note that by a much simpler approach it can be shown that these same frequencies exist. By this same simpler approach it becomes evident that the frequencies given by Mr. Morrill depend solely upon the number of rotor teeth and revolutions per minute and not upon the number of stator teeth or upon the combination.

Consider any single stator tooth carrying flux. As each rotor tooth passes a stator tooth, a pull is exerted on the latter. If there are 48 rotor teeth revolving at 1,800 rpm or 30 revolutions per second, the frequency of the radial force on the stator tooth is

$48 \times 30 = 1{,}440$ cycles per second

If the stator is energized at 60 cycles, the frequency of the force of attraction between the rotor and the stator is 120 cycles. This 120-cycle force is superimposed upon the 1,440 cycles giving two side-band frequencies either side of 1,440. The three frequencies are, therefore,

$1{,}440 - 120 = 1{,}320$ cycles per second
$1{,}440$ cycles per second
$1{,}440 + 120 = 1{,}560$ cycles per second

which are the identical frequencies given in figure 3 of the author's paper.

The second harmonic of the stator tooth pulsation frequency due to the rotor teeth, and the 120-cycle side-band frequencies are,

$2 \times 48 \times 30 = 2{,}880$ cycles per second
$2{,}880 - 120 = 2{,}760$ cycles per second
$2{,}880 + 120 = 3{,}000$ cycles per second

The third harmonic and accompanying side-band frequencies are

$3 \times 48 \times 30 = 4{,}320$ cycles per second
$4{,}320 - 120 = 4{,}200$ cycles per second
$4{,}320 + 120 = 4{,}440$ cycles per second

Observe that these latter six frequencies are the remaining six frequencies shown in the calculated noise force spectrum in figure 4.

It is interesting to note that all of the frequency components given by Mr. Morrill are explained by the simpler method of approach just outlined. By this same simple method of approach, it is seen at once, that the three frequencies listed for each combination in the author's chart VII are the fundamental tooth-frequency pulsations set up by the rotor teeth and the two 120-cycle side bands.

Using this method of approach, which might be called the "permeance method", or the "reluctance method" it is evident that all the frequencies given by Mr. Morrill are due *solely to the number of rotor teeth.* I would like to ask Mr. Morrill if he agrees with this conclusion and also if it is evident from his method of analysis.

Pursuing the permeance method as outlined, we might expect to find other frequencies present which are a function of the number of stator teeth. The pulsation frequency in the rotor teeth at 1,800 rpm, with 36 stator teeth is

$36 \times 30 = 1{,}080$ cycles per second

We might logically expect a pull between the stator and rotor at frequencies of

$1{,}080$ cycles per second,

$1{,}080 - 120 = 960$ cycles per second

and

$1{,}080 + 120 = 1{,}200$ cycles per second

We might also expect to find frequencies of

$2 \times 36 \times 30 = 2{,}040$ cycles per second
$2{,}040 - 120 = 1{,}920$ cycles per second
$2{,}040 + 120 = 2{,}160$ cycles per second, etc.

I have actually found a number of these frequencies experimentally, though even when present they are of less importance than the frequencies due to the rotor teeth. I should like to inquire of Mr. Morrill if his method of analysis would lead him to predict these frequencies which are dependent upon the number of stator teeth, and if he has calculated their relative magnitudes. Also, has he ever observed or looked for any of these frequencies experimentally?

The permeance method as outlined above checks the author's "magnetomotive-force method" because the author uses only tooth harmonics of the magnetomotive-force and not those other harmonics which can be suppressed by a good winding distribution.

The permeance method is given in this discussion to supplement and not to supplant Mr. Morrill's method. I believe the former method is valuable in that it can be used to predict the important frequencies present by a very simple arithmetical computation and can, therefore, be used to check the frequency even if the author's more involved mathematical method is used. The author's method has the advantage, however, of leading to quantitative results, although, as he himself admits, it would be necessary to take into account variations in permeance if a complete analysis were to be made. I believe Mr. Morrill's paper is a worth-while and useful contribution to the art.

Wayne J. Morrill: While I agree with Mr. Veinott's comments concerning the noise frequency being dependent upon the rotor tooth frequency and often make use of the same method to determine where to look for the various component frequencies in a motor under test, I do not feel that the possible noise frequencies are of much help in predetermining the noise of a motor. It is well known that with the same rotor the magnitude and quality of the produced noise will vary greatly with the number of stator slots used. Experience shows that the difference between the number of rotor slots and the number of stator slots is a better criterion of the noise which may be expected than is either the number of slots in the rotor or the number in the stator. My method uses both the stator and rotor slots and attempts to predetermine not only the frequency of the motor vibration but the magnitudes of the magnetic forces and the modes of vibration as well. I believe that a successful theory for motor noise must take into account all these factors.

I do not agree with Mr. Veinott's expectation concerning noise frequencies approximating to the frequency of the stator teeth with respect to the rotor. I believe he is overlooking the fact that the rotor teeth are moving and that therefore it could not be expected that a flux in the rotor would produce an air noise of the same frequency.

I have looked for frequencies other than those outlined in my paper and while I have frequently found others they have been small, as Mr. Veinott says, and they have not necessarily recurred in successive motors of the same design. I have concluded that these other noises, being inconsistent in frequency, must be due to deviations of the motor from the ideal. An eccentric air gap, a high-resistance squirrel-cage bar, or a buzzing lamination are all deviations of this type and should cause noise frequencies and magnitudes to change.

I agree with Mr. Graham that as a rule the stiffness of the stator yoke should greatly limit the noise where 16 or more force poles exist, unless resonance happens to be present.

The tangential forces on the teeth are so much smaller than the radial forces that it seems reasonable to neglect these forces. Undoubtedly, however, the stator teeth and windings load the stator yoke and affect its vibration.

We have looked for other types of vibration but believe the radial motion of the stator yoke to be the important one.

Mr. Noodleman's comments concerning the effect of closed rotor slots upon the noise spectrum. With closed slots magnetomotive-force differentials occur on the rotor surface only as a result of saturation of the magnetic bridges above the bars. It would be expected that such saturation would have the effect of rounding the corners of the rotor magnetomotive-force stair-step curve corresponding to the dotted portion of my figure 1. It is well known that rounding the corners of such a curve has the effect of minimizing the higher harmonic components. It would seem logical, therefore, for a closed-slot rotor to act with the stator to produce less of the high frequencies than would an open-slot rotor.

Our experience has been that the closed-slot rotor has all the frequencies of the open-slot rotor but the higher ones are reduced in magnitude. It would seem that a closed-slot rotor would, therefore, always be better for noise than an open-slot rotor but we have not found it so. It seems that, due to variations in the thickness of the magnetic bridge or the harmonics of saturation, the closed-slot rotor produces some new low pitched noises all its own. The over-all noise instead of being reduced by the closed-slot rotor seems actually to be increased though, due to the large low-frequency component, it is lowered in average frequency.

The Design and Operation of a Metropolitan Electrical System From the Viewpoint of Possible Major Shutdowns

Discussion and closure for the author of paper 40-30 by S. M. Dean, presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940, and published ,in AIEE TRANSACTIONS, 1940 (October section) pages 575–9.

W. C. Stone: See discussion, page 1154.

W. J. Lyman (Duquesne Light Company, Pittsburgh, Pa.): The so-called "loose link" system described in Mr. Dean's paper is an excellent example of a sound principle of system design which strikes an economic balance between two opposing relationships. In general, the more extensive the generation and distribution system which runs tied together in a close network, the better is the generating economy and the more efficiently are the circuit capacities utilized. In contrast to this, as the extent and complexity of the network is increased, the protection becomes more expensive, short-circuit currents require larger breakers, and many of the operating problems become difficult, particularly during trouble. These two opposing tendencies fix an economic limit to the size of the system which should be closely tied together. Following this principle, a large system can be divided into two or more parts, loosely linked together, without any over-all sacrifice in economy and with much better operating characteristics. Relatively high reactances can be placed at natural division points which normally carry little load but which can still take advantage of the diversity between load areas through moderate interchange of power.

As Messrs. Bryson and Hayward brought out so well in their paper, the Duquesne Light Company system is divided into two parts by reactors at the two main power stations. Each half therefore consists of one half of the 66-kv ring and one half of each power plant. Before these reactors were installed (1928), the 66-kv lines operated on one bus at each power station, and heavy line faults near a power station pulled down the voltage on both halves of the ring, leaving little synchronizing power between stations. Much power load was shaken off and severe hunting followed. Since addition of the reactors, 66-kv faults near the power stations leave about 80 per cent normal voltage on the other half of the ring, furnishing ample synchronizing power and reducing the disturbance to customers.

As regards the effect of voltage on system load, after a severe case of instability which occurred in 1927, an analysis was made of the characteristics of the load, taking into account the amount of lighting, induction motors, synchronous motors, and other types of load. At that time it was calculated that a 10 per cent reduction in the load voltage would reduce the kilowatt load 10 per cent and the reactive load 67 per cent. A pure resistance load would be reduced 19 per cent by a 10 per cent voltage reduction, while a motor load, (kilowatts) would be very little affected until the voltage reaches a point where the motors begin to stall.

This analysis was for a Sunday night when the power load would be at a minimum. At other times, the decrease in kilowatts would be less than the decrease in voltage. The effect of induction voltage regulators is important in this respect.

E. E. George (Ebasco Services, Inc., New York, N. Y.): This discussion concerns the four papers on service restoration on metropolitan systems. Troubles on metropolitan systems are always intriguing to engineers of transmission systems. The situation is something like a military expert in this country having the opportunity to hear by radio from an observer in a foreign country a round-by-round description of an air battle or naval battle. A lot of valuable information becomes available to the listener at a safe distance without effort or risk. Undoubtedly the engineers of the transmission companies have profited from the difficulties occasionally experienced on metropolitan systems. The very fine group of papers presented at this session will be of value to the industry generally. The analysis of certain difficulties and their remedies will be of value to design and operating practice on transmission systems. Of primary interest here is what transmission practice can contribute to prevention of trouble or restoration of service on metropolitan systems.

Several items of possible application are mentioned briefly below. On some of these there is a diversity of opinion in the metropolitan groups and other items have been absent from the discussion at this session.

Mr. Juhnke has well expressed the improbability or general impossibility of any operating force handling perfectly any major interruption. Transmission experience would corroborate this viewpoint, further recognizing that metropolitan failures are more difficult to deal with than those on systems of the transmission type.

PREARRANGED RULES

Transmission companies have based their emergency operation very largely on definite written prearranged rules for each major generating station and substation on the system. It is interesting to note that although most of these rules were based on conditions many years ago when very limited communication was available in emergency, the use of these rules is just as extensive today with a very high grade of communication. Communication is a further safeguard and not a substitute for prearranged rules. Although such rules have been in satisfactory service on many transmission systems for at least 20 years and today many companies could not operate successfully in serious emergency without them, only one of the metropolitan companies appears to have given much consideration to the subject.

COMMUNICATION

Communication, not as an afterthought, but as a primary design feature is one of the most important safeguards to the operation of transmission systems according to practically universal experience. The use of independent routes to important stations, of one-way trunks, improved protection (such as neutralizing transformers, and unit-type relay protectors) have done much to maintain communication in serious emergency. Machine switching available in the metropolitan centers lends itself to almost any special type of service required for power-system operation. With machine switching it is possible to give dispatching calls right of way, get back of a busy signal, or automatically tear down conflicting private-branch-exchange connections when emergency calls should go through.

GENERATOR VOLTAGE REGULATORS

A few metropolitan interruptions have been due to instability. Voltage regulators of the high-speed type have accomplished much on transmission systems in the way of improving stability. Some of the metropolitan systems do not use voltage regulators and the reasons therefor have apparently not been presented to the Institute at any time. One interesting development on metropolitan systems is that of phase-angle control between generating stations. Some such arrangement might be used for interlocking voltage regulators to prevent instability in emergency. There is also the possibility of interlocking regulators with governor position. Five or ten per cent overvoltage on customers for a few minutes may be preferable to an out-of-step condition which necessitates starting all over again to restore service.

OVERLOAD RELAYS

The last few years have seen almost complete elimination of overcurrent relays for overload protection on transmission systems. Overcurrent relays are, of course, used to clear phase-to-phase faults but where there is no fault on the system, although some element of the system is working beyond its continuous safe rating, an overcurrent relay is of highly questionable value. Most of the system elements subjected to overload have a thermal time characteristic of several minutes and if automatic rather than manual protection is desired, the relay should be of the thermal rather than the overcurrent type. On transmission systems there is an increasing tendency to let the dispatchers and operators look after overloads reported by temperature alarms.

AUTOMATIC SWITCHING

Practice on transmission systems tends to performing of switching operations automatically. It is difficult to see why an operator should have to clear a bus manually if an undervoltage relay can do the same thing after two or three seconds of power failure. Automatic equipment is available to reclose a dead bus on the first energized line.

OUTDOOR SUBSTATIONS

The industry has had several serious switch-house fires. In some cases the use of more outdoor-type substations might be considered.

UNDERGROUND NETWORKS

The pilot-wire type of network control described by Brownlee and Dent on pages 685 to 690 of the 1938 AIEE TRANSACTIONS has not only had a good operating record but contains interesting possibilities for emergency sectionalizing of a network system. Communication is easily provided from the substation to each vault. Additional pairs of control cable are cheaply available for remote control of emergency secondary sectionalizing.

STAGED TESTING

The transmission companies can rather easily make staged tests of the emergency performance of certain sections of the system without serious inconvenience to customers. The situation in metropolitan companies is entirely different but there are certain opportunities for testing individual elements of the system just as the fire department in the absence of frequent fires carries out fire drills to test out their engines, alarm systems, traffic control, pumping equipment, etc. Transmission experience indicates that it is almost impossible to secure proper operation of equipment or personnel in emergencies occurring only once or twice a year, unless there is considerable testing and rehearsal.

UNUSUAL TYPES OF EMERGENCY

Most of the discussion of metropolitan troubles has centered around floods, fires, instability, and other natural causes resulting from weather or the limitations of materials. Any apparently satisfactory plan for the restoration of service in emergency takes on a much less attractive appearance if it is viewed in the light of what would happen if, for example, the essential personnel of the operating force were not available. Suppose there is intentional damage to equipment, especially at night and in isolated locations. Such has been the experience of several large transmission systems in the middle west. After trying to cope with this source of interruption to service, most operating men thereafter regard major storms, floods, or bus fires as merely minor annoyances.

The good attendance and general interest in this group of papers on metropolitan service restoration leads to the suggestion that the Institute hold a similar symposium on restoration of service on transmission systems. The group of papers last year on the New England hurricane was well received, indicating general interest in procedure following all major emergencies.

H. E. Wulfing (Commonwealth Edison Company, Chicago, Ill): This group of papers on the metropolitan bulk power systems presents valuable information on system planning to insure continuity of service, and operating procedure to provide for the restoration of service after a complete shutdown. Many of the design principles outlined in the papers have been applied by the Commonwealth Edison Company in its system layout where they can be economically justified. It is my purpose to discuss the design features rather than the operating practice.

As you know, Chicago is supplied by four generating stations within the city limits and is connected to three other large sources of power to the south, west, and north by means of 132- and 66-kv transmission systems. The favorable geographic location of these stations, together with their heavy interconnecting ties, adequate reserves (both running and stand-by) tends to insure a continuous source of energy. The problem is to plan the bulk supply system so that a fault in one zone does not involve others.

The 66-kv system in Chicago is similar in many respects to the systems of Philadelphia and Pittsburgh. This system is completely underground and functions to tie solidly together the various generating and distributing stations within the city. It is operated as two independent units, designated in Chicago as the "red" and "blue" systems. All the terminals use phase isolation and all the 66-kv cables are single conductor so that the likelihood of a phase-to-phase fault is very remote. The red and blue busses are *not* tied together except through the 12-kv system, and reactance of this system, together with high-speed relaying, permits isolating of the red and blue 66-kv systems before a fault in one can involve the other. Each red and blue bus is subdivided into sections, and at many strategic points two circuit breakers in series are used in order to limit the possible outage to only *one* section in case of a fault in *one* of the *two* section breakers.

As in other areas, Chicago makes use of high-speed relaying to isolate faults in all of the major elements of the system, including station busses. To provide for failure of the relay equipment, back-up protection is extensively applied. The principle of phase isolation and fault-bus protection has been incorporated in all the modern stations and many of the large substations to limit the destructive effect of short circuits.

The 12-kv busses in the generating and distributing stations are also split into the red and blue systems to correspond with the 66-kv system. Each red and blue bus is further subdivided into sections to limit the amount of equipment taken out of service for any one fault.

The 12-kv transmission system in Chicago is similar to that used in New York in that the load in each generating station is segregated from the load in other zones. This method of supply is very effective in preventing failures in one zone from affecting other zones. In Chicago, however, there are no low-voltage ties between busses in different stations, the only tie being through the 66-kv system.

The supply to substations in Chicago is somewhat different than that in other cities, although the general principle of sectionalization of busses and segregation of blocks of load is common to all. The substations are arranged in groups consisting of from one to five substations, depending on the magnitude of load, geographic location, etc. From three to eight transmission lines supply each group of substations, so that the maximum load supplied by any one group is limited to approximately 50,000 kva. This limits the destructive effect of a fault should it occur in this group. The lines to any one group are distributed among various generating-station bus sections to obtain diversified supply and prevent the interruption of the group in case of failure of any section. In large substations the bus is sectionalized to limit the service interruption resulting from a fault.

In the downtown area supplying the d-c network each substation has a red and blue bus so that a complete interruption of supply on one of the systems at the generating station would not completely interrupt the substation supply.

The bulk power supply system of Detroit is quite different in principle from that of the Chicago system. In Detroit the various generating stations are tied together rather loosely and the system is split into various zones at time of trouble. In Chicago the various zones are closely tied together through the 66-kv system and only a major disturbance can cause a disruption of this system. Both types of systems have their places in bulk power planning, the choice depending on load densities, the geographic distribution of load, the short-circuit current values, and the type of relaying used.

In the design of the a-c low-voltage network the practice in Chicago is practically identical with that of New York. This system is relatively small in Chicago, but it has reached the point where it is planned to segregate it into sections with no low-voltage ties between sections. Each section will be supplied by eight high-voltage feeders with a load of less than 50,000 kva.

The d-c network in Chicago has been undergoing a change in the past few years. The network has been permanently sectionalized and provision has been made to further isolate it into small blocks in case of serious trouble.

The practice of sectionalizing all parts of the system and segregating blocks of load has been found very effective in preventing extensive system shutdowns. Also, as indicated in the papers, this practice simplifies the problem of restoring service in case this shutdown should occur.

The reports of actual experience in restoring service in Pittsburgh and New York are extremely interesting and should be very valuable to the operating engineers in determining what they should do, or possibly what they should not do, in case they should experience interruptions similar to that of these two cities. I am glad to say that we have had no experience with major interruptions in the Chicago area within the past 20 years. However, our plans, designs, and operating procedure are being developed to prevent such an occurrence and to be ready to cope with it in case it should occur.

E. S. Fields (The Cincinnati Gas and Electric Company, Cincinnati, Ohio): The design of the modern power system compared with that of only a few years ago reveals the developments that have taken place to avoid, in so far as is economically possible, major shutdowns. Occasionally, however, unforeseen conditions and unpredictable circumstances do cause such experiences.

The designers and operators of metropolitan electrical systems have for many years been applying layouts and developing operating procedures with the thought of starting up these systems in the event of complete shutdown.

Up to about 15 years ago there were, in general, two types of systems in the metropolitan areas; namely, the d-c network (Edison system) and the radial a-c system. The radial system has not presented a problem from the standpoint of starting up after shutdown, since the individual radial feeder capacities are usually very small compared with the size of generating stations and even individual generating units. The technique of starting d-c networks has undergone many years of development, originally by use of the standby batteries and at present by means of load-limiting equipment applied to the synchronous converters and motor generator sets.

The introduction of the low-voltage a-c network system of distribution has presented a different problem, as large blocks of load served from multiple feeds must be "picked up" instantly. A substantial part of the total number of supply feeders must be energized simultaneously to prevent transformer, protector, and secondary-main burnouts and the block of load energized must be within the range that the available generating capacity can support when it is applied instantaneously.

Both conditions suggest limitation to the size of individual networks. The value of 10,000 kw at Detroit, referred to in Mr. Dean's paper, is of interest in this connection. In Cincinnati, we feel that we can handle at least twice to three times that much load and now have about 25,000-kw peak load on one network. A part of our program for restoration, however, includes disconnection of some of the larger customers' services until the network is restored adequately.

There are other aspects of the problem of starting a large metropolitan system after shutdown that should be referred to even at the risk of repetition:

1 Steam-plant auxiliaries and their steam or electric supply must be designed for starting the plant under totally de-energized conditions. If auxiliaries are largely electrically driven, the layout for the power supply must be based on the fact that it might be necessary to start the plant with one or more of the main and auxiliary busses out of service.

2. Control batteries should be of sufficient capacity to permit considerable switching during the emergency while the charging equipment is out of service.

3. Some emergency lighting should be provided for in the principal operating areas in the power plants and main substations and in the system power supervisors' and telephone operators' offices.

4. Instruction of personnel that would be engaged in starting up should be carried on.

5. Too much stress cannot be put on the layout of the communication system between system-power supervisors, power plants, and main substations.

6. A definite procedure should be at hand for unloading the system in case of partial or entire shutdown, so that load restoration can be carried out in an orderly manner after the generating capacity is restored.

C. A. Corney (Boston Edison Company, Boston, Mass): At the winter convention in January 1939, an attempt was made with considerable success to develop common ground for principles of switch-house design. A similar attempt is now being made to find a uniform basis for logical system development principles to minimize the effects of trouble and facilitate picking up load after a major interruption.

On two of the systems described in these papers the several generating-plant busses are connected via direct lines either overhead or underground. These lines serve practically no intermediate loads and are used for economy load transfer and for emergency capacity transfer.

On the other two systems the plant busses are connected via lines which serve intermediate loads, one apportioning the load on the several plants by direct control and the other largely by transfer of blocks of loads from one plant area to another at interlinking points.

In general it may be said that these papers, each in their own way, develop certain common principles applied to greater or less degree as follows:

(*a*). The systems are developed to provide load areas supplied from one plant as a normal source.

(*b*). Tie facilities are either direct between stations or via the transmission system for mutual support.

(*c*). Load areas are subdivided into blocks small by comparison with the capacity of the plant when considering its own resources and those of its interconnections.

(*d*). These blocks of load are served from segregated sections of power plant switch houses and of substations.

(*e*). Generating capacity is installed as close to load centers as conditions permit.

(*f*). Layouts are as simple as possible.

(*g*). Interconnections with other systems are in use for economy and mutual support.

In Boston the general system policy is developing along these lines:

(*a*). Generating stations tied by direct lines between busses for economy and mutual support.

(*b*). Interconnections via 110-kv and 66-kv lines.

(*c*). Each generating station to serve its own load area and be as near the load center thereof as geographical and other pertinent features allow. Emergency transmission facilities available for each load area from contiguous load areas.

(*d*). Switch houses and other features of the plant developed on the unit principle of segregation. Electrical equipment of adequate capacity properly protected by relay devices and fire-fighting equipment.

(*e*). Substations and networks both direct current and alternating current fed by lines so disposed on the several generator-bus sections that any section may be out of service without loss of supply to any block of load.

(*f*). Urban areas supplied by existing d-c network and by a-c networks with gradual discontinuance of d-c supply.

(*g*). Suburban areas supplied by radial circuits and by primary network mains.

(*h*). A completely co-ordinated plan for handling any type of major emergency.

(*i*). In our experience it is frequently better judgment to shut a station down on the occasion of major trouble than to attempt to continue operation and thus take the chance of spreading the damage. The length of time necessary to restart may thus be materially reduced.

I would like to comment on the Detroit plan and ask a question:

It would seem that their plan of "loose linking" requiring daily shifting of load between load areas to provide for economical loading of plants would encounter complications in relaying, load, and trouble dispatching, provide chances for operating errors due to frequent switching, and require more generating capacity for a given load than the "tightly linked" system. It would be interesting to know whether the saving in cost of direct tie between plants approaches the cost of added generating capacity.

It appears that the Trenton Channel "double throw" generators are an application of the direct-tie principle applied at short range.

The Duquesne paper refers to the small amount of trouble experienced due to storms, hurricane, or sleet. They say their geographical location precludes any great probability of a hurricane or tornado impairing the transmission system. That is what we thought in New England previous to the hurricane of 1938. They say the sleet hazard is great but do not state what is being done to cope with it.

The "service priority list" developed for the Pittsburgh area calls for restoring street lights before domestic, commercial, and industrial service.

In New England, after restoring service to police, fire, hospital, telephone and telegraph, water pumping, etc., we took industrial, commercial, and domestic loads in that order before restoring street lighting.

We thought it best to get industry, commerce, and homes going before restoring street lights. This sequence seemed to meet the desires of the municipalities which we serve.

T. R. Halman (The Detroit Edison Company, Detroit, Mich.): The discussions have shown a fundamental agreement on the basic principles involved in the design and operation of a large metropolitan electrical system from the standpoint of best meeting the hazards of possible major shutdowns. It has also been pointed out that many of the refinements adopted by certain operators cannot be fully appreciated without the background of one who has lived with the individual system involved.

From the discussion particularly of Mr. Juhnke, Mr. Wulfing, and Mr. Corney, it is evident that this is somewhat true regarding the advantages and relative simplicity of the principle of "loose linking" as used by The Detroit Edison Company. There appears to be an impression that this plan of operation tends to prevent efficient loading of power plants, requires additional running-reserve capacity, complicates the relaying, and is inherently awkward and difficult to live with. Much of this might be true if care had not been exercised from the beginning of the modern system design to see that all elements are kept in proportion and balance to yield a maximum of flexibility and utility of all components.

It is relatively easy to obtain maximum operating economy among plants of varying efficiency where all plants and loads are tied together as closely as possible. Conversely it is easy to guard against the spread of trouble on a system consisting of several weakly connected areas. Loose linking as developed and applied in Detroit is an attempt to overcome, by careful system design and operation, the apparent contradiction of these two ideals and preserve within practical limits the outstanding advantages of each.

In general on most systems, the load is somewhat distributed whereas the power sources are concentrated in a few plants usually some distance apart. These power plants are located as close as possible to the heaviest load centers and supply this load directly or through radially fed substations. There are also very likely to be considerable load concentrations which are not very near any source but approximately midway between a pair of power houses. An efficient method of supplying these loads, and at the same time tying the various power houses together into a unified system, involves the use of switching stations at these intermediate load centers, each having transmission ties in two directions to adjacent power sources.

The total tie capacity from both directions must always be considerably greater than the maximum expected value of the local load to allow for outages and sudden load growth. Thus the ties from either direction will carry most of the load excepting during extreme peak conditions. Therefore, by simply installing, in accordance with a well thought out plan, the transmission lines necessary for carrying safely these intermediate loads, it is possible to obtain a great deal of flexibility of area limits without any extra investment in transmission lines. This makes it easy to shift a very large proportion of this load even at peak condition, and probably all of it at intermediate or light-load conditions. Fortunately, it is during these intermediate and light-load conditions that such shifting is most desirable, because at heavy-load periods most of the particularly economical capacity can be loaded without reaching so far. It should be evident that this system design and plan of operation does permit efficient plant loading.

Admittedly the above principles are fairly commonly used. Also it is not unusual to provide back-up relaying in ties between sections of a system to prevent the spread of uncontrollable trouble. The unique feature of the loose-linking method is that as the supply to the intermediate loads is shifted by the altering of the relative loading on the ties from opposite directions, the relaying on these ties is also altered so that in case of separation these loads will remain in the area of the plant which had been supplying them. This is done by having sets of separation relays each side of critical load centers, and cutting in, by means of suitable relay-control switches, only the proper ones to cause tripping of the ties on the side away from the preferred source.

This makes it possible, without running any additional reserve generating capacity, to keep each load area balanced with its plant capacity so that the combination will be self-sustaining and can operate satisfactorily even if completely separated from the remainder of the system. This permits the use of separation relaying sufficiently sensitive so that it should accomplish its purpose of saving the balance of the system in case of an uncontrollable fault in one area and yet does not sacrifice the chance of maintaining service completely should the fault eventually clear. It also permits the use, without hazard, of a rather drastic plan of emergency switching, which calls for opening any area ties at the existing designated points of pull-apart should the voltage fall below 60 per cent of normal for one minute.

It should be understood that this loose-linking principle has been developed without necessitating dangerously weak ties between power houses or load centers, and also without involving relaying of the hair-trigger variety. Including the lines necessary for feeding intermediate load, described above, and the inter-area ties, each power-plant load area has a total transmission capacity across the area boundaries from the balance of the system of the order of 100,000 kw on a short-time emergency basis, and the loose-linking relays are set to take advantage of it. This is ample to care for emergencies such as the loss of the largest generating unit at any plant. Thus it can be seen that no extra generating reserve is required on account of loose-linking operation. During many years of experience with this method there has never been an unnecessary separation either due to relays or emergency switching.

It should be noted that the method used does not involve any major switching but only manipulation of relay-control switches, and cannot be hazardous to service under any normal conditions of operation. In case of major faults, it is true that should the wrong separation points operate, either due to faulty supervision or faulty relaying, the full benefit of loose linking would not be realized. It should be obvious, however, that conditions could never be worse than where no provision is made for sectionalizing the system in case of uncontrollable faults, or where no attempt is made to keep the elements in balance, and therefore self-sustaining after separation. The loose-linking plan practically guarantees that a large portion of the system will be saved, whereas without it the whole is in jeopardy. Without close attention to a self-sustaining policy, even should the system be sectionalized, there is grave danger that the unfaulted portion may be left with too much load so that the generators become swamped.

The supervision of the daily load cycle in each area and shifting of separation points to match may appear rather burdensome; but experience has shown that once a routine has been developed it can be followed with little trouble and actually has a compensating advantage in that it helps to keep the operating personnel alive to bulk power and emergency problems.

From the relay standpoint, it must be admitted that this system does involve additional labor in calculating settings and maintaining some additional equipment, but much of this really should be done anyway on any system where it is desired to have a comprehensive and adequate plan of back-up protection against major faults.

Whether the principle of loose linking can be applied successfully to other systems, requires the intimate familiarity with all details of the system in question which has been mentioned; but on a suitable system it can result in a great increase in safety to service with very little or no penalty in the form of loss of economy or complication of operation.

Restoration of Service on a Metropolitan Power System

Discussion and authors' closure of paper 40-32 by W. C. Bryson and A. P. Hayward, presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940, and published in AIEE TRANSACTIONS, 1940 (October section) pages 563–70.

A. P. Hayward: Mr. Corney has mentioned the statements concerning the probability of hurricanes and sleet storms occurring in the Pittsburgh area. The weather records do not disclose any hurricanes of the type experienced along the seaboard. The mountains to the east are believed to be a very effective barrier to the full force of any hurricane coming inland and to a certain degree prevent the occurrence of any destructive tornadoes of the type experienced in the Midwest. However, local wind storms of hurricane velocity are not uncommon and, in general, the overhead structures are constructed and adequate clearance provided to withstand these conditions. The sleet hazard is relatively great in this area but for some unforeseen reason there have been no major sleet difficulties on the Duquesne Light system for many years, in spite of severe sleet storms immediately adjacent to the Duquesne Light territory.

It was also mentioned that in Boston the priority schedule for restoration of service placed street lighting at the end of the list. Conditions in Pittsburgh were somewhat different than in Boston during the hurricane as the flooded areas were evacuated and all the inhabitants moved to higher land and concentrated in relief centers. This required great precautions to provide adequate protection for the deserted homes in and around the flooded area. Although martial law was in effect, the early restoration of street lights greatly assisted in detecting marauders and assisted in policing these territories. Mention has been made of excessive flood risk in the Pittsburgh area. It is true that floods are quite frequent, but this area has always considered the flood hazard and in general has provided protection for the normal yearly floods. A 46-foot flood stage such as occurred in 1936 had never been experienced since the settlement of the district. The highest previous flood the utilities have experienced occurred in 1907 with a flood stage of 38.7 feet. Probability studies show that a 46-foot flood stage should occur about once every 250 years. The probability of major floods is much lower than the probability of hurricane-velocity winds in the New England area. Since the 1936 flood much work has been accomplished in providing flood protection for the upper Ohio River valley. One flood-control dam has been completed and several others are under construction. It is estimated that upon the completion of this work a flood similar to the 1936 flood will have its crest reduced approximately 8 feet. This will bring these major floods within a range where they will cause less inconvenience to the public at large.

The paper has mentioned the occurrence of several major electrical failures at the Colfax power station, and mentioned that the unit operating setup prevented these failures from interfering with the operation of the balance of the station. A factor which greatly assisted in minimizing these disturbances is the practice of immediately isolating and removing from service all equipment involved in electrical failures and not attempting to reclose this equipment or restore service until the location of trouble is determined.

Mention has been made of skull practice in preparation for emergencies. Flood drills are made during or immediately preceding flood emergencies to review the emergency routine and to train the operating personnel in the proper flood procedure. These drills involve the procuring of material and supplies, the removal of flood gates from storage, and the setup of certain protective equipment and operation of the emergency flood pumps as outlined in the instructions for emergency operation.

Another factor which has been of considerable assistance in training the operating personnel has been an educational program which has been devised to acquaint the operating and maintenance personnel in the plants with the general operating problems of the system. The boiler-room and turbine-room operators have attended electrical courses which have discussed the operation of generators and transformers, interconnected system operation and transmission problems, all referred to specific problems that have arisen on the Duquesne Light system. In this manner they have a much broader realization of conditions that exist on the system and in emergencies are capable of responding in the proper manner.

Restoration of Service From Large Metropolitan Systems After Complete Shutdown

Discussion and authors' closure of paper 40-31 by H. A. Dryar and Raymond Bailey, presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940, and published in AIEE TRANSACTIONS, 1940 (October section) pages 571–4.

E. E. George: See discussion, page 1150.

H. E. Wulfing: See discussion, page 1151.

E. S. Fields: See discussion, page 1151.

C. A. Corney: See discussion, page 1152.

L. G. Smith (Consolidated Gas Electric Light and Power Company of Baltimore, Md.): The paper on the Philadelphia system covers the problem of re-energizing a system supplied by both steam and hydroelectric plants and also interconnected with other systems. On such a system it is difficult to formulate a single procedure of restoring service after a complete shutdown. Several procedures must be considered, depending on the relation between hydro and steam generation; the loads in the various load areas at the time of the trouble; and the amount and direction of power flow in the interconnections. The authors have emphasized one point that is believed to be essential: that is, to clear the busses immediately. Whether one or all stations are involved, the busses in the affected stations should be cleared if differential-relay protection has not already accomplished this. This procedure may prevent the spread of the trouble and will facilitate the orderly restoration of service. The need for co-ordination with the boiler operators stressed by the authors is also of vital importance. Any instructions should require the notification of the boiler operators of the load to be restored so that load will not be connected unless it can be carried. This might involve a detailed listing of duties and responsibilities of all operating personnel.

In a system having several generating stations and load areas, a complete shutdown can be classified into two types; namely, (1) all busses can be re-energized, and (2) the bus on one bulk power source cannot be re-energized. A serious problem is introduced if either a complete or partial system shutdown is experienced and it is found that a 13.2-kv bus in a generating station cannot hold voltage.

In the past the most serious failures to service in metropolitan areas have been due to bus failures in generating stations. It is believed that the difficulty in restoring service has not been entirely due to the original failure but to the fact that it was not cleared promptly and could not be readily located. In such cases the operators know only that a bus is in trouble. The first step is to clear the bus. However, to determine what bus sections are in trouble and what sections can be used to re-establish service, the only procedure is one of trial and error; that is, to connect units to various bus sections in order to see if they will hold voltage. This practice often causes additional damage and sometimes a spreading of the trouble. While differential relay protection is proposed to prevent this type of trouble, in some cases it is difficult to install in existing stations. Might not some method of quickly testing the individual bus sections with a low-capacity potential testing device be desirable for installation in stations not having differential or ground-fault bus protection?

W. C. Stone (nonmember; Public Service Electric and Gas Company, Newark, N. J.): The electric system of the Public Service Electric and Gas Company is an arrangement of generating stations and switching stations linked together by 132-kv transmission circuits and interconnected with adjacent operating companies, the most important interconnection being the 220-kv Pennsylvania-New Jersey ring. With one exception, each generating station and switching station distributes power to areas of from 50,000 to 150,000-kva demand, one generating station feeding directly into the 132-kv system.

Restoration of Service to Generating Stations and Bulk Power Systems

The restoration of service to a generating station or bulk power system after a complete shutdown is necessarily a matter of coordination between several departments.

Without proper instructions and team work, it can be expected that unnecessary interruption to service will result.

Usually a complete station shutdown is the result of a bus short circuit or a failure of major equipment. The switchboard operators should open the necessary oil circuit breakers to isolate all rotating equipment from the station bus. Then open all oil circuit breakers on circuits which may act as feed backs from the system or other sources of supply.

The location of the fault and isolation of damaged equipment follows. While this is being done, the remaining radial-feeder oil circuit breakers should be opened and the turbine room, boiler-room engineers, and load dispatchers informed of what has taken place.

After the fault has been located and damaged equipment isolated, the station bus is ready to be energized from the main power system or another generating station. This applies to stations where there are no house turbines.

Energizing the bus and station power transformers from the system allows the starting up of all auxiliary equipment simultaneously, thereby speeding up the time of returning the boilers to full steam pressure and allowing a number of generators to be brought up to synchronism simultaneously. It also allows the immediate restoration of service to a number of feeders depending upon the capacity and number of the circuits available from the system.

As soon as the station shutdown occurs, it is the function of the load dispatchers to order in additional generators at other generating stations and arrange for purchase of power from interconnected companies, in order that he may be in a position to restore as much of the interrupted service as possible should there be a delay in returning the generators to service in the interrupted station.

It may be necessary to relieve the system of overload caused by loss of generation. This is done by dropping blocks of load listed in a manner showing those least affected by loss of service.

Bulk Power System Interruption

Each power system is somewhat different from its neighbor in design of busses and transmission arrangement, and the methods of restoration necessarily differ to some extent.

It becomes the responsibility of the load dispatcher to take control of the situation immediately after the fault in the generating station has been isolated and the operator reports "ready for service."

Orders are given to energize feeders to various substations or groups of substations as fast as generators and boiler capacity are available, synchronizing wherever necessary until all service is restored.

No difficulty should be experienced in restoring service to the various substations or networks, as the majority of substations do not exceed a demand of 15,000 kva. Those that do exceed 15,000 kva can be restored by way of group oil circuit breakers, energizing several transmission circuits simultaneously.

Differential-Relay Protection

All generating station, switching station and important substation busses are fully equipped with differential-relay protection or soon will be.

Bus-section oil circuit breakers which are part of the differential-relay scheme should be backed up by a second oil circuit breaker at points where a failure of a breaker will result in a station shutdown.

AUXILIARY STATION POWER

The key to service in a generating station is the auxiliary power supply.

Station power transformers should be properly isolated and, if possible, receive their source of supply from bus sections which cannot become involved in the same fault, the secondary bus being provided with two or more sectionalizing breakers.

Where it is not practicable to feed station power transformers from two or more sources, their common primary bus should be provided with two sectionalizing breakers.

DESIGN

It is desirable to give busses and switching equipment, either indoor or outdoor types, as much clearance and isolation as possible. Fire walls should be installed between transformer units and fire-extinguishing methods should be provided.

The pedestal type of outdoor bus structure is preferable, we believe, because it is economical and convenient, and safe for maintenance.

The indoor busses, transformers, and equipment should be separated in compartments where failures can be confined to prevent as far as possible the spread of trouble to other equipment which might cause a major interruption.

INSTRUCTION OF OPERATORS

It being impracticable to shut down generating stations for the practice and education of the operating personnel, the next best method must be adopted, that of issuing general instructions which will act as a guide to each department that may be involved pointing out the desired methods to be used. These instructions should be reviewed periodically, and often, in order that the efforts of each department may be directed in the proper course without confusion or loss of time, and that each department may know what the other departments are attempting to do, in short, team work.

In closing, I wish to point out two important items:

1. The choice of men who will later become engineers, operators, watch-foremen, and load dispatchers.
2. The necessity of properly and continually instructing them and training them in their duties.

H. A. Dryar and Raymond Bailey: The opinion of L. G. Smith that the difficulty in restoring service is attributable mainly to the duration of the fault conditions finds support in our experience of a ground fault on a generating-station bus having to develop into a phase-to-phase failure before relays become operative. In the meantime, both busses were affected and complete service restoration was delayed until the equipment was cleaned of soot and smoke.

In our opinion the remedy is to be found in a greater number of bus sections, each differentially protected. With this arrangement, bus faults will be relayed promptly, equipment damage will be minimized, and interruptions will be reduced.

The opinion of P. B. Juhnke that prevention is the better part of the cure, and that approach to this very desirable end is to be found in adequate spacing to avoid fault communication and such sectionalizing of the system with adequate relay protection as will permit isolation of a fault without interruption to load, has our hearty support.

As the power system grows in size and complexity, assuming increasing importance is the training of the men whose responsibilities demand complete knowledge of the system, instant and correct analysis of disturbance reports which are not always accurate, and an initiative that begets instant decision as to the measures to be applied.

Because of the variety of possible forms of trouble and the variations in procedure to cope with them, the training seeks to promote the habit of a daily review of potential problems, the effects, and the methods of restoration.

Our training method is to submit monthly to each load dispatcher via the telephone 12 hypothetical problems and grade him on the basis of knowledge, analysis, decision, and explicitness of instructions. Two supervisors, one giving the problem and the other listening, are the judges. His individual rating is then given him as a spur to continued good performance or an urge to greater efforts.

We dislike to admit the inability of a good dispatching organization to handle satisfactorily major system troubles. A few minutes daily given to a conscientious study of hypothetical system problems by each member of the organization will so improve one's performance that the monthly test problems should indicate his ability to function properly under stress.

Provisions for Re-energizing the Electric System of the Consolidated Edison Company of New York, Inc.

Discussion and authors' closure of paper 40-33 by G. R. Milne and H. C. Otten, presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940, and published in AIEE TRANSACTIONS, 1940 (October section) pages 579–85.

E. E. George: See discussion, page 1150.

H. E. Wulfing: See discussion, page 1151.

W. C. Stone: See discussion, page 1154.

E. S. Fields: See discussion, page 1151.

C. A. Corney: See discussion, page 1152.

W. E. Caldwell (nonmember; Consolidated Edison Company of New York, Inc., New York): The paper by Messrs. Milne and Otten presents a practical procedure for re-energizing a large electrical system and the comments I have to offer deal primarily with the incidental problems in the mechanical plant and more especially in the boiler plant.

The response characteristics and limitations of moderate-pressure boilers with various combustion systems is fairly well established and the suitability for meeting normal load variations is seldom questioned. In meeting extreme conditions, such as re-energizing large network areas, little direct experience is available.

The rate of load pickup on moderate-pressure boilers may be limited by the response of the combustion system and/or carry-over resulting from rising water level with increasing load. The rising water level is caused by an increase in the steam-water ratio in the boiler, coincident with a sudden decrease in pressure accompanying increased steam demand. A rapid increase in heat input produces a similar effect but in general this is not a serious handicap in a well-designed boiler. This fault in some boilers is partly compensated by maintaining a low water level, at low rating to afford a greater margin to accommodate the swell which accompanies increase in output. Boilers with large water capacity in relation to drum capacity are sensitive in this respect.

From the standpoint of response or ability to take large load increases, the boiler should have water capacity consistent with the heat inertia of the absorbing surfaces and the lag of the combustion system. Some accumulator effect is also desirable for maintaining more uniform combustion conditions so that minor variations in steam demand will have little effect on steam pressure, which is the usual source of control of the combustion regulators. The steam drum should be large enough to provide a reasonably stable water level. A certain amount of water capacity is necessary to act as a heat accumulator during the normal period of load pickup preceding the increase in heat input, which may vary from a few seconds to a half minute.

Acceptable characteristics are economically obtainable during the design stage by a rational allocation of surface between boiler, economizer, and air heater. There are other important considerations in boiler design but these need not be treated here. Aside from lag deliberately introduced in regulators, a delay in response is due to the combustion system and part is due to the materials transmitting the heat in establishing the new heat-flow gradient. A reasonable figure for normal load pickup may be taken as 15 per cent capacity per hour per minute. It is possible to better this increase substantially but it represents a fairly safe range for control apparatus setting with due consideration to minimizing smoke and cinder emission.

Obviously, a steaming boiler responds more readily than a banked one and a pickup from 50 per cent to 75 per cent capacity is quicker, on account of the available overtravel capacity, than from 75 per cent to 100 per cent. There are differences in the rate of response of the various combustion systems, that is, stoker and pulverized coal, but these differences generally are of minor significance. For example, a modern stoker-fired boiler at Hudson Avenue (300,000 pounds per hour capacity) developed

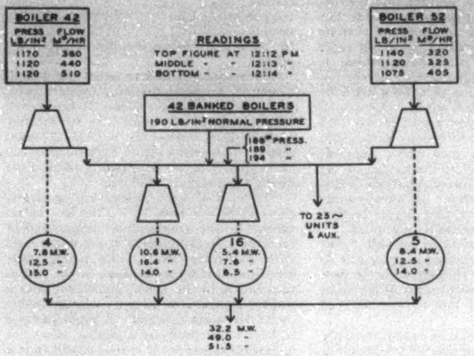

Figure 1. Load-change test, Waterside station, December 17, 1939

an increase, on test, of 35,000 pounds per hour per minute from a banked condition. Another Hudson Avenue boiler (150,000 pounds per hour capacity) was raised from 50,000 pounds per hour to 120,000 pounds per hour in 27 seconds, or a rate of increase of 155,000 pounds per hour per minute. A unit-fired pulverized-fuel boiler at Hell Gate, with type *B* ball mills picks up 15 per cent capacity per hour per minute, while other boilers in the same plant with impact mills respond quicker. East River boilers with bin system of pulverized coal are capable of still more rapid response. With constant header pressure more heat input is required for a given increase in steam output than with a declining pressure, since heat is absorbed by the water as a result of increasing boiler pressure incident to increased flow.

In re-energizing the electric system by the method described in the paper, lag in boiler response is minimized by proper co-ordination in closing the switches controlling the network feeders. The lag in repositioning regulators, etc., is entirely eliminated and a major portion of the lag in the combustion response is eliminated so, under these conditions an instantaneous pickup of 25 per cent by the boiler plant is a reasonable expectation. Substantial loads have been picked up by the system unexpectedly and much greater increases may be accommodated by prearranged co-ordination.

While the moderate-pressure plants on the system have demonstrated their ability to meet re-energizing conditions, such information was lacking in the case of the high-pressure installation at Waterside. Accordingly, tests were made to provide practice in picking up loads anticipated in the paper and to determine inherent characteristics of the high-pressure equipment. Briefly, the 60-cycle high-pressure and low-pressure units at Waterside were separated from the system with enough load on the bus for almost full load on the two high-pressure boilers in service. About 15,000 kw of this bus load was supplied by a tie from Hell Gate, so that the tripping of a breaker dumped this load on the high-pressure units. Banked boilers were floated on the 200-pound header as a precaution and adequate safeguards generally were provided. The results of the test were very reassuring, the general arrangements for which are shown diagrammatically in figure 1 of this discussion.

While the high-pressure units were separated from the main system the governor regulation was entirely satisfactory. Previously, some erratic behavior of the units had been ascribed to the high-pressure governors, so this experience with isolated operation dispelled any suspicion of inadequacy.

In picking up the load all speed control was effected on the high-pressure machines with the boilers on manual control. There was no increase in steam from the low-pressure banked boilers, as may be seen from the pressure indications at the high-pressure exhaust which actually increased with the load.

The momentary dip in frequency, indicated in figure 2 of this discussion, occurred immediately after the load was dumped and within the time required for governor response the greater part of the drop was restored. After a readjustment of speed by the operator the normal frequency was practically restored within eight seconds, although a longer period was required for the boilers to recover. Actually, the frequency was substantially restored before the heat input to the boiler had appreciably increased.

Some of the more important observations of the test are presented graphically in figure 3 of this discussion.

The steady water level with this rapid increase in load is due largely to the greater density of the high-pressure steam, as contrasted with lower pressures but it also reflects good design proportions.

During this test the back-pressure control was not in service on the high-pressure machines. The stable back-pressure characteristics indicated in this test result from the low inertia of the rotating masses and more responsive governor on the 3,600-rpm high-pressure machines than on the lower-speed low-pressure units. With increasing load the steam flow through the high-pressure unit increases before the low-pressure governors have responded, tending to raise the cross-over pressure and, with falling load, the pressure declines.

From the curves it may be seen that the boilers responded adequately to the instant demand of 28 per cent increase in output with but slight drop in pressure. This test confirms our belief that the high-pressure units are capable of meeting re-energizing demands, just as effectively as the time-tested low-pressure installations.

L. G. Smith (Consolidated Gas Electric Light and Power Company at Baltimore, Md.): This paper is of considerable interest to the system design engineer as well as to the operating engineer, because it presents fundamental points to consider in the design of the transmission and distribution system in order to facilitate restoration of service. By a system designed so that each load area is wholly dependent upon one generating-station bus, the New York system greatly simplifies the operating procedure of restoring service. However, the generating-station bus becomes a vital element in the supply of electric service to the load area. Therefore, as the authors state, extreme care is required in the design of generating-station switching. Experience indicates that walls with doors in them do not constitute adequate isolation. Walls with no openings or even geographic separation are necessary to insure adequate isolation. The company with which I am associated has a project in progress in an important generating station to obtain the necessary isolation by adequate barrier walls and by moving part of the switching from a switch house to an outdoor structure.

In the procedure outlined for re-energizing an a-c network by simultaneously closing a number of feeders, a difficulty may be introduced by one or more of the oil circuit breakers to which the feeders are connected being unable to withstand operating voltage. In the event of a bus failure, damage may be done to the wiring or oil circuit breakers associated with a feeder, making it necessary to determine which switching equipment is in operating condition.

In re-energizing parts of a system service may be restored to parts. In restoring

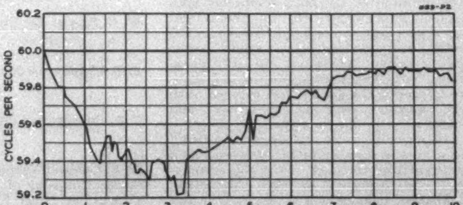

Figure 2. Waterside bus frequency during loading test

15,000-kw load interrupted at 12:12 p.m., December 17, 1939 service to other parts sufficient generating capacity may not be available; however, by lowering the voltage on the parts of the system to which service has been restored, the load may be reduced so that sufficient generating capacity is available.

P. B. Juhnke (Commonwealth Edison Company, Chicago, Ill.): I somewhat recklessly promised to discuss two of the papers presented here today, those dealing with New York and Pittsburgh. On closer scrutiny I found that it is no easy task to keep this promise. In systems of such size there are fine points which the authors have fully in mind, but which an outsider can absorb only after a prolonged study and intimate contact. My remarks, therefore, will be very, very general.

There occur in these and other papers references to the training of the operating force, and especially of system operators or load dispatchers. This training is one of the knotty problems confronting us. We cannot well maneuver with great power systems, yet something of this sort is really called for. Expecting a dispatcher to size up a system in trouble and quickly to map out a strategy to cope with it is expecting a great deal. The difficulties incidental to such a task are fully appreciated by anyone who has ever sat at an inquest following a bad case of trouble. There, with every item of available information in predigested form, with premeditation covering perhaps a day or more, it is sometimes difficult, if not impossible, to reach correct conclusions, such as the operating personnel must reach in moments of uncertainty aggravated by lack of information given or by conflicting reports received.

To give the men in our organization charged with this responsibility some familiarity with system procedures, we have simulated cases of trouble by stating effects and have quizzed them as to the proper procedure dictated. Difficulty lies in shaping a probable problem, and in the unreality of it.

We have also prepared an operating routine for cases of trouble in generating and distribution stations, unknown in location. The study given to these by the operating personnel has had the effect of broadening appreciation of the problems involved.

It should be borne in mind that the responsibility for training of these specialists rests with the operating executives, that the problem is far from being solved, and that much more remains to be done. I personally doubt that a really big case of system trouble can ever be efficiently dealt with by the best operating organization in existence. A big case of trouble corresponds to retreat for an army, and retreat always dictates tremendous sacrifices.

With specific reference to the New York system, I have some doubt as to whether 20 out of 60 d-c substations can pick up the entire load without damage to equipment, but a positive answer requires more information than is available from the paper.

With reference to picking up the a-c network, we are averse to making relays inoperative, though the size of the networks in New York seems to make such action necessary.

From an outsider's point of view, the concentration of load at Hudson Avenue and Hell Gate stations would seem excessive, but again this is a mere opinion which may not be based on all the known facts. Lack of sectionalization would seem to dictate excessively expensive switch structures.

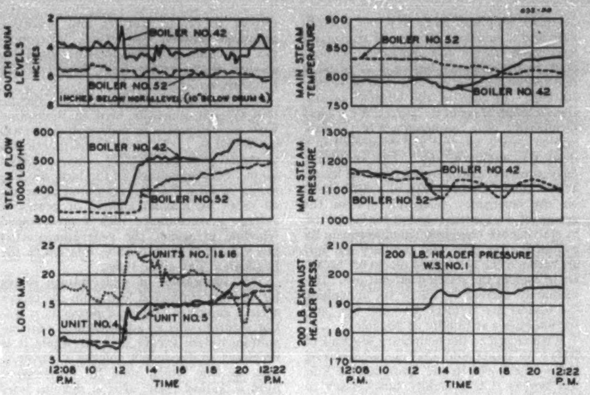

Figure 3. Rate of load change, topping-unit boilers, Waterside station test of December 17, 1939

In regard to the Pittsburgh system, this seems woefully at the mercy of uncontrollable forces of nature, which do not yet seem to have recorded their maximum in viciousness and brutality. The trouble resulting from them, however, involves submersion of load, as well as of generating capacity, which eases the responsibility considerably.

It appears that some of the cases of trouble of the past may be attributable to relay setting and limitation in relays, both of which, since the dates of those cases, have made great forward strides.

The Pittsburgh system, in its latest operating setup, seems to have made considerable progress since the days when those cases of trouble occurred, and is now perhaps better fortified than ever before to weather storms such as have befallen it before.

In regard to both of these systems, I lean to the belief, and express it rather meekly, that for them the ultimate in system structure has perhaps not yet arrived.

There have been recited here a number of cases of trouble which have occurred in the distant past. These cases have played a prominent part in shaping our systems of today. These cases were analyzed as to causes, mostly unforeseeable, and for whose anticipation not a single index was available. From such analyses conclusions were drawn. These conclusions all point to one outstanding fact, namely, that the effect of the initial trouble with its train of attending development was not sufficiently confined. If the design of the system involved had been such that the hazards effectuated had been limited in exerting their parallelizing effects upon smaller portions of the system involved, then the interruption which resulted would have definitely not been recorded.

May I be permitted to express my humble belief that sectionalizing of generating capacity and trunk transmission lines in load areas will render inoccuous most of the hazards reposing, but not identified in our systems? This sectionalization should be carried so far that every metropolitan system in reality will consist of two parallel systems, each sufficient unto itself and separated, if not in space, at least by effective means imparting the element of space, and so adequately relayed that in the event of misfortune befalling the one, the other will not be affected thereby except by resulting load transfers. This sectionalization should be extended to a point where the largest amount of generating capacity in any one location supplying each such section at that point, and the transmission elements on the same section may be lost without embarrassment to more than the load zone directly involved. Such structure can be envisioned, can be classed as economic in the light of the responsibility confronting electric service systems, and should contain a guarantee against general service interruptions in the future.

In conclusion, may I be permitted to paraphrase an utterance of a great authority: In the end there remains but these two, prevention of interruption and restoration of service, and the greater of these is prevention.

G. R. Milne and **H. C. Otten:** P. B. Juhnke expressed some doubt regarding the ability to re-energize the d-c network in New York City from a limited number of substations without damage to equipment. While there has been no actual experience to indicate the adequacy of the method prescribed for re-energizing this network, calculations show that if the operations are executed as planned, the magnitude of current which the d-c feeders, substation bus-tie breakers, and converters are called upon to carry will be within safe limits. No attempt would be made to re-energize the d-c system until an adequate supply of 25-cycle power is available and a sufficient number of converters have been started and connected, without load, to the main d-c busses in 27 or more selected substations out of a total of 41 substations. In each of the selected substations a group of six of the longest d-c feeders terminating near the boundary of the substation area is selected and connected to a dead d-c auxiliary bus. The remaining feeders are left disconnected from the busses at this time. Upon receipt of a code signal on the emergency telegraph system the groups of d-c feeders selected for initial use in starting are energized simultaneously by connecting the main and auxiliary d-c busses through the heavy bus-tie circuit breakers in each of the selected substations. Immediately thereafter, all of the remaining d-c feeders are connected to the live substation busses as rapidly as possible.

With regard to the temporary blocking of relays we might add that in re-energizing the a-c networks in the Consolidated Edison system it is generally unnecessary to make inoperative any relays on the distribution feeders. In the case of the direct-tie feeders between generating stations it is considered advisable to block the back-up overcurrent relays only, to prevent tripping the ties as a result of the current surge at the instant of re-energizing a large network. It should be noted however that in any case, the ground relays, pilot-wire relays, and impedance relays always remain operative and that the first-line-of-defense protection for faults in the tie feeders themselves remains intact.

An impression seems to have been given that because of the relatively large capacity of the Hudson Avenue and Hell Gate generating stations the current-interrupting duty imposed upon the circuit breakers is severe and requires excessively expensive switch structures. The actual breaker duties are not excessive since the busses are always sectionalized. The number of sections operated separately at any given time is adjusted according to the amount of generating capacity connected. The interrupting duty imposed upon the breakers does not normally exceed 1,500,000 kva and the experience with breaker operation has been generally satisfactory.

E. E. George has, in his discussion, presented some interesting comparisons with respect to design features and operating practices between the typical "metropolitan" systems and the systems supplying smaller load centers from large-capacity transmission lines.

The fact that automatic voltage regulators are not generally used in connection with the generators in metropolitan system is referred to. It has been found practicable to render very satisfactory service without them. Service voltage on the large a-c networks in New York is regulated in nearly all cases by manual control of generator voltage in accordance with a prearranged schedule in which the generating-station bus voltage bears a definite relation to the bus load at any given time.

The application of undervoltage relays for clearing connected load from the busses after a complete failure of power in a station seems to offer no advantages in a metropolitan system except in cases where it is necessary to disconnect quickly a transmission tie line which may be re-energized from a distant point after a definite brief interval of time in accordance with a prearranged schedule. Likewise, equipment for automatically re-energizing busses from the first energized transmission line would have limited application in metropolitan systems because in any case of complete shutdown of a station, resulting from an electrical fault, it would probably be necessary to make a brief inspection at least, of the main busses and switchgear before attempting to re-energize the equipment.

L. G. Smith referred to the influence of doors upon the adequacy of barrier walls. In the Waterside 60-cycle generating station in New York, which was recently modernized to meet the requirements for supply to a-c networks, rather unusual provisions were made for the operating personnel to pass from one isolated section to another in the switch galleries. Instead of providing any doors in the heavy barrier wall itself, two open passageways or balconies were provided, one outside the building wall and one in the turbine room high above the turbine room floor. Each of these balconies is reached by doorways in the walls of adjacent isolated bus structures, the doors opening outward in each case. In the event of failure of a door as a result of a pressure wave originating within a bus structure the gases would be vented out of doors or into the upper space in the large turbine room and could not enter the adjacent isolated bus structure. In other cases where space was limited doorways in barrier walls were each equipped with two heavy doors opening in opposite directions so that a pressure wave originating on either side of the wall would tend to hold closed the door on that side of the opening.

In any case where a shutdown involves a failure of electrical equipment and renders one or more distribution feeders to a network unavailable temporarily, provision is made in the written procedures for indicating the minimum number and grouping of the available feeders which would be adequate for the purpose of re-energizing the network.

The reduction of load which may be effected by lowering the system voltage has been investigated. A reduction of 10 per cent below normal bus voltage at the generating station is considered to involve little risk of damage to motors and other utilization equipment. The effect of such a reduction of voltage was determined for a portion of the Consolidated Edison system including representative proportions of 60-cycle residential, commercial, industrial, and rapid transit load at about the time of the evening peak. The magnitude of this load was 460,000 kilowatts at normal voltage. A 10 per cent reduction of voltage caused a reduction of 13 per cent in true power and a reduction of 17.4 per cent in the reactive-power load. The voltage was gradually reduced to 90 per cent of normal over a period of five minutes, held at that value for two minutes, and gradually restored to normal over a period of five minutes. When normal voltage was restored the original values of true power and reactive power load were re-established. During this test all induction regulators at company substations were fixed at their normal operating position so that the reduction of generating-station bus voltage was effective throughout the area supplied. Reports of adverse effects on the operation of utilization equipment were negligible in number. The most noticeable effect was the fading of sound output in motion-picture-theater installations. It was estimated that at the time of this test the proportions of lighting and power load were 90 per cent and 10 per cent, respectively.

Railway Power Supply (40-4)

Power Supply for Railroad Electrification and Fundamentals of Power Contracts

(40-27)

Discussion and authors' closures of paper 40-4 by Philip Torchio and paper 40-27 by E. R. Hill, presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940, and published in AIEE TRANSACTIONS, 1940 (September section) pages 550–3 and 560–2.

Sidney Withington (New York, New Haven and Hartford Railroad Company, New Haven, Conn.): The papers by Messrs. Torchio and Hill cover in an interesting manner the salient requirements of railroad power supply. Mr. Torchio points out that where the railroad operates its own generating station, jointly with purchase of power, the less-efficient railway plants may be operated for a minimum number of hours, as is the case with utilities owning generating capacity of older vintage. This may be advantageous if the price of energy in connection with purchased power is sufficiently low. It is, however, often the fact that even in the case of a relatively inefficient railway plant, as modern plants go, the incremental or energy cost may be less than the incremental or energy charge of purchased power. This removes the incentive for the railroad to take all the energy possible through its purchased supply.

Mr. Torchio also mentions, in instances where a railroad purchases all its power, operating no plants of its own, that a guarantee of payment for a minimum amount of service each year should be included. This may be definitely not of advantage, and if insisted upon by the power company, may force the railroad to install its own generating facilities, rather than risk paying for dead horses in the event of reduction of service requirements during the term of the contract. As Mr. Torchio says, this feature may be taken care of in stipulating a minimum billing demand which will be a specified percentage of a previous demand in each month. It is of course necessary that the power company should be assured of some such protection; on the other hand, however, it may be the case that if railroad service diminishes to a point where this guarantee might be embarrassing to all concerned, the power company may be able to plan to use its installed capacity for supplying other customers, in which case the railroad should not be required to continue to pay for the capacity which it cannot use. This of course would not apply to facilities installed solely for the railroad supply which cannot be applied to other purposes.

Mr. Torchio points out the advantage of the utility furnishing housing and operating apparatus necessary for conversion of power of commercial characteristics to power of railroad traction characteristics. This is fundamentally important and may be a controlling factor in determining the economics of a given electrification project. If a railroad embarks on electrification of a section of its system, considerable capital expenditures are necessary. If the utility supplying power can be persuaded to install all power-supply apparatus, leaving to the railroad the furnishing of the distribution facilities only, the railroad's capital problem may be much reduced. Furthermore, as has been pointed out, and perhaps a more important consideration, the railroad organization is not as a rule adapted to handle technical details connected with power-supply and substation conversion apparatus, and it would be in many cases very desirable to relieve the railroad organization of such responsibility.

Mr. Torchio mentions the advantage in the power-supply utility continually improving the economics of power generation on account of the continual growth in load and improvements in the technique of power generation. This is important and in any contract covering a long term, some provision should be made to permit the railroad to get some advantage of subsequent increased economies in this respect.

Mr. Hill has mentioned the fact that peak loads occurring frequently at irregular and unpredictable times, tend to make the supplying by the utilities of such requirements somewhat difficult and relatively costly. This is no doubt true; on the other hand, however, demands of these characteristics may also increase the difficulty of generation by the railroad itself in an isolated plant, and such demands can often be handled more effectively by the utility having some diversity in load than by the railroad. If the railroad peak demands occur on off-peak times with reference to the utility's commercial load, the advantage is obvious in purchase of power as compared with production by the railroad, provided the utility will recognize the fact in preparing the contract.

Mr. Hill's tabulated statement indicating a load factor for suburban service (based on three maximum clock hours per month) of 33 to 34 per cent, would presumably be relatively considerably less if applied to an annual basis, on account of electric-heat requirements for suburban coaches. If the railroad is furnishing its own power, this would have to be recognized in the design of the power plant.

Mr. Hill has pointed out that where a substantial portion of the energy is generated in hydroelectric plants, a correction factor should be applied because of the high first cost and low operating cost of such plants. This thought might be expanded to permit the railroad to obtain the advantage of plentiful water in wet years, the power company, conversely, obtaining recognition of excess steam generation costs in unduly dry periods.

All things considered, as has been pointed out from time to time by the present commentator, it would seem logical in developing a contract for railroad power to so construct the contract that the power company would obtain its compensation as a return on the invested capital set aside for the railroad service, in the form of the demand charge, including interest (or dividends), depreciation, insurance, and other items which are not chargeable to operating expense; and not to expect any profit over and above this proper return on the invested capital in connection with the actual energy sold, but merely reimbursement to cover unit cost of operation per kilowatt-hour output of its plants. It might be thus specified that the power company would supply to the railroad each month a statement covering its actual operating costs and the kilowatt-hour output of its plants, and the railroad would pay exactly the production cost thus computed per kilowatt-hour. This would make unnecessary the inclusion of contingencies in cost which might never occur, and would take care of fluctuations in other items, such as fuel, labor, social security, and other taxes, etc., and both parties would be thus protected.

D. R. MacLeod (General Electric Company, Erie, Pa.): The papers by Messrs. Hill and Torchio on railway power supply are of very great importance, not only to the public utilities, but also to the railroads which will be electrified in the near future. The situation today is radically different from what it was 20 years ago, when steam locomotives were relatively inefficient. Great strides have been made by steam-locomotive designers in the past two decades, and today it is not unusual to hear operators quote figures which indicate that steam locomotives use approximately four pounds of coal to do the same work as one kilowatt-hour with an electric locomotive. Wide variations will be found in different applications and in different interpretations of what we mean by a steam locomotive doing the same work as an electric locomotive. Actually electric locomotives are in everyday service in this country which can do far more than any steam locomotive under certain conditions.

It is generally accepted that modern methods of generation can deliver one kilowatt-hour by burning one pound of coal. Thus from the standpoint of conservation of natural resources, electrification would save 75 per cent of the coal now consumed by the railroads. To accomplish this saving, great capital expenditures would have to be made. With present labor and material costs, only a fraction of the total railroad mileage would show any real saving if electrified. We have grown accustomed to the idea that the natural resources of the United States are inexhaustible, and therefore we must look to real savings, as understood in our present-day economy, for the justification of electrification.

After all the advantages of electrification are evaluated it is usually found that the cost of electric power should not be any greater than the cost of coal delivered on the tenders of steam locomotives. For the sake of this discussion we will assume that coal delivered to the tender of a locomotive costs the same as coal delivered to a power plant. If this is approximately true, the three pounds of coal which is saved per kilowatt-hour must pay for the capital, labor, and equipment cost of delivering the power to the railroad if we are to secure a balance between the cost of electric energy and the cost of fuel.

The tabulation given in Mr. Hill's paper gives a load factor of 62 per cent. While very few railroads would have a load factor as high as this, it will be used for this discussion. It may be assumed that the ratio of the average load to the maximum one-minute demand is of the order of 45 per cent, and that when due allowance is made for system growth, reserve power supply, unusual load demands, etc., that the installed capacity required may be at least three times the average load.

If coal costs 1.25 mills per pound and maintenance and wages on a plant enjoying a good load factor are taken as 0.75 mill per kilowatt-hour (*Electrical World*, October 9, 1937), the capital expense (including taxes, insurance, depreciation, and a fair return) must not exceed 3 mills per kilowatt-hour if the three pounds of coal that is saved is to pay for the cost of generation. With a capacity factor of $33^{1}/_{3}$ per cent the equipment required to deliver power to the railroad must cost between $70 and $90 per kilowatt.

These figures indicate that even with railroads having very dense traffic, such as the one considered by Mr. Hill, it is essential that the required generating capacity and the cost of that capacity be kept at a minimum. The situation is better in those regions where the cost of coal is high, but a number of railroads with fairly high traffic density are operating in regions where the cost of coal is lower than we have indicated.

Mr. Hill has called attention to the tremendous potential market which exists for power. His figures are a challenge to every power salesman to see what he can do to develop the market in his territory. Those of us who have lived with its development for a number of years are convinced that we have only seen the beginnings of railroad electrification. We are also convinced that this goal will not be achieved without effort on the part of the power companies interested in the sale of power and on the part of the railroads who wish to take advantage of the tremendous possibilities of electric traction.

The most obvious method of approach for the power companies is to work with the railroads in an effort to fit the railroad load cycle into their industrial and domestic load cycles so as to improve their system load factor. They may also consider means of reducing the capital expense of generation by locating plants near the load centers of the railroad.

The railroads can contribute by studying means of fitting their load cycle into that of the power company and of reducing the peaks in their power demand. A railroad is designed to move traffic, and therefore it is not possible to approach the ideal which would exist if trains could be made up and dispatched in accordance with the requirements of the power system. We will always have small trains with large trains and a somewhat random distribution of these trains. Improvements in the methods of handling trains in classification yards, in train dispatching, signaling, etc., have shown that it is possible to improve the load factor very appreciably while at the same time improving service.

H. F. Brown (New York, New Haven and Hartford Railroad Company, New Haven, Conn.): The transportation committee is to be congratulated on the number of valuable papers presented to the Institute at this convention. The papers of Mr. Hill and Mr. Torchio on power supply for railroad electrification are timely and worthy of careful consideration by both railroad and utility executives, in view of the national prominence now being given to the railroad problem. Both of these papers are very much in agreement in general, considering that one author presents his paper from the viewpoint of the railroads and the other from the viewpoint of the utilities. Both papers indicate that the cost of electric power for electrification is not one of the major reasons deterring the railroads from further electrification, and although it is possible that power costs for railway electrification may be somewhat further reduced, it is not clearly indicated that such reductions alone will result in a saving so pronounced as to encourage further investment in electrification by the railroads.

In spite of the more recent development and application of internal-combustion locomotives to the railroads, electrification is still the only solution for those particular railroad problems to which it has been applied during the past three decades, and no other form of motive power has been substituted for such electric operation. The electric locomotive is still the only form of motive power which does not have to haul its power plant around with it, and therefore can more readily handle traffic on grades. As both Mr. Hill and Mr. Torchio point out, operating savings alone are not the criterion of electrification advantages, and after a system has been electrified in part, the indirect savings may often outweigh the direct savings. Still greater proportional returns may be realized where specific conditions have already necessitated a partial electrification of a terminal, or part of a route, if such installations can be extended over enough mileage to utilize fully the investment in electric motive power, and to improve the power load factor. It would be of interest in this connection, to supplement the table shown in Mr. Hill's paper by one more column showing the average total unit cost of power for the various services operated, as this particular reference electrified system grew. It would doubtless show a distinct downward trend.

Electrification should be considered and adopted more in the light of what it will do to hold existing traffic and attract new traffic, such as was the case with air conditioning of passenger cars, rather than in the evaluation of its immediate and direct economies. Once adopted it has been demonstrated that it is one of the most flexible tools available to the transportation industry.

As to purchased power versus power from railroad-owned plants, there is still much to be said on both sides. Bulk electric power generated from steam stations may be said to consist of three important costs, each of which is surprisingly of about the same proportion, namely: one-third fixed charges, one-third fuel costs, and one-third other operating and maintenance costs. The larger the plant or system, the smaller the values which can be assigned to each of these three proportionate parts, but in general their range is within relatively narrow limits.

It is fair to assume that where power is purchased the vendor naturally must make a profit on the sale, as otherwise he would not be in business. Therefore, the railroads must weigh whether they can afford the capital to build smaller independent plants, and pay approximately the same unit cost for their own power as they would for purchased power from a larger system, which price includes the profit to the utility, and often, the cost of conversion to the type of electric power required. Total unit costs today vary between three-fourths of one cent to one cent per kilowatt-hour, and in the present state of the art there does not seem to be much prospect of greatly reducing these costs, either for railroad produced, or purchased power.

As Mr. Torchio points out, a utility, because of its expanding business, can afford to keep its power plants up to date with efficient modern generating equipment at increment investment costs which are soon amortized. If railroad electrification were to be considered as something to be started in a small way to relieve, for example, a terminal congestion, and slowly expanded to cover an entire important main route of considerable mileage, having important traffic, the question of power supply would be without doubt settled by (*A*) purchase where existing plants and interconnecting facilities would give the service with minimum investment charges, and by (*B*) railroad-owned plants interconnected with purchased power on parts of the route where such plants could be justified by a smaller total capital expenditure, with corresponding lower unit energy cost. Such railroad-owned plants could be developed with an increase in business, just as the utility plants are developed. To be sure, this requires a high degree of special technical skill, but this is as available to the railroads as it is to the utilities. An electrified railroad thus would become a quasi-electric utility in itself, (as did some of the former street and interurban railways) and oftentimes would be interconnected with other *defacto* electric utilities, and as such should be able to make more favorable interconnection and exchange rates, much as do the large interconnected electric companies themselves. Power contracts for such interchange of power should recognize the difference in production costs of off-peak versus peak power. Such power purchased by the railroads on this basis would be at a much more favorable rate where the electric-utility load factor was improved, than when the railroad demand added to the utility peak. A great deal could be accomplished in expert co-ordination of railroad-produced and utility-produced power under such conditions, with important savings to both producers and consumers.

The conclusions of both papers as to the future possibilities of electrification and the trend of electrification costs should be heartily endorsed by all railroad and utility electrical engineers.

F. A. Allner (Pennsylvania Water and Power Company, Baltimore, Md.): Mr. Hill's paper is a comprehensive review of the major economic aspects of the power-supply problem for trunk-line electrification of railroads comprising passenger and freight services over an extended area. From the point of view of a group of utilities that had co-operated with the author in the actual solution of this power-supply problem on a regional basis, it cannot be emphasized too strongly that because of its high investment cost, the whole power-supply system, from the source or sources of generation to the points of delivery at the step-down stations, should be planned for a minimum total capital expenditure by both the railroad and the utilities.

Especially in those regional power systems that comprise diversified sources of generation (hydro and steam), located in close proximity to the electrified trackage of the railroad, opportunities of various sorts will be found to effect over-all savings in investment cost, accompanied by other advantages such as economy in operation and greater reliability and flexibility of service. For example, it may be found advantageous to substitute in part for the conventional type of frequency-conversion equipment, direct single-phase generation; or, as pointed out by the author, portions of the railroad right of way may be used for transmission lines of the utility, or joint use by the utility of the railroad's electrification structures may be feasible. In that latter case, the same permanent structure on the railroad right of way supports the catenary construction, the railroad's single-phase transmission circuits, and a three-phase high-voltage circuit serving the dual purpose of large capacity tie line between load centers and of a power supply back-up for the frequency-changing equipment at or near the terminal point of the electrified zone.

However, no generalization should be drawn from the above example of joint use of right of way or structures as each case must be studied and solved under the specific conditions inherent to each problem. Thus, in the same electrified region in which the joint use of railroad structures was found advantageous along a certain straightway route between two large cities, along another route of approximately the same mileage, but the tracks hemmed in on one side by steep hills and on the other by a winding river, the very opposite solution was found preferable, namely, to limit the structures on the railroad's right of way merely to the support of the catenary construction and to let the utility erect the single-phase transmission circuits on a long-span tower line further back from the river over a newly acquired straight right of way through rural territory.

Characteristics of Load

Considerable experience is now available on the characteristics of railroad electrification load as described by the author and it may be of interest to engineers concerned in the planning of power supply for future electrification projects to hear a discussion in greater detail of some aspects of these load characteristics.

The average load factor for the whole electrified system of some 675 route miles is shown by the author as 62 per cent based on the average monthly billing demand calculated from the three maximum clock-hour power drafts but taken from separate days and, of course, excluding days when there were abnormal or emergency conditions. The author also estimates that this average load factor might have been of the order of 75 per cent if suburban electrification, consisting largely of commuters' traffic, were excluded. This trend for further improvement of load factor is well confirmed by the experience of that group of utilities that had been supplying the power for approximately 44 per cent of the electrified route miles of the system described by the author, an area which has only a negligible amount of suburban passenger traffic. In that area the average load factor calculated on the same basis as in the tabulation given in the paper in respect to the whole electrification, was 66.5 per cent during the year 1939. In that same area, also, in part at least, because of the negligible amount of suburban traffic handled by multiple-unit trains, the power factor of the single-phase supply measured at or near the terminals of the single-phase generators was relatively high, rarely dropping below 80 per cent and averaging in the neighborhood of 85 per cent. The other cause of the favorable power factor situation in that area, is the relatively large amount of leading-power-factor charging current contributed by a sizable mileage of high-voltage underground cables and overhead lines.

Utility engineers may also be interested in certain other aspects of electrification load that must be carefully considered in the planning for such power supply and in the successful carrying out of the operating task. In an electrified zone which has relatively little suburban traffic with its pronounced peaks occurring with clocklike regularity during commuting hours, the peak loads of the day as pointed out by the author frequently occur at irregular and unpredictable times. Nevertheless, taken over the year as a whole, the daily peaks occur most frequently during the hour or hours of the highest load demand of the utilities' other commercial load.

As pointed out by the author, fluctuations of load on short railroad electrifications are severe, but are described as not unduly severe where the railroad electrification is extensive and traffic is dense and composed of a large number of train units. Experience in the electrified area previously referred to confirms this statement in so far as it refers to load fluctuations expressed in per cent of clock-hour average. In the earlier period when the electrified zone was approximately one-half of the present, load swings frequently exceeded the one-hour integration by more than 100 per cent. As the electrified zone was extended, these load swings, while at times somewhat more severe in kilowatts, are now only about 40 per cent to 70 per cent of the one-hour average.

The variations of load above and below the one-hour average do not have the characteristics of a very sudden impact or dropping off as certain industrial loads of violently fluctuating character. Therefore, notwithstanding their greater magnitude, these load variations do not present a serious problem of voltage or frequency regulation, except in cases where a relatively small power system or the railroad's own plant would attempt to supply load requirements of this character. However, even in large regional power supply systems feeding an extensive electrification from several sources of supply, as described by the author, parallelism being maintained on the 60-cycle side as well as on the single-phase side at several points, these heavy fluctuations of railroad load create quite a problem for the proper control of power flow across the several tie lines or points of parallelism on the three-phase and single-phase side.

There is a gratifying diversity in daily energy requirements, as distinguished from peak-load requirements, of railroad electrification in respect to the occurrence of 24-hour heavy energy drafts of the other commercial loads of the utilities. Trunk-line electrification in an area with relatively little suburban traffic is a classical example of greater than average load on Sundays than on weekdays. What may be still more gratifying to utilities serving the average type of medium-size cities, including suburban and rural areas, is the fact that on the proverbially heavy Tuesdays of commercial load, the 24-hour energy requirements of railroad electrification are nearly at the lowest among the seven days of the week.

Disregarding the effect of holidays and other special events the seven days of the week, according to the average of daily energy requirements during the year 1939, range in the following sequence in respect to the 365 days average:

	Above Average +	Below Average −
Friday	6.6	
Saturday	6.1	
Thursday	2.5	
Sunday	1.9	
Wednesday		1.4
Tuesday		7.4
Monday		8.4

It should be pointed out, however, that there is no consistent relationship between heavy one-hour peaks of the week or the month and heavy 24-hour energy requirements. Large one-hour power drafts may fall on days of average or below average daily requirements and vice versa.

Power Contracts

With few exceptions, utility engineers will concur with the list of requirements expressed by the author in the concluding part of this paper as representing from the railroad company's point of view desirable features of power contracts.

These exceptions refer to the railroad's preference to purchase power on a straight kilowatt-hour basis rather than on the principle of fixed charges and energy cost. Such a move would be a distinct step backward and would be contrary to all trends during the several past decades in rate making and rules of regulatory bodies aimed at allocating to certain classes or groups of services those components of total power costs that may properly and correctly be allocated to any particular type of power supply.

In the case of railroad electrification loads, there are three elements of cost which can be identified and segregated from each other within relatively small margins of approximation. These three elements are, first, the cost of providing the prime-mover capacity for handling the railroad company's kilowatt demand of power; this will be a component of cost in the form of fixed charges more or less independent of the fluctuations in the amount of energy requirements of the railroad; then the cost of generation suitably expressed in a rate per kilowatt-hour, the dollar payment fluctuating in accordance with the amount of generation required for railroad purposes; and lastly, a third component of cost in the nature of fixed charges independent of the amount of railroad's load requirements in kilowatts or kilowatt-hours, namely, the carrying charges for various special equipment, such as frequency changers, single-phase substations, transmission lines, etc., which have been provided by the utilities exclusively for the purpose of serving the railroad and which are not suitable except to a very minor degree for any other use except that of serving the railroad electrification.

A brief analysis of the nature of these three components of power cost will suggest certain reasonable limits within which the utility may feel permitted to go to meet the railroad's wishes expressed by the author in regard to elimination of provisions on minimum demand or of guarantees of other payments to the power supplying agency. For example, compensation for carrying charges on special equipment not suitable for other than railroad uses cannot properly be allocated to other groups of ratepayers; on the other hand, the payment for energy, provided the unit rates stipulated in the contract are not intended to take care of any substantial element of fixed charges, may properly be expressed without restrictions as to minimum load factor to be paid for whether used or not; the power demand charges usually expressed in a certain rate per kilowatt may be permitted to vary within certain upper and lower limits subject to such limitations as to minimum payment over a given period that would be substantially less of a burden to the railroad than under conditions where the railroad itself would have provided its own generating equipment, and yet not too burdensome on the utility to the extent that it should be given the opportunity of a substantial time lag to permit the building up of load demand from its other commercial customers to make use of the generating capacity released by a sustained drop in the load demand of the railroad.

CONCLUSION

It is believed that there will be general concurrence with the author's conclusion that further extension of railroad electrification will in a large measure depend on the ability of both railroad and utilities to hold the combined capital expenditures necessary for the electrified service as a whole to a real minimum consistent with reliability of service and realization of the major advantages to be secured from electrification as described by the author. The cost of energy, that is, the running cost per kilowatt-hour has for some time past been at a relatively low level and any further reduction of this element of cost will probably appear of lesser importance than economies possible in capital cost for electrified service.

E. L. Harder (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): Referring to Mr. Hill's paper, I believe the cardinal principle to be emphasized is that the power supply system—railroad and utility—should be so planned as to involve the minimum total cost consistent with the requirements of the service.

With a complete system of railroad high-voltage transmission lines along all electrified tracks, the utility cost is certainly a minimum. The utility has the choice of generating at the railroad frequency and phase, for example, 25 cycles, single phase, or at 60 cycles, three phase, and converting. Or it may use a combination of these methods if that proves more economical in view of the 60-cycle and 25-cycle load factors. There is a wide choice in the selection of power-supply location. In fact, the utilities may even secure a certain amount of off-peak or emergency load-transfer ability over the 25-cycle lines. However, these high-voltage transmission lines are an important element of over-all cost of electrification.

Passing to the other extreme, complete elimination of 25-cycle transmission lines would require power generation or frequency changer locations at spacings not much greater than present-day substation spacings, if the present trolley voltages are used. Frequency-conversion units at the resulting spacing and load factor would be highly uneconomical and generating units even more so. That is, even though the 60-cycle systems had at smaller pro-rata cost entirely adequate interconnections to distribute the railroad load on the desired plants, the cost of numerous frequency changers at short spacings and poor load factors might prove uneconomical because of the increased cost of frequency changers as compared with transformers.

The 25-cycle lines along a railroad served two main functions:

1. To transmit large blocks of power from one area to another whenever required.
2. To distribute power to the substations.

Utility 60-cycle lines can supplant only the first function, and that only at the expense of more frequency-changer capacity. However with the bulk transmission function eliminated from the railroad the wayside system may be designed most economically to perform the single function of getting power from the supply points to the trains.

Somewhere between these two extremes lies a system in which, by co-ordinated design of the railway and utility facilities, a minimum over-all cost is obtained.

Railway electrification is one of the bright spots in engineering contributions to society. It makes the railroad faster, cleaner, more comfortable, more economical, and more effective. It is certainly to the interests of all concerned to determine the over-all arrangement of power-supply facilities that will result in the minimum cost of delivering power to the trains with the requisite reliability.

N. E. Funk (Philadelphia Electric Company, Philadelphia, Pa.): Mr. Hill has presented a fine paper discussing the major features relating to the supply of power for the electrification of steam railroads. I am in accord with most of what he says. There are, however, some items which I feel must be amplified to prevent the development of an erroneous impression.

Under "Cost of Electric Energy," Mr. Hill states that the trend in average cost per kilowatt-hour has been downward for practically every type of power supply except the electrification of steam railroads, and that the reduction in that case is due mainly to improved load factor or other special conditions.

Fundamentally, the decrease in rates of all types of service has been due to the change in conditions of supply; in the residential supply, particularly, due to a very large increase in use per customer. The rate for the supply of power to an individual large customer such as a steam railway, where practically the only facilities involved are those of generation and the bulk power system, is generally based upon an individual contract of long-term duration which is negotiated with the railroad, and in which the cost of supply over the period of the contract has been considered rather than the immediate costs at the date when the contract was first effective. Thus, the railroad has received all the advantage of rate reductions which it should expect from the beginning of the contract.

The material improvement in steam-generating-station efficiency has been to a material extent offset by the increasing cost of fuel. As an example, for my own company the total cost of fuel f. o. b. stations in 1916 was practically the same per ton as the cost of freight, alone, per ton in 1939.

The tremendous increase in size of turbines and boilers which tends to produce lower over-all power plant construction costs has been practically offset by increased costs of material and labor, so that the net result has not been any material reduction in total power-plant investment cost per kilowatt of capacity. Thus, the fundamental factors affecting the cost of bulk power supply have not been as favorably affected by increased use as have the local transmission and distribution facilities which supply other customers.

Under "Power Contracts", item *d*, Mr. Hill mentions that the railroads would like to purchase power on a flat or sliding-scale rate per kilowatt-hour. It is quite true that this would materially simplify a contract. Unfortunately, the costs of supplying power do not vary in such a simple manner, and it is impossible for me to see at present how any equitable arrangement between the railroad and the power company could be attained unless the rate for power supply is established on the basis of a demand and energy charge.

Under item *h*, Mr. Hill states that no guarantee of load factor should be required of the railroad, nor a minimum demand guarantee depending upon any percentage of the previously established maximum. Since all lasting contracts must be based on fair treatment of both parties, it is hard to see how Mr. Hill could expect to obtain arrangements of unified supply from several utilities and thus obtain diversity benefits and protection from loss of power supply at any locality while omitting these two factors.

If two or more companies are to supply power to the railroad at different points, it is quite essential that both be protected as to the load factor and load supplied, since their investments are based on these considerations. Without these features, the railroad could claim the right, and probably would, to shift the load between companies to its own best advantage, irrespective of the investment made by the supply companies based on the understanding that each was to obtain all the load in its own supply territory, and that the rates in the contract were definitely based upon that fact. Either a minimum load factor or some device to effect the same result should be a definite contractual understanding between the parties.

The railroad must spend large sums of money for electric transmission and transformation facilities and for motive-power equipment; the power company for production equipment.

With variations in load, the railroad company can hardly expect to eliminate the fixed charges on the investment made in its facilities, so there is therefore no reason why it should expect to eliminate the fixed charges of the power company from electrification costs.

A guaranteed minimum demand based upon either two-thirds or three-fourths of the previously-established maximum demand does relieve the railroad of from one-fourth to one-third of the power company's fixed charges for their electrification, while the railroad must continue to pay the full 100 per cent on the facilities which the railroad installed. It seems to me that it is unreasonable to ask for more.

One of the material advantages of purchased power from the railroad's point of view is that after a railroad has once been electrified, the rate of growth is relatively small, and for that reason there will be little necessity of physical additions to their power production plant. Thus, its economy is fixed with the original installation with little chance of betterment, while with purchased power, the production system continually increases in size with the development of other types of business, so that the railroad has a joint advantage of the improvement in production economy that results from the installation of new high-efficiency equipment to care for the increased growth of the total business of the power company.

E. R. Hill: The discussions which have been contributed by engineers representing the railroads, utilities, and electrical manufacturers have been constructive and most interesting.

With reference to the point raised by Mr. Withington, the load factor for suburban service only, expressed on an annual basis, was 28 to 30 per cent—being materially affected by the severity of winter weather.

The data given by Mr. Allner on nature of railroad load, days of the week in relation to daily energy averages, and the diversity in such occurrence with respect to the other general power load, all point toward the feasibility of working out a plan that should result in minimum payments by the railroads for power and energy furnished by the utilities.

Mr. Allner's suggestion regarding the introduction of a "time lag" in working down to more nearly normal a particularly high demand established during a period of great prosperity and heavy railroad traffic is well worth developing in detail in connection with future contracts.

Mr. Funk's explanation of the lack of a pronounced downward trend in the cost of power to railroads is interesting—it lends background to the preference expressed by the writer to provision for payments on a cost basis which should automatically reflect year by year any reductions in unit costs due to advances in the art, growth of customer load, and improvements in diversity. Mr. Funk appears to hold that an unusually high demand established in time of great prosperity and heavy traffic should remain the yardstick for payment of demand throughout the life of the contract, whereas, as above cited, Mr. Allner thinks that this should be gradually worked down by means of a suitable "time lag" in which the utility might build up its load demand from other customers to compensate for a drop in load demand of the railroad.

From the railroad viewpoint the main objection to the guarantee of a minimum demand, expressed as a percentage of a previously established maximum, is not because of normal seasonal variations in load but rather because of periodic business cycles, times of great prosperity, and pyramided railroad load (for handling which the utility has probably had insufficient time to provide more plant capacity) followed by times of great depression. Such depression cycles are a burden on all business and every kind of utility, including the railroads, and one group cannot fairly be asked to take its own punishment and in addition protect another group against loss of load or business. If the percentage is applied only to the maximum demand established during, say, the preceding 12 months the burdensome feature of such a clause would be largely eliminated.

Philip Torchio: The contributions of the various discussers of these two papers have been very interesting and show a widespread understanding of the fundamentals of the contractual relations between railroads and utilities, as well as the broad economic bases on which further progress in electrification rests. I think we all agree that the provisions of railway-electrification contracts must be worked out individually for any given case, and the papers and discussions indicate that both railroads and utilities are agreed on the principal elements of the power contract and the desirability of supplementary provisions covering those special considerations applicable to particular situations. Mr. Withington's suggestion of a "rental" charge plus an apportionment of operating expenses is, basically, the principle which has been followed in all current "demand and energy charge" contracts, and would be directly applicable if the utility property involved were devoted to the exclusive use of the railway or the railway's demand were constant. Unfortunately, such is rarely the case, and consequently the demand charge, which varies the "rental" according to the use made by the railway, will probably continue. In any case, it is apparent that, granting the incentive to electrify, no difficulty in formulating a mutually satisfactory contract exists.

On the larger question of the underlying economies of further electrification, it is gratifying to note a general recognition of the possibility that the relative operating costs, while a very important factor, may not be the true criterion of whether or not to electrify. Up to the present, the relative costs have apparently been the controlling factors, and little attention has been given to the indirect advantages of electrification. There is no serious question of the fact that the electrified road offers attractive possibilities for holding present business or expanding it in competition with other carriers, because of its many advantages of speed, flexibility, cleanliness, reliability, increased capacity, operating efficiency, etc. Mr. Hill's paper and Mr. Brown's comments both support me in this. Unfortunately, these factors are difficult to evaluate, and the tendency has been to disregard them.

But they do exist and must be evaluated before the true value of electrification can be demonstrated. Therefore, I cannot urge too strongly the necessity for continuous study and analysis of the relative economies of steam and electric traction in order to arrive at convincing and acceptable data. As long as we continue to *speculate* as to the indirect value of electrification, progress will continue to be hesitant and uncertain. It is only by a clear demonstration of the net results of all the direct and indirect advantages which are accruing to those roads which have electrified that the incentive for further projects, with great benefit to both railroads and public, will be provided.

Network Coupling by Means of Static Electronic Frequency Changers

Discussion and author's closure of paper 40-16 by Othmar K. Marti, presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940, and published in AIEE TRANSACTIONS, 1940 (September section) pages 495–503.

I. K. Dortort (Allis-Chalmers Manufacturing Company, Milwaukee, Wis.): Mr. Marti's paper recapitulates the development of static frequency changers. Much has already been written on this subject, pioneering installations have been made, and there can be little doubt that the near future will see an expansion in this field.

One factor which will probably cause a great deal of misunderstanding among engineers not familiar with this subject is the effect of the single-phase load on the three-phase supply system. Besides the difficulties inherent in the analytical solution of this problem, there are and will be additional difficulties due to lack of agreement on terminology and the loose use of terms originally designed to cover narrowly limited quantities, now expanded far beyond their original meaning.

One of the chief victims in this respect is the term "power factor". Originally this term was applied to sinusoidal voltages and currents, and is generally used to designate synonymously the ratio of watts to volt-amperes, and cos ϕ. As a matter of fact, these definitions have been under fire for a long time and now the situation is still further complicated by the advent of the static frequency changer.

As pointed out in the paper, power pulsations of the single-phase load may be reflected in part or in whole in the three-phase supply. Ammeters in the supply line will measure the rms value of the current integrated over a complete cycle of the low-frequency system, as this current will consist of a 60-cycle fundamental modulated at the lower frequency. This current will, of course, have in-phase and reactive components, to say nothing of the distortion caused by normal rectifier operation. The question is, then, how shall we define the power factor of such a system? It would appear that the term "power factor", if used at all, should be used only in its broadest sense, namely, ratio of real to apparent power.

Two additional complications must be included. The first one applies to frequency-changer systems having an integral frequency ratio. In this case, the three line currents will not be equal, and the in-phase and reactive components of the three phases will therefore be unequal. The second complication can arise in certain systems in which a reactive single-phase load will not only cause fluctuation of the three-phase power, but may actually cause reversal of power flow. This reversed flow takes place not twice in each 60-cycle period, but twice in each low-frequency period.

A rational attempt to define, segregate, and evaluate some of these quantities appears in an article by Doctor R. Feinberg, published in the October 1939 issue of the *Journal* of the Institution of Electrical Engineers of Great Britain. Doctor Feinberg makes use of the term "efficiency factor", defining it as the ratio of "active power" to "mean apparent power". It is equal to the product of the "fundamental wave factor" and the "displacement factor", cos ϕ. This product, as well as its component parts, may not stand rigorous analysis, but a logical means of comparison is provided.

The term "efficiency factor" may cause some trouble. It is used in the same sense that "load factor" is used for daily load cycles, but applies actually to the average loading over a fraction of a second. The term "loading factor" might be applied here with less confusion.

There are two more points that need to be stressed. The statement is frequently made that a certain system can transmit reactive power. It is not really that simple, since it will seldom occur that the power factor or, let us say, displacement factor of the load and supply will be the same. As Mr. Marti has pointed out, at least in some systems the reactive kilovolt-amperes of the load will be taken care of by power pulsations and distortions on the primary side, and there is no simple relationship that can be applied generally.

The other point I wish to make concerns the misunderstanding, or perhaps misinterpretation of the term "leading-power-factor load". One of the systems described in this paper includes a rectifier and an inverter with a d-c link between them. The statement is frequently made that an inverter or frequency changer of this type can supply only a leading-power-factor load. To those familiar with the subject it may seem strange that anyone can misunderstand this statement. Nevertheless, it has been the cause of some confusion. The suggestion was actually made that a frequency changer of this type be employed to correct the power factor of a network. The line of thought must have been something like this: "The inverter can supply only leading power factor and, when connected to a network, will operate at leading power factor. It will therefore improve the power factor of that system." The confusion, of course, is due to a failure to appreciate the direction of power flow. If the inverter can supply only leading-power-factor load the system to which it is connected must supply reactive power to the inverter, and the power factor of the system is therefore decreased and not increased.

D. R. MacLeod (General Electric Company, Erie, Pa.): The rapid development of the multianode grid-controlled mercury-arc rectifier, during the last decade, for d-c conversion applications has been accompanied by intensive investigation of the frequency-changing schemes discussed by Mr. Marti, besides others suggested by our own engineers and by foreign investigators. The use of the grid to control the voltage of a d-c rectifier opened up a new field of investigation and presented new problems for the designer. In the last 15 years a great deal has been learned of the effect of the circuit on the performance of the rectifier and many other factors which govern the performance of a rectifier. The fund of knowledge which we have accumulated will enable designers to produce electronic frequency changers for applications in which technical and economic considerations warrant their selection. New circuits will undoubtedly be developed which will have advantages not possessed by those which have been investigated, and it is hoped that this discussion will be of some assistance in developing them. The discussion is limited to the three-phase to single-phase frequency changers, which would be used to supply power to 25-cycle railway electrification, in the United States.

About six years ago one of the power companies became interested in the work which we were doing in developing electronic frequency changers which might be used to supply power for a single-phase 25-cycle railway electrification. After considerable investigation it was decided that in the present state of the art the electronic device would be higher in cost and did not offer sufficient compensating advantages over the rotating frequency changer to justify its application. In our opinion the situation is essentially the same today in spite of the fact that great improvements have been made in the art and the single-anode ignitor type of unit has entered the picture in the interval.

The most obvious advantage of the electronic frequency changer is the elimination of heavy moving parts and the special foundations which these require. In place of these we have electrical equivalents such as capacitors and reactors, and it becomes a question whether the cost of one offsets the cost of the other.

Mr. Marti claims an advantage in efficiency for the electronic frequency changer, and this claim is well founded when comparing 5,000-kw sets as shown by his figure 11. In major railroad electrifications, large frequency changers are used. The paper does not hold out any hope for an improvement in efficiency of electronic frequency changers as their sizes increase. We assume, therefore, that in the present state of the art, electronic frequency changers three to eight times the size of the one discussed by Mr. Marti and using the circuit which he advocates will have an efficiency of approximately 90 per cent at full load, 93 per cent efficiency at 60 per cent load, and 85 per cent efficiency at 25 per cent load, as shown by his figure 11. Contrasting with this, the efficiency of the motor-generator type of converter increases as the size increases. For example, the 42,900-kva three-phase 60-cycle to single-phase 25-cycle motor generator sets supplying a railway system in this country have an efficiency of 94.5 per cent at full load, 94 per cent at 60 per cent load, and 89.5 per cent at 25 per cent load. Even the 21,500-kva sets show better efficiencies than those indicated by Mr. Marti's curve. The reason for this disappointing showing is that the rectifier loses its essential simplicity when used in a frequency-changer circuit and the consequent losses nullify the advantage which the rectifier has in d-c work. It is our hope that the efficiency curve shown by Mr. Marti will be improved as the art develops. In one analysis made by our engineers the efficiency of electronic frequency changer worked out about two per cent higher than shown by Mr. Marti. It is nevertheless doubtful whether significant improvement can be shown over the efficiencies of large rotating frequency changers in the present state of the art when all the losses are properly compared. The sets operate at high load factor so that loads below 25 per cent of the rating seldom occur for any appreciable length of time. The expectation of an advantage in efficiency has not yet been realized.

Another hoped-for advantage is that the grid control may be used to shut off the flow of short-circuit current. Tests on d-c rectifiers and experience in the field have shown that arc suppression by grid control is a valuable means of reducing the duty on circuit interrupting equipment but that they cannot be depended upon to the exclusion of conventional circuit-interrupting devices. Even when arc-suppression devices are developed to the point where they have the same reliability as conventional circuit-interrupting devices it will be found that circuit breakers will be required to clear certain faults that cannot be handled by the grid control.

A disadvantage of all electronic circuits is that transformer equipment is required to give the necessary number of phases. A rotating frequency changer on the other hand may be connected directly to the three-phase bus as the large sets are usually located in generating stations. This leads to some question in our minds in regard to space requirements. If existing designs of rectifiers are used, we would expect the electronic frequency changer with its auxiliary equipment to occupy more space than one large 42,900-kva rotating-type frequency changer with its starting equipment. The reverse is true in the case of the small equipments discussed by Mr. Marti.

One of the principal disadvantages of the electronic frequency changer is its inherently poor wave shape. On the 25-cycle side this will cause inferior commutation on the series motors, with the result that the locomotive ratings in tonnage which they can haul would have to be reduced appreciably. On the 60-cycle side the poor wave form will cause severe losses in the alternators due to the fractional harmonics due to the pulsating nature of the single-phase load. It would probably be necessary to use amortisseur windings on the turboalternators with any economical design of filter circuit.

When frequency changers are used to supply power to 25-cycle single-phase railway systems, consideration must be given to the fact that the railroad's transmission and distribution is in effect a tie line between parts of the same system or between systems which are tied together by 60-cycle lines. The performance of the frequency changers and the associated 25-cycle tie line must be studied in relation to the remainder of the 60-cycle systems of which they are a part. In some cases it may be desirable to limit the power that may be transmitted through frequency changer sets and variable-ratio units are used which limit the power that can be transmitted through the set within the range of frequencies for which it is designed. In some systems synchronous equipments are used and the sets are free to transmit power in accordance with the difference in phase between the two ends of the 25-cycle tie. They are then able to help hold the 60-cycle systems (or part of the same system) in step, assuming that their ratings are adequate for this purpose. Even in the case of large single-phase systems the ultimate result may be worse with the rigid tie than with the variable-ratio tie, and only careful analysis of the actual systems will show which to use. Either the electronic or variable-ratio rotating-type of frequency-changer set will permit power to flow to the 25-cycle system, even though parts of the 60-cycle system are not tied together. This is a definite advantage of this type of equipment, but it is not apparent that the single-phase electronic frequency changers discussed in this paper would have any great advantage over the rotating type which they would replace.

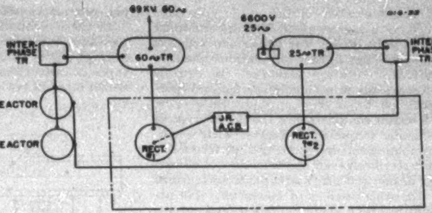

Figure 2. Schematic diagram of main connections, electronic frequency converter

A rotating type of frequency changer delivers the reactive kilovolt-amperes required to transmit blocks of power at nearly constant voltage in a 25-cycle single-phase transmission line and the reactive kilovolt-amperes required by the series type of motor. This is accomplished by means of the field on the single-phase generator under the control of a voltage regulator. The portion of the reactive output handled by each set may be varied by means of the phase shifter. The automatic control of the reactive in accordance with the instantaneous requirements of the 25-cycle system is an important advantage of the rotating-type frequency-changer set which does not appear to have a satisfactory equivalent in the electronic device.

In a companion discussion A. G. Darling discusses the three-phase to three-phase electronic frequency changer and compares them with conventional types.

A. G. Darling (nonmember; General Electric Company, Schenectady, N. Y.): The paper by Mr. Marti describes various means of obtaining frequency conversion using electronic types of converters, and discusses applications of electronic converters to transportation systems.

Transportation-system use of frequencies differing from the usual 60-cycle frequency, in this continent, offers a moderate field for converters. The single-phase transportation system, as contrasted with the three-phase industrial and public-utility system, involves some characteristics and solutions peculiar to itself. When electronic frequency conversion is contemplated for the single-phase system, solutions of the pulsating current, real and reactive, must be found so that the reflections on the three-phase system will not be objectionable. Still another field for frequency conversion, possibly found more frequently, is that of the industrial plant and other power systems which, for one reason or another, have found, and are likely to continue to find, need for electrical conversion ties between their own and other frequency systems.

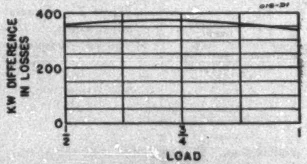

Figure 1. Kilowatt difference in losses in favor of electronic as compared with Scherbius frequency-converter sets of 10,000-kw output, 25 to 60 cycles

The progress made in the design and successful operation of mercury-arc rectifiers is sufficient reason for considering their use as frequency converters. Their relatively high efficiency and low cost of housing tend to offset their lagging reactive current.

Some system ties can be at fixed frequency ratios while others appear to require variable-ratio frequency converters whose load transfer can be adjusted at the converter.

Of the various a-c types of converters using a mechanical link, the Kraemer and the Scherbius are the conventional varieties which are capable of varying their frequency ratio and therefore are capable of keeping the normal load transfer under control. Still another possibility which considers present and future uses for power and equipment consists in converting alternating to direct current and direct to alternating current of another frequency. Many industrial plants have large investments in constant-potential d-c utilization equipment and means of obtaining direct current from a-c sources. Continued use of the present a-c to d-c conversion equipment is the objective in frequency conversion of this order. Additions of d-c to a-c conversion equipment to complete the circuit to the second-frequency power is the next consequence. With the d-c machines paralleled, power may flow from either frequency to d-c load or to the opposite frequency, or to both simultaneously. This method, while expensive in initial investment and less efficient in operation than other systems considered herein, has the distinct advantage of permitting salvage of a large part of the initial-frequency to d-c and second-frequency to d-c conversion equipment as the necessity for continuation of either frequency diminishes. Motor generator sets, synchronous converters and inverters, as well as mercury-arc rectifiers and inverters, all of suitable direct voltage for plant use, are the several means of making possible this type of conversion while supplying d-c plant load.

The mercury-arc rectifier and inverter, when used in the circuit illustrated in figure 2 of this discussion, gives the designer the opportunity to select that voltage of d-c tie which best suits the conditions to be met. For economy and efficiency of the frequency changer, a voltage will be chosen, which, in general, will be much higher than in common use in industrial plants—say 1,500 volts or somewhat higher. This type of electronic converter has been used to compare with a Scherbius set as given in later paragraphs.

The industrial plant offers an ideal location for the electronic converter to interconnect parts of its system or with the system of a public utilities. The variable nature of the industrial plant load from low valleys to high peaks at rapid rates of change suit

Table I. Comparison of 10,000-Kw Frequency Converters, Electronic Versus Scherbius Type

	Electronic	Scherbius
Normal operation		
Motor, input	3 phases, 25 cycles, 6,900 volts	3 phases, 25 cycles, 6,900 volts
Power factor	0.88 underexcited	1.0
Generator output	10,000 kw, 3 phases, 60 cycles, 69,000 volts	10,000 kw, 3 phases, 60 cycles, 69,000 volts
Reactive kva	5,250 kva underexcited	7,500 kva overexcited
Permissible 25-cycle frequency variation	1¹/₄ cycles from 25 cycles	1 cycle from 25 cycles
Maximum loads (per cent)		
One minute	200	200
Momentary	225	200
Frequency ratio without regulation of frequency-changer ratio	Fixed 25/60	Will change with load 25/60 at no load to 25.35/60 at full load
Reversed operation		
Motor, input	3 phases, 60 cycles, 69,000 volts	3 phases, 60 cycles, 69,000 volts
Power factor	0.88 underexcited	0.88 overexcited
Generator output	10,000 kw, 3 phases, 25 cycles, 6,900 volts	10,000 kw, 3 phases, 25 cycles, 6,900 volts
Reactive kva	5,250 kva underexcited	3,300 kva overexcited
Permissible 25-cycle frequency-variation	1¹/₄ cycles from 25 cycles	1 cycle from 25 cycles
Isolated-operation capacity		
Stub feed 60 cycles	None	10,000 kw, 0.8 power factor overexcited
Stub feed 25 cycles	None	None

the characteristics of the static converter which has a high overload capacity and small loss at light load. The equipment requires less space and lighter foundations than an equivalent rotating machine. It can be automatically or manually started and operated.

A recent comparison of the d-c tie type of electronic frequency converter with a synchronous-Scherbius rotating-type frequency converter brings out certain points of advantage in one and other advantageous features of the other variety of converter. No attempt has been made to draw a final conclusion since local economic as well as operating factors must be included to obtain the final answer.

The general requirement to be met by the equipment under comparison for this case was the conversion, under load control, of power from one frequency to power of the second frequency and in reversible directions without break in continuity of service. The details of normal and reversed operation are given in table I.

A comparison of the losses of the two types is distinctly in favor of the electronic converter giving a difference of 7 per cent of the one-half load output, 5 per cent of the three-fourths load output, and 3.4 per cent of the full load output to assist in justifying the use of the electronic type. Figure 1 of this discussion illustrates the difference in losses.

Installation arrangements and housing will vary with local conditions and with personal preferences. However, the cost of installation arrangements and housing for the two types of converters should be comparative for equivalent specifications. One specification, illustrated in figures 3 and 4, was selected for comparison. In this specification, main transformers, reactors, and 60-cycle high-voltage switching were to be installed outdoors on suitable foundations and with transfer tracks and trucks for transformers. The 60-cycle high-voltage switching is not illustrated in these figures, but would be identical for both types of converters. Approximately 1,400 square feet more space is required for outdoor apparatus for the electronic type than for the outdoor apparatus for the Scherbius type. All other apparatus and equipment was housed with foundations, cooling arrangements, switchgear, control, station service power, crane for heaviest parts, oil storage tanks, pumps, and installation material. For the electronic converter, housed floor space came to 2,400 square feet on one elevation, while 7,800 square feet on two floors was required for the Scherbius set. The crane rail in the building used to house apparatus was 18 feet in height for the electronic set and 44 feet for the Scherbius set.

Considering the cost of apparatus and installation material, installed, connected, and housed as planned, the electronic set is estimated to cost in this case 10 per cent more than the Scherbius set.

Many of the more recent installations of rotating frequency converters have been of the so-called "outdoor" type which includes a sheet-metal housing for the converter. Cranes are sometimes omitted. If a comparison of relative installed, housed costs of the electronic and Scherbius converters were made on the basis of "outdoor" designs, the difference in cost would favor the Scherbius type by a much larger amount than the 10 per cent mentioned for the "housed" types.

In these comparisons no effort was made to evaluate the effect of the reactive component of power input and output of the two types of converters. This again is a factor which must be reviewed in the light of local conditions. One system may have an excess of overexcited machines and another a deficiency. The cost of adding capacity to correct the lagging component of the electronic set will have a material bearing on its selection inasmuch as the cost of purely corrective capacity is relatively high. For certain surrounding conditions, the wave shape of the electronic set may need correction. The cost of improving the wave shape, like the cost of adding power-factor correction, should be investigated to draw a conclusion. It is expected that the operating and maintenance costs of the two types (not including cost of losses) will be approximately equal.

Figure 3. General arrangement, 10,000-kw frequency changer

Mercury-arc rectifier and inverter

With equal fuel cost, 25-cycle power is more expensive to generate than 60-cycle power; 60-cycle apparatus is more available than apparatus for other frequencies. There are so few speeds obtainable with greater economy at 25 cycles than at 60 that the over-all cost of drives from 60-cycle source is less, in general, than from 25-cycle sources. For these reasons there is a tendency to discontinue the use of 25-cycle industrial power and substitute 60-cycle power. Interconnection of power sources often is advantageous at equal as well as at odd frequencies. These several factors draw attention to the types of frequency-converting equipments that are at present available. Without prejudice toward one or another type, the conclusion reached from various investigations and a review of the design, reliability, as well as purchase cost and operating cost, leads to the conclusion that the electronic converter has many merits deserving consideration in comparison with several points of advantage obtainable in the rotating converter for use in three-phase to three-phase frequency conversion.

Scherbius motor generator set

W. S. H. Hamilton (New York Central Railroad, New York): The writer was very much interested in the presentation and discussion of this paper and also in those by Messrs. Torchio and Hill (Transactions, pages 530–3 and 560–2) which were presented at the same session covering a closely related subject. The discussion of those two papers especially brought out the need for keeping the total investment for the supply of railway power to a minimum regardless of whether this is financed by the power company or the railroad company, in order to secure the minimum over-all cost of power.

Mr. Marti's paper deals with a phase of this same subject and a very interesting one, namely the possibility of securing 25-cycle single-phase power from a 60-cycle three-phase system at good efficiency and by static conversion.

It seems to me, however, that more emphasis has been placed in recent years on the single-phase 25-cycle trolley and its related transmission lines than is really justified by the facts. By using 3,000 volts direct current on the trolley, the power-supply problems for both the power companies and railroads are greatly simplified, inasmuch as this system uses static rectifiers operated from three-phase, 60-cycle commercial power systems and no special railroad transmission lines are necessary, except in those localities where the power companies have no adequate tie lines of their own. Such cases are quite scarce now.

It would seem to me that a further study of the 3,000-volt d-c system especially by the power companies might indicate the advantages of this system of electrification more forcibly than they appear to have been brought out at the present time.

Also in this connection the possibility of a high-voltage 60-cycle single-phase trolley system should not be lost sight of. The Electric Railway Traction Supplement to the *Railway Gazette* (London, England) for December 8, 1939, gives an interesting description of a locomotive for such a system which is under development in Russia at the present time. It is of course too early to discuss the probable economics of such a system but it can well be given further consideration.

A. Schmidt, Jr. (General Electric Company, Schenectady, N. Y.): Mr. Marti has made a timely contribution to the literature in this country regarding the use of electronic devices in static frequency changers. Several equipments are already in operation in this country.

The first static thermionic frequency changer built by the General Electric Company is a 300-kva 60-cycle three-phase to

$25{}^{5}/{}_{7}$-cycle two-phase unit, built for the New York Shipbuilding Corporation in 1934 and described in Electrical Engineering, October 1935. This is a fixed-ratio type of frequency changer with no d-c reactor. The number of anodes firing in each half-cycle is the same, but the firing position of an anode changes in successive one-half cycles, consequently there is no low-frequency pulsation in the output voltage and anode duty is uniform. With this circuit reactive power is supplied by the 60-cycle system to the load. An output frequency of 25 cycles with similar anode duty would require a five-phase 60-cycle transformer. Grid control is through 60-cycle saturable grid transformers, saturated periodically through a thyratron-controlled $25{}^{5}/{}_{7}$-cycle saturating circuit.

In 1936 a d-c link type of frequency changer was installed between a 40-cycle power source in Mechanicville, N. Y., and a 60-cycle system in Schenectady, 17 miles away. This is the first d-c transmission system of commercial size in America. Power up to 5,250 kw is transmitted at 30,000 volts direct current. A total of over 86,000,000 kilowatt-hours have been transmitted to date. The combination of separate rectifier and inverter, with d-c link, results in wave forms in both a-c circuits having minimum interference factors for a given number of anodes.

More recently, a model-size frequency changer has been built and operated in a textile mill, where a variable-frequency output of 100–210 cycles is needed. No intermediate d-c link is employed in this circuit. Reactive power is supplied by static capacitors and electronic voltage-regulating means are provided.

It may be noted that there is a choice between, on the one hand, the d-c transmission type of frequency changer with separate rectifier and inverter and a d-c link which may be feet instead of miles in length, and on the other hand, a composite type of circuit with no d-c link. The designer must weigh the relative advantages of the two circuits. The total number of anodes is the same for given current wave forms. The d-c transmission unit requires two anodes in series, with resultant higher losses than the composite circuit. On the other hand, the composite circuit requires more complicated transformer construction and grid circuits which combine control functions at both frequencies.

While this is a recent application of a power-converting device which has comparatively recently reached its majority, the reliability of the mercury-arc rectifier merits its consideration in this field. As a measure of its acceptance as a power-converting device, it may be noted that the present world installed capacity of rectifiers exceeds ten per cent of the installed generating capacity in the United States.

Sidney Withington (New York, New Haven and Hartford Railroad Company, New Haven, Conn.): Mr. Marti's paper is very stimulating and opportunity is taken, from a railroad viewpoint, to emphasize some of the advantages which he has mentioned in the development of the static frequency changer for railroad power supply. The motor-generator frequency-changers which, for economic reasons, are installed in large capacities in concentrated substations for railroad electrification, make necessary the installation of transmission facilities along railroad right of way. In some cases these railroad transmission circuits would be obviated by the installation of apparatus described by Mr. Marti, which, in relatively small units, might be installed outdoors at convenient points wherever the railroad right of way is crossed by 60-cycle circuits. These static substations would presumably be operated automatically or by supervisory control of a simple nature.

A not unimportant feature of the electronic device described is as an interrupter of fault currents by means of manipulation of grid excitation, to which Mr. Marti calls attention. This might well make unnecessary high-capacity circuit breakers which represent one of the costly items in substations serving railroad traction circuits. The savings thus made might well be credited to the electronic device.

It is recognized that much development remains to be done before it can be said that the static frequency changer is commercially practicable from all points of view; nevertheless, it may be said somewhat definitely, I believe, that if such apparatus can be developed it may constitute a deciding factor in some individual electrification project. It is to be hoped that efforts will be continued and that the practicability of such apparatus will be demonstrated, as was the case 12 or 15 years ago with mercury-arc rectifiers applied to railroad traction.

O. K. Marti: I was indeed very glad that my paper brought forth the release of such valuable studies as contributed by Mr. Darling. The table showing the comparison of a 10,000-kw frequency converter (electronic versus Scherbius types) and the layouts of such stations are highly instructive. It may be well to point out in this connection that a three-phase electronic converter could be employed which would permit full freedom of frequency variation in either system. This may be kept in mind when studying table I of Mr. Darling's discussion.

In considering Mr. MacLeod's discussion, referring to efficiencies of rotating versus electronic converters, it must be kept in mind as Mr. Withington pointed out in his comments that electronic sets of small capacity as proposed in my paper could be located along the railroad right of way, being automatically controlled, etc. This might partially or completely eliminate the 25-cycle transmission line along the railroad track. If large converter equipment of the order of 40,000 kva, for instance, as mentioned by Mr. MacLeod, is used, then it is necessary to step up power and transmit it over a 25-cycle system, stepping it down again to be fed to the trolley system, and this, as can easily be seen, involves additional losses. It would have been interesting, therefore, if Mr. MacLeod, in order to arrive at a fair comparison of both systems, would have enumerated the total losses and not only referred to the partial losses, namely of the rotating converter.

Extensive investigations in Europe have shown, contrary to the assumption of Mr. MacLeod, that the wave shape did not affect the commutation of series railway motors nor did it increase the losses in the three-phase alternators, including the power pulsations, more than it does in a single-phase generator of a present rotating converter.

"Excitron" Mercury-Arc Rectifiers

Discussion and author's closure of paper 40-74 by O. K. Marti, presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940, and published in AIEE TRANSACTIONS, 1940, pages 927–31.

G. F. Jones (nonmember; Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): Mr. Marti has given an interesting description of the Excitron. He has also made several statements about the ignitron which we believe he would not have made had he been more familiar with its construction and operation.

The single-anode tank rectifier is of course not new. The ignitron rectifier has been under development for eight years. It has been in commercial operation for over three years. A paper describing it was presented during the 1939 winter convention and was published in the 1939 AIEE Transactions, December section. In view of the present paper it is most interesting to note Mr. Marti's discussion of the paper referred to.

The method of ignitron ignition shown in figure 2 of Mr. Marti's paper has been obsolete for several years. A choice of schemes using either thyratron tubes and capacitors or an impulsing generator is available. Neither method of firing is dependent upon the power-circuit conditions. The firing impulses, which are peaked in nature, are accurately controlled for time and power input to the ignitors. Positive pickup is assured, and, contrary to Mr. Marti's statement, delayed firing does not exist. The losses of either system are small.

The adverse effects of an anode misfiring are exaggerated. In regular commercial electrochemical service, one anode has been taken out of service for 24 hours. With the remaining anodes carrying full load, normal service was maintained with only slight transformer temperature rise and without any surging. During this unusual operation, the harmonics are increased.

The need for a cathode insulator for the ignitron rectifier has been very definitely eliminated. Except experimentally, it has never been used. The need for a cathode insulator for a continuously excited rectifier is just as definitely established. While vacuum seals are reliable, it is desirable to keep them to a minimum. Large-sized insulating seals are a difficult problem. The cathode insulator in particular should be eliminated. It is located in a vulnerable position; that is, adjacent to the heat of the cathode spot. The number of vacuum seals used in the present Excitron design is 50 per cent greater than for the ignitron.

The excitation arc for any type of rectifier must supply sufficient ionization to ensure reliable pick up of the main anodes. This ionization is sufficient to cause a high arc-back rate unless deionization is accomplished during the negative half cycle by shields and grids or by extinction of the ionization source. A figure showing a complete cross section of an Excitron would have been of interest. We believe it would show additional baffles in the arc path. Some, not shown, are mentioned in the paper. "The ignition and excitation anodes are arranged and shielded in such a way that little ionization is added to the residual holding over during the negative voltage period." Figure 6 shows a rapid increase in arc drop with increase of load. This rate of arc drop increase is comparable to that of a conventional sectionalized rectifier of similar rating. The increase in arc drop from 2,000 to 4,000 amperes is three volts. For the ignitron the comparable figure is approximately 50 per cent of this value.

Based on our experience with single-anode rectifiers and the results of extensive testing we question whether the arc drop values given in figure 6 can be obtained in a rectifier having the freedom from arc back required for commercial service. Similar low arc-drop values have been obtained from experimental ignitrons. However, the arc drop of the ignitron, suitably designed to ensure reliable operation, is somewhat higher than the values given by the curve. At the same time, the efficiency of the ignitron, for the conditions specified in the paper, is several per cent higher than the efficiencies given for the Excitron. The information is not consistent.

The Excitron excitation circuits and apparatus shown in figure 5 are not complete. The starting anodes with their d-c source consisting of transformers, Rectoxes, and control relays or equivalent equipment are not shown. The paper lists and the figure shows only a simple transformer. If the additional devices necessary had been shown, it would be apparent that the excitation system is quite complicated and that there are many moving parts requiring maintenance. It might be pointed out that the circuit shown is not operable. There is no provision for maintaining the excitation arc, from the single-phase source, through the zero-voltage period. The individual excitation circuits are subject to failure due to apparatus faults and arc instability. This of course would give rise to misfiring of the associated main anodes. While we do not believe this is of much consequence, Mr. Marti regards this operation as a hazard. Are there any precautionary measures taken?

According to records available to us, there have been approximately 40 power rectifier units, having a combined capacity of 140,000 kw, purchased during the past 12 months. Of these units, 36 are ignitrons with a combined capacity in excess of 130,000 kw.

H. C. Myers (nonmember; Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): The writer would like to call attention to figures 2 and 3 of Mr. Marti's paper. Here are illustrated a diagram of connections for a six-phase ignitron rectifier with a diametrical six-phase connection, and the corresponding voltage wave form when one ignitron fails to carry load.

It has been the practice of the company which originated the ignitron type of rectifier to operate power rectifiers in multiples of three-phase groups. With this method of operation, the direct voltage produced by the rectifier appears quite different from that produced by a diametrical six-phase rectifier when one anode fails to carry load. The writer has drawn a curve to illustrate this condition (figure 1 of this discussion). It will be noticed the disturbance to the voltage output is relatively unimportant compared to the case of the diametrical six-phase-connected rectifier.

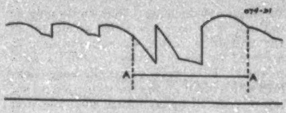

Figure 1. Diagram of voltage wave of double three-phase rectifier

Section *A-A* indicates wave form when one anode fails to pick up load

The writer has conducted tests on rotating machines of the series-motor type when operated from double-three-phase-connected ignitron rectifiers in which one ignitron was deliberately prevented from carrying load. The quality of commutation observed was very good with either six-anode or five-anode operation, the difference being of very small degree.

Joseph Slepian (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): The major conclusion towards which the author seems to strive is apparently the first sentence in his closing section labeled "Conclusion". "From the above it may be seen that a single-anode mercury-arc rectifier having continuous excitation can be just as reliable and free from backfires as a rectifier with intermittent ignition". However, nowhere in the paper are any figures given for the backfire rate for either type of single-anode rectifier.

During the course of the development of the ignitron rectifier at the Westinghouse company the question as to whether similar results could not be obtained with continuous excitation was repeatedly raised. At at least three stages in the development this question was put to experimental test.

At the very beginning, before the discovery of the ignitor principle, it was attempted to run single-anode tubes with unshielded anodes close to the mercury with continuous cathode arc excitation. For currents of even less than 50 amperes and with less than 300 volts, this proved quite impossible. The arcback rate was many times per hour. But as soon as intermittent excitation was tried, successful operation was obtained. In fact one of the first commercial ignitron rectifiers, installed in coal-mine service at Union Collieries, Pittsburgh, three years ago, is of just this simple type and has been operating at rated load of 167 amperes per anode at 275 volts with no arcbacks reported during that period.

To carry larger powers, even with the ignitron, so far it has been found necessary to interpose baffles and shields between anode and mercury. When a structure was developed in the laboratory which was suitable for 400 amperes per anode at 600 volts, it was felt necessary again to check whether continuous excitation might not give results as good as intermittent excitation. The same tubes were used in the two tests. For the continuous excitation, direct current was applied to the ignitor terminals and a continuous arc was maintained, the ignitor upper terminal serving as excitation anode. When sufficient continuous excitation current, about 20 amperes, was used so as to insure stability of the arc, and reliable pick up of the main anode, six arcbacks in a single day were obtained, with currents not over 300 amperes. But with intermittent excitation a laboratory run of three days did not give a single backfire.

I do not want to appear dogmatic and say that satisfactory single-anode rectifiers with continuous excitation cannot be made. However, I do wish the author had given some figures for the arcback rate actually obtained in his rectifiers. But whatever the results with continuous excitation in any one tube, my own experience indicates that much better results can be obtained if intermittent excitation is substituted for the continuous.

J. H. Cox (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): Mr. Marti has presented an interesting description of a single-anode tank rectifier. It is gratifying that Mr. Marti has finally published an arc-drop curve for conventional rectifiers and also has agreed that the arc drop increases with increase in size of tank. Incidentally, single-anode tanks have this same characteristic.

It is unfortunate that Mr. Marti failed to include some of the points on which his single-anode-rectifier arc-drop curve was based, and also a statement of the method of measurement. Arc drop is influenced by the amount of protection given the anode, that is, the shielding around the anode and the anode-cathode spacing. Although not the only cause of arcback, an important cause is the ionization in the tank during the negative-voltage portion of the cycle and the most important reason for protecting the anode is that the tank is not "blacked out" during all of this period. Following commutation of current to another anode, there is a residual ionization determined by the current commutated and the geometry of the space. This residual ionization decays over several electrical degrees and is the same for ignitron or Excitron. In addition to this residual ionization, the Excitron has an ionization due to the excitation arc that continues over the entire cycle. In view of this, it is fundamental that the anode protection required with continuous excitation could never be less than that with synchronous excitation. Of course, there is a relationship between the degree of shielding, arc drop, and arc-back frequency. Reliability may be sacrificed by an attempt to lower the arc drop by reducing the shielding.

The "relatively high current" required for ignition of an ignitron and the "very small current" sufficient for excitation of the Excitron are mentioned in the paper, but no figures are given. I would be interested in the current and voltage required for Excitron excitation for reliable cathode-spot maintenance. Present ignitron ignitors require a current of the order of 25 amperes for only a few microseconds, for reliable and accurate firing. From the operator's point of view, it is the excitation loss that is important and this varies with the circuit used. In any event the loss of ignitron excitation circuits is not usually the determining factor in choice of method.

I wish to correct the impression given in the paper that ignitors are delicate and require highly accurate immersion. No trouble has been encountered in maintaining satisfactory immersion, which may vary as much as one-fourth inch, in normal service even during extreme overloads. With proper excitation circuits, ignitors do not erode away, or otherwise fail, due to either normal currents or severe arcbacks.

Mr. Marti again discusses arc extinction during fault conditions by grid blocking. This is an interesting possibility of controlled rectifiers of all types, but not highly important because it is not reliable, and it is no more reliable in single-anode tank rectifiers than it is in multi-anode rectifiers. Such arc blocking somewhat reduces duty on breakers, but it does not eliminate breakers because it is not dependable. The performance is only from 80 to 90 per cent.

O. K. Marti: I agree with Doctor Slepian that in my paper more specific references should have been made to the backfire rate. The rate of backfire, however, was assumed to be similar to that experienced in connection with the well-known multiple-anode type of rectifiers and the recently introduced ignitron rectifier. Therefore, my statement that the Excitron rectifier is just as reliable as the ignitron rectifiers is based on the fact that it showed about the same backfire rate as any type of commercial rectifier on the market today.

I was indeed very glad to learn of the experience Doctor Slepian had with single-anode rectifiers having continuous excitation. From his figure given for the excitation current as being 20 amperes, it may be concluded that the unsatisfactory results obtained by him are due to his high excitation current. In our excitron rectifier only a fraction of this value is necessary for reliable operation.

It is possible that using a design where the anode is relatively close to the cathode (three or four inches), the backfire rate may be less if intermittent excitation is used. However, we found that in order to obtain an appreciable output from a tank the anode had to be located at such a distance from the cathode that no difference would result whether intermittent or continuous excitation was used.

As to Messrs. Cox's and Jones' references to the arc-drop curves as shown in my paper, I would like to say that the curves were chosen simply for illustrative purposes and were measured using methods approved by the AIEE Standards. The slope of the curve for the single-anode tank is somewhat steep due to the fact that the tank was very restricted in diameter, being less than ten inches, which may explain to Mr. Jones the rapid increase with increasing load current. Mr. Jones must realize that the slope of the arc-drop curve is a function of the design of a single-anode tank rectifier, similarly as in the case of a multiple-anode rectifier. The tank as illustrated in my paper had only a grid, and no shield as inferred by Mr. Cox and Mr. Jones, and still the arc-back frequency was well within the limits I mentioned in connection with Doctor Slepian's discussion. We do not agree with Mr. Cox that arc-back susceptibility is a function of the degree of shielding. This would only be the case if all backfires would occur during the transition period as was erroneously assumed by many rectifier engineers until recently. It is possible that the very backfires which occur during the transition period can be reduced by additional shielding, and if the tanks are increased in diameter or if the current for a given tank is raised to a high degree, then shielding may mean an improvement in arc-back rate.

D. C. Prince's publications in the book "Mercury-Arc Rectifiers and Circuits", refer to several tests calling attention to the fact that arc backs could not be noticed during the transition period. This fact was also more or less confirmed by data disclosed by Messrs. Pakala and Batten in their paper presented during the 1940 winter convention in New York (AIEE TRANSACTIONS, volume 59, 1940, June section, pages 345–7), and was also proved by many investigations our company carried on during the last three years. Therefore, the rate of arc backs cannot be affected by merely reducing ionization by the means referred to by Messrs. Jones and Cox.

Referring to Mr. Jones' discussion of the typical connections for ignitron and Excitron rectifiers, I would like to say that they were shown of the simplest kind for both types, merely to illustrate the difference between both in the principle used. I am fully aware of the latest method used in connection with the most recent schemes of ignitron rectifiers, which, as Mr. Jones admits, requires the use of additional auxiliaries, such as capacitors, etc., which were apparently all necessary to obtain stable operation and a proper picking up of the main anodes.

With reference to Mr. Myers' discussion, it will be understood, of course, that the diametrical connection is seldom used by any one, and figure 3 was based on this connection merely for simplicity. We cannot understand, however, how Mr. Myers obtained the wave form which he shows in his discussion for five-anode operation. We wonder if that figure was obtained from actual oscillographic measurements. We find that from purely theoretical considerations the wave shape of the direct voltage, when using an interphase transformer and one anode missing, the voltage not only comes down to zero, but stays there at least one-sixth of a cycle, which is considerably worse than the case illustrated in figure 3. It would seem that Mr. Myers failed to take into account the fact that the output voltage will be the average of the two three-phase groups, and that the group in which one anode is not firing will go negative by an amount equal to the voltage of the other group in the positive direction.

Operation of a double three-phase system with only five anodes firing for any length of time may cause damage to the interphase transformer, as a high 60-cycle voltage will be impressed across the interphase transformer which is designed for a 180-cycle voltage of much lower value.

Papers are in preparation which will describe in more detail the design of the Excitron unit as well as the method used for ignition and excitation. As I said before, the purpose of my paper was merely to bring out the reasons which induced designers to make a new attack upon the development of a single-anode tank, and furthermore to give some comparative data between a rectifier having intermittent ignition-excitation and one with continuous ignition-excitation, and to show that such a tank can be designed to operate properly using either method of ignition.

Electric Braking for Railroad and Urban Transit Equipment

Discussion and authors' closure of paper 40-28 by F. H. Craton and F. M. Turner, presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940, and published in AIEE TRANSACTIONS, 1940 (September section) pages 489–94.

Sidney Withington (New York, New Haven and Hartford Railroad Company, New Haven, Conn.): One item in this valuable paper which it may be of interest to note, is that in development of dynamic braking as compared with regenerative braking on heavy trains, the dynamic method is relatively more common abroad. It is of interest to note that in this country the regenerative braking has been developed in territory where the power supply is either from hydroelectric sources or from power plants located in the midst of coal fields where the cost of fuel is minimum. The value of the regenerated energy in both cases is thus relatively very low.

Joseph F. N. Gaynor (Great Northern Railroad, Wenatchee, Wash.): There is an old axiom among railroad operating men that lack of speed is only a small worry. The real worry is "How fast can I stop in a pinch". Regarding the advantages of regenerative braking, the saving in power alone adds up in direct money value to the saving in brake shoes and wheel tires varying with location, but here in the Cascade Mountains the over-all amounts to 25 per cent of the power to operate the system. In addition to this we haul twice the tonnage which we used to in 25 per cent of the time. The overtime saving and the ability to haul fewer, faster, heavier trains are the direct result of (1) electric locomotives, and (2) regenerative braking. The limits of regenerative braking are mainly motor capacity and adhesion. Our experience on the Great Northern on 2.2 per cent and 1.6 per cent grade operation indicates 15 per cent to 20 per cent adhesion as the ultimate tonnage hauling limit, and commutation or field-to-armature ampere ratio of one to three as the top speed limit with any given tonnage. When regeneration capacity of locomotives is inadequate to hold a tonnage train between the two limits given, supplementary air braking is used freely to maintain top speeds beyond the regeneration range or to limit the substation regeneration load. On the Great Northern system, power is supplied by one 25-cycle 5,000-kw hydro station and two 6,500-kw frequency-changer stations. Hence the maximum regeneration load at the frequency changer stations must not exceed 8,000 kw. To keep within this limit, by many road tests we have rated our station regeneration kilowatts against train gross-ton miles per hour for the different grades. For example, on 1.6 per cent grade the gross-ton miles per hour per kilowatt is 30. Taking the gross-ton miles per hour capacity of locomotives of 225,000, with a tonnage freight of 6,570 gross tons including locomotives, the speed at which the locomotive continuous capacity will not be exceeded is 35 miles per hour on a 1.6 per cent grade. Under this condition the frequency station regeneration input is 7,500 kilowatts. Hence in figuring regenerative-braking limits it will be noted that adhesion, motor capacity, commutation limits, locomotive mechanical speed limits (often approached with lighter tonnage trains on the Great Northern grades), and finally the system capacity for absorbing regenerated power all combine. Theoretically, train sheets can be made up so that trains are regenerative while others are motoring to help absorb regenerated power, but practical railroading can only move tonnage as it is received and operation is based on that system.

In decelerating trains in regeneration, once continuous speed and full load have been reached, all decelerations must be made by air braking. The Great Northern has found by experience that in fast passenger service even where ample capacity for regenerative deceleration exists, more satisfactory operation results and time is saved by using air in station stops or short distance slow orders. Comfort and safety in both passenger and freight service are guaranteed by regenerative operation as slack surges are missing.

During steam and all-air braking operations over mountains, the wrecker was a constant visitor to the territory. While we have had derailments pulling trains up grade where draft gear failed or cars folded up, in 13 years there has been only one derailment chargeable to regeneration, when cars were telescoped in a freight. This was found on investigation to be a case of the helper engineer holding too much in the middle of the train, stretching out slack between the head-end engine and the helper and then suddenly shutting off power as the head end began to stop. The slack piled down against the head end kicking cars out of the train.

From observation of our Great Northern 1,000-horsepower Diesel-electric switcher, I have noted one thing lacking to make this locomotive an even better switching unit. Switching moves are practically all accelerations and decelerations kicking cars, etc. The steam locomotives which the Diesel replaced were easy to stop quickly. While the brake at present can be set up for a quick stop, due to rotational effect of armatures and the concentrated weight of the engine itself of 125 tons on four axles, a severe brake is very likely to skid wheels and the engineers must get accustomed to the new power. The result is that they are afraid of flattening drivers and thus do not use as much power as is available so that safer stops can be made. The final result is that the locomotive is not being worked at the speed and capacity it is capable of simply for lack of a good dynamic brake. A fairly moderate outlay for equipment would pay for a good dynamic brake which would more than pay for itself in increased work which the engine would put out because of being able to stop more quickly.

There is no reason why the same kind of application would not work satisfactorily on a streamliner as in stopping a train where the locomotive weight is approximately 30 per cent of the train weight, dynamic braking would help reduce wheel checking and skidding.

Joseph C. McCune (nonmember; Westinghouse Air Brake Company, Pittsburgh, Pa.): I would like to congratulate Messrs. Craton and Turner upon their able paper, a paper particularly well written and very effectively presented.

Confronted with an audience of electrical engineers, I am not tempted to venture comments upon the technicalities of electrical apparatus. The authors have, however, and especially in their introduction, made mention of the capabilities of air brakes. Since the air-brake field is the one in which I am directly engaged, I would like to point out, from an air-brake viewpoint, some of the problems encountered when electrical brakes are employed to supplement air brakes.

These problems are not new as electrical brakes of one sort and another have been employed for many years. Thus, combined dynamic, track, and wheel-tread brakes were introduced some 40 years ago; regenerative braking some 30 years since; and eddy-current brakes have been employed in England for highway vehicles for a considerable number of years. Modern developments have greatly improved these brakes, especially in the direction of giving the operator a more precise and positive control of the retardation produced and of reducing initial and maintenance costs.

As the authors state, electrical brakes of the regenerative type, installed on the electric locomotives of certain large railroads, have made an excellent showing in actual service. Automatic interlocks have been devised which very satisfactorily interlock electrical and air brakes so that each type is adjusted to its proper place in the combination brake system. This experience indicates that electric locomotives used in grade service offer an attractive field for electric brakes, the air brakes being held in reserve for emergencies.

To the air-brake engineer, however, this is quite a limited field. By this I mean that grades where electrical braking might be employed probably amount in the aggregate to less than three per cent of the total railroad mileage of the country.

A condition exists in this service, moreover, which should not be overlooked. As the authors of the paper point out, if a certain locomotive is able to take a train up a grade, it should be able, with even less difficulty, to get the same train down the same grade. But many important grades, particularly on ore and coal roads, involve the movement of empty cars up the grade, as to a mine, and the movement of loaded cars down the grade. If the electric locomotive is designed with only sufficient capacity to take the train up the grade, it is clearly inadequate to take the loaded train down. It is obviously uneconomic to increase the size of the locomotive merely to be able to use electric braking in the descent of the grade.

But grade braking, although very critical in isolated instances, represents, as I have already pointed out, only a very small percentage of train miles operated. The most important task of the brake is to stop trains in emergencies to save lives and avoid property damage. These emergencies may arise at any time, in either grade or level road service. To the engineman confronted with a washed out bridge, a stalled automobile, or a displaced rail, no stop can be too short.

When an attempt is made to provide for short emergency stops in high-speed service, with any form of brake, two difficulties are encountered. First, rail adhesion makes the minimum stop possible from high speeds of considerable length and, in fact, the best that can be done, from the adhesion viewpoint, is none too good. Second, the heat to be dissipated in a high-speed stop taxes the capacity of any form of brake.

The adhesion available makes it impossible to do all the braking on the locomotive because then the stops would be prohibitively long. It is clear that if satisfactory stops are to be obtained, each wheel in the train must be braked close to the limit of adhesion. Only by distributing the braking throughout the train and by developing the maximum practical retarding force at each wheel, both on cars and locomotive, can short stops be secured. To shorten stops for the new high-speed operation, therefore, it is necessary to provide effective brakes on both cars and locomotives. The problem is so closely associated with available rail adhesion that it is important to work both car and locomotive brakes, as nearly as can be done, to the limit, having in mind the adhesion realizable in practical everyday service.

The second problem faced by any brake in high-speed service is the matter of heat dissipation. A brake may be considered to be a mechanism for converting mechanical energy into heat just as a motor is a machine for converting electrical energy into mechanical energy. Brakes tested for service on modern cars have dissipated, as an instantaneous maximum, 2,000 or more horsepower per axle, which obviously represents a heat problem of considerable magnitude.

Braking apparatus for high-speed service must, therefore, be adapted to producing braking torque on all wheels of the train, both cars and locomotive, approaching the slipping value. The braking apparatus must also be capable of dissipating very great quantities of heat in very short times. But it cannot have too much bulk, for space on cars and locomotives is at a premium. It cannot be too heavy but on the contrary, its weight should be an absolute minimum. It must bring the train to a dead stop and hold it stationary on grades. It must be absolutely dependable because the lives of passengers cannot, in any way, be jeopardized. It must retain its efficiency with the minimum of maintenance attention in order that equipment may be freely interchanged throughout the country. All this must be accomplished without an undue initial or maintenance cost because the railroad must have low operating costs to meet competition. All importantly, the brake apparatus must be of a character which will permit it to harmonize with existing brakes in order that the ability to interchange cars freely over the North American continent may not be impaired. In view of these requirements, which represent by no means an exhaustive catalog, it seems to me that the authors are somewhat too optimistic as to the part electrical braking may play in future high-speed train operation. New forms of friction brakes, applicable to both cars and locomotives, seem likely to overcome the current difficulties with conventional brakes.

L. K. Sillcox (The New York Air Brake Company, Watertown, N. Y.): The authors are to be complimented on their achievement in covering a broad subject most effectively in a few concise paragraphs.

The applications of regenerative and dynamic brake equipment upon locomotives must always be supplementary to a complete conventional air-brake system. Electrical-braking means and the value of any dual equipment for braking service possess merit from a reliability standpoint; yet any possible supplementary safety features of electrical braking forms are of negligible value as such, in view of the variety of automatic safeguards surrounding conventional air-brake designs. For instance, the Bureau of Safety of the Interstate Commerce Commission recognizes the automatic protective features of air brakes as they are now installed and in no cases does it recommend a supplementary system.

As the authors point out, electric braking is available only on the power unit and the measure of its adequacy is governed by the proportionate weight carried upon the wheels to which the regenerative or dynamic braking may be applied. Consequently, its value is limited to that of control. On descending grades a brake which dissipates train energy electrically, limiting its action to the power car, is of peculiar value. In controlling the speed of trains down long grades by the use of air brakes, it is the practice to apply the brakes on all trailing cars, holding the brakes upon the locomotive released during much or all of the braking cycle. This is the opposite practice of that employed with regenerative or dynamic substitute. The merit in employment of the locomotive brake for the purpose resides in the fact that, in braking a train from the forward end, slack between cars is compressed throughout the train and, in the usual case, the inherent resistances due to changes of grade or by reason by intervening stretches of curved track, cause no change in the slack condition. On the other hand, with pneumatic braking, brakes applied to all cars uniformly, any portion of the train is susceptible to local changes in track resistance which may cause slack directional changes and internal train shock of relatively minor consequences so long as there is no interruption in the descending grade.

The dynamic brake is offered as a practicable application for Diesel-electric locomotives. The necessary electric equipment can, of course, be readily applied but the problem of dissipating the heat generated must always prove a burden to this type of motive power. Provision of elements for this purpose will be supplementary to any other equipment provided and the use of the cooling water is undesirable inasmuch as no greater capacity is built into the cooling system than is required for normal engine operation. The tremendous cooling overload due to heat dissipation in braking would have to be separately provided for.

Electric-retardation control is complex and has ever been costly, adding considerable weight in many cases. It has definite merit which can be readily evaluated but, under present operating conditions and with the equipment as it has been made commercially available to date, anything which is done to assist the flexibility of control by superimposing a regenerative or dynamic braking system must be in addition to a complete and co-ordinated air-brake system.

F. H. Craton and **F. M. Turner:** As Mr. Sillcox points out, the electric brake cannot be expected to displace the air brake. Electric braking inherently fades out at low speed. This in itself necessitates the use of the air brake in conjunction with the electric. Furthermore, it seems probable that in any practical application of electric braking on individual cars, the electric brake would be used to provide only a portion of the total braking power at medium and high speed. There would be some optimum point of division of the braking duty between air and electric braking on a given car. The electric brake would be of such capacity that in high-speed decelerations it could relieve the air brake of that portion of the load which now makes the difference between an easy, practical problem and an extremely difficult one. It would have sufficient capacity to handle all or most of the braking duty in retardations on mountain grades. The air brake would assist the electric brake in all duty demanding more than the electric brake could handle and the electric brake would handle entirely any braking requirement within its capacity.

Electric braking supplementing the air brake is a similar application in successful operation on hundreds of trolley coaches, and although the electric brake alone can produce only two miles per hour per second deceleration against a maximum of seven miles per hour per second with the combined electric and air systems, brake-shoe life has been multiplied several times.

We are indebted to Messrs. McCune and Sillcox for their valuable comments on this subject. No one can fail to have the greatest respect for the aggressive way in which the air-brake manufacturers have assailed the problem of high-speed braking. The accumulation of fundamental data, of which there were none in the region of 80 to 100 miles per hour, was carried out in the now famous Zephyr tests in 1934. New devices were developed to refine the air-brake control to meet the demands of new conditions. Experiments with nontread friction brakes are under way. Today, high-speed trains are in successful operation using 100 per cent air equipment except for electropneumatic control. Why then any need for another approach? Only because friction braking appears to be approaching its limit. Even at today's peak speeds of about 100 miles per hour, it may well be that partial electric braking can provide the relief necessary to ease a difficult operating problem at best. With any appreciable increase in top speeds, it is quite conceivable the braking demands may prohibit the use of 100 per cent friction braking from the standpoint of practical everyday operation. It is suggested that the proper approach to the problem may be a blending of friction with electric braking of the eddy-current type, which will project the practical top speed range well beyond anything we have today.

One point in connection with railroad braking which Mr. Gaynor brings out in his excellent report on electric braking on the Great Northern, is the possible application of electric braking to Diesel-electric switchers. In competing with steam switchers, the Diesel-electric is handicapped by a deficiency in braking power due to absence of a tender whose adhesive weight is used to augment the braking power of the steam locomotive. Because of the importance of braking in speeding up switching operation, particularly in kicking cars, the reduced braking power of the Diesel-electric is a handicap which now must be made up by faster acceleration and easier handling. While Mr. Gaynor recommends dynamic braking, we wish to suggest also the use of magnetic track brakes to supplement the wheel brakes on the Diesel-electric. Magnetic track brakes would overcome a large part of this deficiency, resulting in a clear gain in switching performance over present Diesel-electric operation. Although magnetic track brakes have not, to our knowledge, been employed in such an application, the handicap in braking performance mentioned is one frequently cited, and magnetic track brakes, possibly in conjunction with dynamic braking, offer a solution.

In connection with Mr. Withington's comment regarding the common use of dynamic braking abroad, this may be influenced by the electrification systems employed. There are various applications of regenerative braking on high-voltage d-c systems in Europe and South America. The application of regenerative braking to single-phase systems using locomotives with a-c commutator motors has presented a difficult problem although we believe that when there is a demand for such braking in this country the problem will be worked out satisfactorily.

A brief review of the principal types of electric brakes used in urban transit service appears desirable in this closure. The electric holding brake, which is primarily designed to hold a vehicle at a safe speed while descending a grade, is not a particularly new application. This form of electric brake is most successfully applied only over a relatively limited speed range, and usually requires a separate manipulation of a controller handle or actuating switch to place it in operation. This type of electric brake has been used almost universally on the older types of gas-electric busses, but its limitations in application preclude its general use during service stops.

The more recently developed types of electric service brakes, which are operated automatically by either the conventional power or brake control pedal, and which are utilized during each service stop, have the widest field for future application. The major portion of new street cars and trolley coaches is being furnished with electric service braking incorporated in the equipment. It is believed that the use of electric service braking on gas- and Diesel-electric busses will also show a marked increase in the near future.

There are three principal types of electric service braking now in successful operation.

1. A single-rate, self-regulated dynamic brake designed for use with one or more series-wound motors. This type of service brake is applied to older-type street cars and trolley coaches equipped with manually operated, nonautomatic control, and to gas- and Diesel-electric busses.

2. A multipoint variable-rate dynamic brake designed for use with one or more series-wound motors. Applications of this type of brake are limited to modern street cars and trolley coaches equipped with automatic control.

3. A multipoint variable-rate dynamic or regenerative brake designed for modern trolley coaches equipped with a single compound-wound motor and automatic control.

We wish to thank Mr. Clardy for bringing up the subject of using accelerating and braking resistors to heat the vehicles, with a consequent reduction in energy demand during cold weather.

Unsolved Problems of Electrical Engineering in the Field of Transportation

Discussion and author's closure of paper 40-15 by J. A. Noertker, presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940, and published in AIEE TRANSACTIONS, 1940, pages 992–6.

G. M. Woods (nonmember; Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): A common weakness of human nature is to feel that one's particular line of work is very ably conducted, and there is room for only minor improvement. Mr. Noertker's paper points out new lines of activity for improvement of electrical engineering in the transportation field.

There is no question of the ultimate desirability of using commercial frequencies for a-c electrification and the subject warrants continued investigation. Present commercial systems probably can be adapted to handle the single-phase loads imposed by major electrifications.

The commercial compound motors available for trolley coaches reduce resistor losses in slow-speed running. But the over-all energy consumption is slightly greater than that of the modern series motors. It is interesting that the author recognizes that the metadyne is too complicated and heavy for general application to urban transportation units.

The modern capacitor-type lightning arrester answers the requirement of an effective d-c arrester without high maintenance.

The PCC street car is an excellent example of a successful development financed by operators and manufacturers. However, any new apparatus requires development costs, regardless of the organization doing the work. There is no evidence that an organization of the type suggested would be able to make these developments even as economically as the manufacturers. What can be accomplished is to co-ordinate the efforts of the operators and avoid a multiplicity of parallel wasteful developments for both operators and manufacturers.

L. C. Josephs, Jr. (Mack Manufacturing Company, Allentown, Pa.): Mr. Noertker's paper has been particularly interesting to the writer, because of the very stimulating viewpoint. The writer has been a nonconformist in transportation matters for many years, and, therefore, particularly appreciates some of the suggestions. Although the nonconformist's life is not always smooth sailing, there ought to be a certain number of them in every industry. They are a means of keeping industry moving by insisting on being different, and out of these differences, come the better things.

Coming now specifically to the trolley coach, is the idea of 600-volt d-c series a "sacred cow" that we all must worship? If we could get over this fixed idea, there might be many new fields of improvement opened up. For example: a-c 60 cycle; the possibility of using a motor that had more induction motor characteristics; the possibility of using some type of control built around the Spinner principle. It might even be an advantage to use a gear box or two-speed axle with mechanical ratio changes to improve the efficiency of the electrical system.

The metadyne control development in Europe is apparently a step along this direction. Whether the advantages to be gained are worth the price is always the deciding question. Usually, the answers to these questions cannot be found from a theoretical discussion, but someone has actually to try these out, and learn painfully all the things that are wrong with it.

I want to express again my thanks to Mr. Noertker for his very valuable contributions to this subject.

D. R. MacLeod (General Electric Company, Erie, Pa.): The 12-kv 25-cycle single-phase system of electrification has been developed for use by railroads handling commuter traffic and heavy through trains. No particular technical problem would be encountered if it were decided that contact-line voltages of 24 kv, 25 cycles, or even higher were desirable. The 3,000-volt d-c system has also been developed for the same purpose. The public utilities are the logical suppliers of power for these electrifications; nevertheless, it is important to note that in the case of both the a-c and the d-c system, special generators or means of converting power must be supplied since the three-phase 60-cycle power cannot be used directly on the existing systems. This introduces additional losses and increased cost of power, which is always important in any electrification study. The cost and difficulties of operation of a two-wire overhead permitting the supply of three-phase to rolling stock prohibits its use in main-line work. Single-phase 60-cycle locomotives could be built, although they would probably prove uneconomical. It would also be possible to design a distribution system using this frequency. Unfortunately, the large blocks of single-phase power would cause such losses in the three-phase system that it would be necessary to use phase-balancing equipment. This would largely nullify the advantage of going to 60 cycles. It is possible to use different phases of a three-phase system to supply different trolleys so that a reasonable balance could be obtained. This method has been tried on 25 cycles and while it was satisfactory for a small local electrification it would be difficult to justify this compromise on a main-line electrification.

The picture is somewhat different, although the conclusion appears to be the same on an urban transportation system, especially on those properties where the trolley coach with its two-wire overhead is designated. The load factor on the power supply to existing d-c trolley coach systems is very poor and the all-day efficiency is probably between 30 and 50 per cent from the 60-cycle power supply to the wheels of the coaches. Modern rectifiers have over-all efficiencies of the order of 90 per cent and load-responsive starting by automatic control is available to reduce the standby losses. The efficiency of the power supply is therefore comparable with that of direct transformation. The maintenance expense of rectifier substations and their relatively high cost are the principal disadvantages of this method of power supply. On the other hand the recent development of the d-c compound-wound traction motor has improved the efficiency and flexibility of the d-c trolley-coach equipment while retaining the light weight which makes this type of equipment so desirable. The d-c equipment is of the order of 50 per cent of the weight of any 60-cycle competitor. "Metadyne" equipment with d-c motors would give efficient control with no greater increase in weight than would be required for a-c equipment.

The part of a trolley-coach system which costs the most and is used the least is the overhead trolley. The conversion equipment also has a very poor capacity factor. The restriction of the use of this equipment to the trolley coaches is therefore almost as uneconomical as if the streets on which they operated were restricted for their use. Here then lies the principal argument for a 60-cycle trolley-coach system. If the utilization of the overhead can be increased by using it for other 60-cycle services along the right of the way it may be possible to justify the disadvantages to the rolling stock of the single-phase 60-cycle system. A 60-cycle trolley coach could be developed since the experience on 25-cycle series motors could be extended to 60 cycles. A 60-cycle series motor would probably weigh over twice as much as a d-c motor, and would require a step-down autotransformer. The individual currents taken by a coach are relatively small and a compromise scheme of balancing the phases as indicated before would probably be quite satisfactory without the use of rotating-type phase balancers.

In another part of this paper Mr. Noertker suggests that there is a great need for a better lightning arrester. The capacitor-type lightning arrester was developed a number of years ago for d-c circuits. It does not have the valve action possessed by the aluminum-cell arrester, but functions by sloping the front of the lightning impulse. The capacitor is charged through the surge impedance of the line which may be considered as a resistance for the purpose of approximate analysis. This arrester is used on practically all PCC car equipments, and is applicable to other equipments as well. They require no maintenance and may be left in service the year round. They are not effective on relatively low frequency switching surges. The Thyrite arrester for a-c circuits has a gap unit which interrupts the follow-up current when it passes through zero. Since there is no means of forcing direct current to go through zero with a simple gap unit, this type of arrester has not been developed for d-c systems. Thyrite can, however, be used on d-c circuits. For example, it is used to reduce the inductive kick which accompanies the opening of d-c solenoids.

E. W. Brandenstein (General Electric Company, Erie, Pa.): Mr. Noertker's paper peers into the transportation of tomorrow, and stimulates our consideration of future problems. Undoubtedly the best method of tackling a problem which deals with future transportation is, first, to set down the aims of the rail transportation industry relative to future improvements in their service. It is, therefore, desirable and necessary for designers of transportation equipment to work very close to operating men so as to obtain from them their ideas as to future requirements.

There are no continuous electrifications in this country of, say, 1,000 route miles or more. The economics of a long electrification of this nature are, therefore, unproved. Such an electrification would result in high locomotive mileage; low engine maintenance; high load factors and commensurate low power costs; and a type of superior service which has never been provided anywhere in the world. An electrification of this size would introduce a large number of possibilities which would automatically assist in solving a number of the problems suggested in Mr. Noertker's paper.

A trunk-line railroad should be able to set down specifications relative to the size of passenger trains, the weight of cars, the maximum speeds, the distance between stops, the frequency of trains, the heating requirements, air-conditioning requirements, lighting requirements, the freight-train sizes, freight-train spacing, freight-train speeds, the train communication requirements, etc. With such basic specifications, it would be possible for the electrification engineers to make comparative studies and definitely determine the trolley voltage and head-end power for auxiliaries, so that once the distribution voltage was decided upon, the other problems would be comparatively easy to solve. It is, of course, understood that the solution would apply to electrified trunk line because the cars as well as the locomotives would have to be assigned to that system and would not be transferable to other roads.

Modern locomotives should be designed with due consideration for the many auxiliary power requirements on passenger and freight trains. It might be possible to design a head-end auxiliary power plant for a steam or Diesel-electric locomotive that would duplicate the head-end power furnished by an electric locomotive. This would permit interchange of passenger cars between roads having electric engines and modern steam or Diesel-electric locomotives.

It would be highly desirable to consider the possibility of forming a committee which would work with representatives of the American Association of Railroads in order to formulate definite specifications relative to passenger-train lengths, car weights, schedule speeds, number of stops, top free-running speeds, air-conditioning loads, lighting loads, heating loads; freight-train sizes, car weights, top speeds, communication requirements, and other general specifications on which railroad operating officials would agree as being necessary for meeting competition in the future. These various problems should then be tackled by the designing engineers for two types of railroading—electrification and steam or Diesel-electric locomotives.

The results of such an investigation should lead toward a standardization of the fundamental power equipment for the various train services.

Sidney Withington (New York, New Haven and Hartford Railroad Company, New Haven, Conn.): The AIEE is to be congratulated in the presentation of this paper which courageously covers many items of fundamental interest. The proposed research group which Mr. Noertker suggests would appropriately consist of men with primarily scientific approach, supplemented of course by operating men in making practical, operating application of the analysis. The primary stimulus, however, should be that of the scientist rather than the operator.

Many other items which might well be analyzed by such an organization as has been mentioned, would be the economics of electrification. The unprejudiced and scientific viewpoint of this important problem in railroad operation would be, in the long run, invaluable.

Mr. Noertker mentions the advantages of standardization. It is apparent that it is not logical to wait for perfection, as many feel necessary, before definitely adopting a standard. Had this philosophy governed, the rail guage would not have been standardized and untold confusion would have resulted in multiple gauges. The same reasoning would apply to car couplings, air brakes, and other devices now generally used in railroad operation and necessarily adapted to interchangeability of equipment.

Matters which might be referred to the committee which Mr. Noertker suggests, include servicing of air-conditioning equipment at terminals, which now must be capable of supplying cars with battery voltages of 32, 64, and 110 volts direct current and with a-c supply of several different characteristics. Standardization in this regard must necessarily ultimately take place, and the sooner agreement is reached, all things considered, the less will be the operating inefficiency.

J. W. McNairy (General Electric Company, Erie, Pa.): Those of us directly interested in transportation are indebted to Mr. Noertker for this paper. It is both timely and stimulating. Let us hope that the challenge will not go unheeded and something practical can be accomplished, at least along some of the lines suggested.

The paper mentions many lines of development, some of them radical, all of them interesting. A few brief comments having to do with the activities of equipment manufacturers along some of the lines suggested in the paper, particularly in connection with urban transportation, might be of interest.

Wasted power is always an admission of imperfect engineering and the lack of perfection is strikingly illustrated by the figures given on the paper applying to existing types of trolley coaches and PCC cars. As suggested in the paper, considerations of first cost, low maintenance, and simplicity at the expense of power wasted determined the use of the straight rheostatic type of control on these vehicles. Some compensation for these relatively high rheostatic losses has been attained in modern equipments by using this energy for heat, and some further improvement results from the use of motors which permit a relatively large amount of field control, and by the adoption of relatively high accelerating rates to reduce the length of time the rheostats are in the circuit. The extent to which these innovations can be carried is obviously limited by practical considerations of size, weight, and cost in the one instance, and rail adhesions and passenger comfort in the other.

The balance between first cost, maintenance, and cost of power, of course, varies with the location. Series-parallel equipments of the PCC type with dynamic braking have been developed and are now operating in at least one European country. In so far as transitions are concerned, a very practical method of making these transitions over the entire range of accelerating rates without noticeable surges or shocks has been worked out on these equipments and tests and operating experience in service have demonstrated that a degree of smoothness comparable with that of the rheostatic type can be obtained. The first cost and additional equipment required are such, however, that the rheostatic type still meets with the most favor with the power costs as they are in this country. The more complicated series-parallel type appears to be justified in localities such as that mentioned where power costs are relatively much higher.

The application of the compound motor to the trolley coach both in this country and abroad has provided a degree of flexibility which is equal to and, under some circumstances, decidedly superior to the series-parallel type of control used in combination with standard series motors. At the same time this flexibility is obtained without sacrificing simplicity and low maintenance but the power wasted is still high. This type of equipment is meeting with increased favor and its popularity is attested by the fact that 57 per cent of all trolley coaches ordered in this country during 1939, and 67 per cent of those having electric braking, were of this type.

The armature-excited d-c machine, one type of which is known as the metadyne, has introduced numerous new possibilities both for the control and conversion of d-c power. The English application of a machine of this type on subway equipments has aroused considerable interest and is being followed very closely. Comprehensive studies of the possibilities of this type of equipment to subway systems in this country have also been made. Unfortunately, at the present stage of the development, the amount of control apparatus is not reduced and the complications and added weight have interfered with commercial developments. Attractive energy savings are possible, however, and these machines do have enticing characteristics and great flexibility. It is therefore difficult to predict at this time what the future may bring forth in this direction.

It might also be interesting to note in passing that a d-c transformer of the general type suggested in the paper, making use of relatively small light mechanical parts in combination with highly efficient static apparatus operated at frequencies considerably higher than 60 cycles was built more than ten years ago. A relatively large amount of d-c power was transformed in various ways by this equipment. Certain mechanical difficulties in maintaining exact synchronization and timing between mechanical parts and the electric frequencies necessary to insure arcless commutation prevented commercial application. Perhaps there is something more to be learned in the light of modern developments.

Vibrating inverters have been successfully applied for fluorescent lighting of railway cars, taking power from the low-voltage battery circuits as a source. As this development proceeds it is possible that an extension of this type of equipment to other fields may take place and it is also possible that the development may proceed to a point where power can be taken directly from third rail or trolley circuits and inverted for use by certain auxiliaries. At the present moment the motor generator set seems to meet with the most favor for converting high-voltage rail or trolley power for use by auxiliaries and there are numerous applications operating successfully. Designs of tube-type inverters for applications of this type have been worked out and tested but so far they have not been competitive from a cost, weight, and reliability standpoint, with the more conventional motor generator sets.

Several methods of modulated heat control for passenger vehicles have been studied and there seems to be no engineering reason why this type of control cannot be used. The use of saturated reactors or transformers on a-c powered equipments permitting fine graduations of power for heating with a relatively small amount of controlling energy presents attractive possibilities. Modulated vapor systems have also been developed which seem to meet all of the requirements. Here again the type of equipment adopted seems to have been dictated by consideration of first cost, and maintenance, but there still doesn't seem to be any good reason why a problem of this nature could not be satisfactorily solved if the project is given sufficient impetus and there is a persistent demand.

Perhaps, as the author suggests, the thing that is most needed in our field of endeavor is a better method of initiating our research programs and a better type of organization for directing such activities. Certainly it is important that we keep abreast of the times in transportation fields and to this end that we investigate each new scientific development in the light of what it might or can do for the transportation business.

W. S. H. Hamilton (New York Central Railroad, New York, N. Y.): Mr. Noertker's paper should be of great interest to all of us who are in or interested in the transportation field. It was very interesting and instructive to participate in the collection and collaboration of some of the underlying data for this paper, which was part of my duty as a member of the AIEE committee on transportation.

We owe a great deal to Doctor John C. Parker who first suggested that papers of this type be attempted, as the committee found it quite difficult to set down concretely in black and white a number of the problems that confront us in the transportation industry. I believe it would be well worth while to present another such paper in say five years from now, and it would be very interesting to see then how far we had progressed in the solution of these problems.

Mr. Noertker is to be congratulated on the very able and interesting presentation he has made of this matter, for the number of unsolved problems which he has enumerated that the committee as a whole did not think of, and especially for the suggestion he has made in regard to a centralized research organization for the transportation industry. The manufacturers of equipment for the transportation industry should view this paper as a challenge to their ingenuity and resourcefulness to produce solutions for these problems which have been enumerated primarily by those of us in the operating field.

It is not expected that all of these problems can readily be solved within the next few years and some of them, perhaps, never, but I have great confidence in the ability of the manufacturers to solve these problems once they are convinced of the desirability of so doing, which I hope we shall at least have demonstrated by our discussion of this paper today.

Now, I wish to give my own personal comments briefly on one of the problems of this paper, namely that of a standard system of electrification for trunk-line railroads in the United States. Many papers have dealt with this and also with the desirability of using commercial power sources for feeding the catenary system.

In considering such a standard system, I desire to point out that while the motive power is not always the governing factor in an electrification, it usually represents from 50 to 60 per cent of the total cost and hence it is on the side of economy to keep the cost of the motive-power units to a minimum. To accomplish this, it has usually been found most economical so far to do the converting of energy at the wayside substations and make the motive-power units users of energy only and not converters as well.

The difficult problem of the 25-cycle single-phase system is the operation of series motors on heavy mountain grades, particularly where helper service is involved, and wherever this system has been used to date in this country other and less efficient types of locomotives have been employed.

The difficult problem of the 3,000-volt d-c system is to keep down the cost of multiple-unit cars although this problem was well solved in the Delaware, Lackawanna and Western electrification.

Both systems require conversion of commercial power to special power for feeding the catenary and hence are pretty much on a par so far as this factor is concerned.

Many attempts have been made to combine the ease of transformation of the a-c system with the ruggedness of the d-c series traction motor but to date such combinations have been handicapped by high costs of motive-power units and by considerably lower efficiencies than either of the two systems they attempted to replace.

The Electric Railway Traction Supplement to the *Railway Gazette* (London, England) for December 8, 1939, gives a very interesting description of a locomotive to be operated from a 50-cycle 20,000-volt a-c trolley but with d-c motors supplied by a variable-voltage mercury-arc rectifier. If such a system can be worked out at reasonable cost, weight, and good efficiency for locomotives, and if rectifiers, let us say of the sealed-in type, can be made available for multiple-unit cars without unduly increasing their cost and weight, we might very well have a system suitable for universal adoption in the United States, incorporating therein the advantages of the 3,000-volt d-c system of which I have long been an advocate.

J. A. Noertker: The author appreciates the sympathetic and constructive nature of the discussion presented. There seems to be little dissent from the idea that the problems mentioned are both real and significant. The conclusion that there is need for a more effective research organization in the transportation field, seems to be accepted by both operators and manufacturers.

It is gratifying to have men of such wide experience and such diverse interests as Sidney Withington and E. W. Brandenstein point out additional potential values of a transportation research organization.

Mr. Josephs' comments concerning trolley-coach motor control are stimulating. It is a satisfaction to hear that trolley-coach builders are not satisfied with present types of control and realize that further development is possible and desirable.

Mr. Woods' pertinent comments indicate that the fundamental idea of the proposed research organization was not clearly expressed in the paper. The author had in mind that the primary purpose of this group would be to determine reasonable and possible performance specifications. There would be little overlapping with existing manufacturers research activities, which would continue to be devoted to the development of new and more efficient methods for meeting the required performance. Such an activity would parallel—in a modest way—in the railroad and urban transportation field, the work now being carried on for the benefit of the aviation industry, at Wright Field, where a huge staff of scientists and engineers are engaged at government expense, preparing performance specifications and testing equipment submitted.

J. W. McNairy has presented an excellent review of the status of many of the problems mentioned in the paper. It is apparent from his discussion that solutions for several of the problems mentioned are already at hand.

The discussion by D. R. MacLeod, in addition to containing very pertinent factual material, developed several novel ideas that could well be expanded into a paper. Mr. MacLeod's brief discussion of Thyrite for use on both a-c and d-c circuits was particularly informative.

Perhaps as several of the discussers have indicated, the simple capacitor-type lightning arrester is the answer for d-c circuits. From a maintenance standpoint there is no question, but the author is still doubtful as to whether they are equal to the aluminum cell in their surge discharge capacity.

W. S. H. Hamilton, as chairman of the AIEE transportation committee, was primarily responsible for having this paper written. It was at his request and through him that various members of the committee submitted suggestions concerning unsolved problems.

In closing the author thanks those who contributed to the paper by their suggestions and discussion.

Engineering Features of the 230-Kv Boulder-Chino Transmission Line

Discussion and authors' closure of paper 40-17 by Alex A. Kroneberg and E. M. Hunter, presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940, and published in AIEE TRANSACTIONS, 1940, pages 982–7.

Eric T. B. Gross (Ithaca, N. Y.): Appreciation is due to Messrs. A. A. Kroneberg and E. M. Hunter for publishing their paper, which contains some new and very important data, and seems to me to be one of the most interesting in the field of the application of earth-fault coils, published recently in this country. Although earth-fault coils have been used on 220-kv lines for the past ten years on the lines of the R.W.E., connecting the water-power stations in the region of Vorarlberg in Austria with the steam power stations in northwest Germany, by a double-circuit line not far from the French and Belgian border, no data concerning tests or practical experience have been published by the R.W.E. (Rheinisch Westfaelisches Elektrizitaetswerk) so far. But as I am somewhat familiar with these questions, I want to report that the results were satisfactory and that nothing unexpected has been observed, besides perhaps the necessity of cleaning the insulators more often in the misty coal-mine district near the Belgian border. The length of said double-circuit line is more than twice that of the Boulder-Chino line, but the in-phase component of the fundamental wave of the compensated earth-fault current of one circuit is only about 70 amperes or seven per cent of the whole capacitive earth-fault current. It may be worth mentioning, that earth faults on one of the circuits of the double line do not influence the other circuit, as decoupling coils are also in use.[1]

The residual current of about 80 amperes mentioned in the paper seems to be extremely high, as it is about 25 per cent of the capacitive earth-fault current. I should like to ask what the in-phase component of the fundamental wave of the residual current really was and whether it has been really measured, as described in the technical literature[2] by wattmetric measurements or found by analyzing oscillograms. From such measurements it is possible to find the "loss resistance" R in the resonant circuit of the earth-fault coils, and it would be interesting to see how R varies with increasing line-to-ground voltage of the faulted phase. One point of the variation curve of R can easily be found from the circle diagram[2] of the neutral-to-ground voltage and some hint can be found from the oscillograms of the decreasing neutral-to-ground voltage, following the quenching of the arcing ground. If we then eliminate too the influence of the Thyrite resistances shunting two of the coils, I would assume that the result will be near the percentage of in-phase component found for other very high-voltage lines. In accordance with previous investigations[3] I think that the value of the residual current itself is not so important as the smooth and slow recovery of the faulty phase due to exact tuning and small losses. As the corona losses decrease very rapidly with the decreasing neutral-to-ground voltage, the velocity of the recovery of the voltage of the earthed phase after a quenched arcing ground is determined mostly by losses which may be represented by a constant loss resistance $R_1 > R$ (shunting the coil in the simplified diagram of a compensated network), where nearly all additional corona losses are excluded from R_1. This consideration will always explain the satisfactory operation of earth fault coils in high-voltage lines when corona losses at normal system conditions are small. A similar investigation, fully confirmed by past experience, shows that the influence of higher harmonics in the residual current is always negligible, as far as the quenching effect is concerned, even if it increases the uncompensated residual earth-fault current to about 25 or 30 per cent of the whole capacitive earth-fault current. Among the more than 1,500 earth-fault coils with which I had experience in Europe, devices for compensating higher harmonics have been found advisable only in one case.

W. A. Lewis (Cornell University, Ithaca, N. Y.): The statement in the paper that the difference between the calculated currents in the ground-fault neutralizers and the measured currents "is derived from the capacitance in the towers, line insulators, transformers, and other connected electrical apparatus" appears open to question. Although the difference is not great, it is important to properly analyze the contributing factors, so that they may be taken into account in future installations. If the calculations can be made more precise, the engineers responsible for the application of such devices can proceed with greater confidence, and smaller margins are necessary in the design to allow for uncertainties.

In the first place I question whether a correction for corona is justified. The coil current is a residual current, composed of the zero-sequence components of current in the three phases. As such, these components are in phase and reach their maximum values at the same instant. On the other hand the potentials of the two unfaulted conductors are different, and reach their maximum values at different times, so that not more than one of them can be at its maximum value at the instant the coil current is maximum. Actually the coil current will lag the voltage from one unfaulted conductor to ground by approximately 60 degrees and the voltage of the other by approximately 120 degrees. Since corona is present only during parts of each cycle, near the maxima of the voltage wave, it does not appear that intense corona will be present on either unfaulted conductor at the maximum of the coil current. The stress at the surface of the faulted conductor will, if anything, be less than during normal operation, so that that conductor will have no corona unless corona is present during normal operation. Hence, it does not seem probable that corona will increase the effective diameters of the conductors near the maximum of the coil current wave, and therefore will not add appreciably to the fundamental of the coil current.

Although the space charges surrounding the two unfaulted conductors, remaining from the previous cycle, will affect the results to some degree, it appears that one will be positive and the other negative when the residual charge is a maximum, and therefore the effect on the residual charge, and hence on the residual current, will be compensating, leaving the fundamental of the residual coil current essentially unchanged.

Approximate figures are available for the capacitance of suspension insulators, from which the capacitance of a string of several insulator units in series may be estimated. Since the resultant capacitance of several capacitances in series is much smaller than one of them individually, the capacitance of a string of insulators will be very small. Such calculations carried out for lines similar to the one described here indicate that the capacitance of the insulators affects the residual capacitance by much less than one per cent. With approximately four towers per mile, it is difficult to see how the towers can have an effect which is appreciable or even comparable to that of the insulators, and the towers may therefore be neglected.

Capacitance of the transformers and other terminal apparatus are more difficult to evaluate, but here again the information available indicates that the effect is negligibly small.

From the above discussion it appears that the effects cited are, in this case, unimportant factors in the difference between calculated and measured current values. The important factor which has not been mentioned is the effect of distributed constants. In the calculation of transmission lines longer than approximately 100 miles, it is a well-known fact that the distributed character of the capacitance and inductance of the line must be taken into account, if precise results are to be obtained. A similar statement also applies to the residual or zero-sequence circuit used in the application of ground-fault neutralizers. To check the effect of this factor, approximate calculations were made for the line in question. From the data given in this paper and also the paper by Mr. Michener (reference 3 of the paper), the coil current was calculated, without correcting for corona or for distributed constants. For 234 miles the value obtained was 294 amperes. The authors of the paper give 301 amperes including 3.5 per cent for corona correction, which corresponds to 290 amperes without the corona correction, or a difference of approximately 1 per cent. The effect of distributed capacitance was then calculated, for different arrangements of ground-fault neutralizers. With a single coil, of full capacity, at one end only, the correction is approximately 14.5 per cent. For duplicate coils, at both ends, the correction is 3.1 per cent. In this case two-thirds of the coil capacity is at one end and one-third at the other, for which the calculated correction is 6.3 per cent, giving a corrected coil current in the two coils of 312 amperes, or within 1 per cent of the measured current of 314 amperes. Thus, in this case, the correction is just sufficient to account for the necessary difference between calculated and test values.

To obtain further verification of this agreement, similar calculations were made for another line which has been described in the literature. Messrs. W. D. Hardaway and W. W. Lewis have described the installation on the line of the Public Service Company of Colorado. ["Test and Operation of a Petersen Coil on the 100-Kv System of the Public Service Company of Colorado," AIEE TRANSACTIONS, volume 57, 1938 (June section) page 295.] Although tests made before the installation of the coil gave the residual charging current as from 123 to 138 amperes, when the neutral was ungrounded, later tests with the coil installed indicated that the coil current, when the system was in tune, was only 98 amperes. Sufficient data are given to allow approximate line calculations, and the coil current, without correction for distributed constants was calculated to be 92.7 amperes. In this case there is only one coil installed, and the correction for distributed constants was found to be 6.8 per cent, giving a calculated current of 99 amperes. The difference from the measured value of 98 amperes is approximately 1 per cent, indicating a very close agreement in this case also.

Although the accuracy obtained in these two cases would not always be expected, the results indicate that the correction for distributed constants is an important factor in calculating ground-fault-neutralizer applications to long lines, and should be taken into account if accurate results are desired.

It should not be inferred that the capacitance of insulators is always negligible. For lower-voltage lines, using pin-type insulators, short spans, and grounded metal crossarms, similar calculations indicate that the insulator capacitance may increase the coil current five to seven per cent, or in extreme cases, perhaps as much as ten per cent. Loads tapped at frequent intervals, either directly or through transformers, will add apparatus capacitance, which, in the aggregate may be appreciable. Hence some judgment must be exercised as to what factors have a significant effect in each case.

Alex A. Kroneberg and **E. M. Hunter:** The application of ground-fault neutralizers to the 230-kv Boulder line of the Southern California Edison Company is the first 230-kv installation in the United States and when it was first considered, reference was made to the technical press for operating experiences on 230-kv installations made in other countries. Very little information was available on this subject and we wish to thank Mr. Gross for his report on the 220-kv installation of neutralizers in Austria.

Mr. Gross has asked how the in-phase component of current in a line-to-ground fault on the system was measured. The figure of 80 amperes given in the paper is an rms value obtained from an indicating ammeter connected to a current transformer located on the path of the ground-fault current. This, of course, gives a value of current slightly higher than the 50-cycle rms value, the error being due to harmonics in the current.

W. A. Lewis questions the justification of a correction for corona in the calculations of the zero-sequence currents on this system. In this connection, we believe that the AIEE TRANSACTIONS records instances when tests on transmission systems show increases of charging current as the system voltage is raised beyond the corona limit. For example, in the Consumers Power Company Petersen-coil installation tests ("Petersen-Coil Tests on a 140-kv System," J. R. North and J. R. Eaton, AIEE TRANSACTIONS, volume 53, 1934) it was reported that about ten per cent less reactance was required in the coils for tuning at 140 kv than at 70 kv. It has been generally accepted that this apparent increase in the zero-sequence capacitance was due to corona.

On the Boulder line, corona was plainly visible at night when one conductor was grounded. Calculation methods which checked the Consumers Power Company tests results were used on the Edison company's application of neutralizers and indicated the 3.5 per cent correction credited to corona.

We are in agreement with Mr. Lewis that the distribution characteristics of the inductance and capacitance of the line should be taken into account in calculating the amount of current to be compensated by the neutralizers. However, some comments are in order on what is to be considered preciseness between test and calculating current requirements for neutralizers. The test values of current given in the paper probably have an error of at least five per cent. Experience with a large number of neutralizer applications in the United States leads to the conclusion that with existing methods of calculations, a correlation between test and calculations results closer than ten per cent cannot be depended upon. Almost invariably the measured currents exceed the calculated currents, the additional current undoubtedly being supplied by those structures on the system, the capacitance of which are not readily calculable.

What Wood May Add to Primary Insulation for Withstanding Lightning

Discussion and authors' closure of paper 40-25 by J. T. Lusignan, Jr., and C. J. Miller, Jr., presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940, and published in AIEE TRANSACTIONS, 1940 (September section) pages 534–40.

R. M. Schahfer (nonmember; Northern Indiana Public Service Co., Hammond, Ind.): The authors' method of presenting data on the impulse value of wood alone and in combination with other types of insulators commonly found in transmission lines is new. The graphs accompanying the paper are excellent and are readily applicable for analyzing various structure problems.

In commenting on the paper, I have applied the figures to one of our problems of design. In so doing, certain questions were raised. These questions are those of a field engineer applying the data, rather than those of a laboratory man questioning the values and laboratory methods. The questions raised are summarized in the following comments.

1. The time to flash is largely controlled by span length. For very short spans 2 microseconds is about right. For spans in the neighborhood of 300 feet this value is about 4 microseconds. For longer spans, 800 feet and up, this value is from 8 to 12 microseconds; the authors' critical value, I believe. A curve for 4 microseconds, added to the graphs would increase their usefulness.

2. In figure 1, values for insulators nominally rated at 35 kv and 45 kv would be useful.

3. In figures 2 and 3, the two-microsecond curve seems to be based on values somewhat higher than values previously published.

4. In figure 6, it would be advantageous to extend values to six feet of wood.

5. In figure 8, it would be advantageous to extend values to eight feet of wood.

6. In figure 10, it would be advantageous to extend values to six feet of wood.

7. A graph similar to figure 10, but covering suspension insulators and crossarms would be useful.

8. Two graphs similar to figure 10 but covering porcelain insulation, wood and air in series; one graph for pin-type and one for suspension-type insulators are needed where ground lead wire is set away from the pole.

9. Wherever graphs involving porcelain insulation is involved, it would be helpful to have sufficient values to cover the amount of insulation commonly used. That is for pin type there should be insulators nominally rated at 35 kv, 45 kv, and 69 kv. For suspension insulators there should be values for one to ten units.

10. Apparently there is an error in Example 1. The first value for insulation flashover is given as 260 kv. The value in figure 1 is about 280 kv. Then the first ratio would be 100 per cent, and the second $99\frac{1}{2}$ per cent.

11. In the case of porcelain, wood, and air insulation in series, there is a question as to whether or not the reduction factor of 65 per cent for rain applies to porcelain and wood only, or to the porcelain, wood, and air total.

12. In the third paragraph under "Rain", the authors state that the reduction factor for critical flashover is 65 to 70 per cent, and for two-microsecond flashover 75 to 80 per cent. Would it then be conservative to use the following reduction factors:

Critical	65 per cent
Four microsecond	70 per cent
Two microsecond	75 per cent

And for creosoted pine which would take up more moisture than lacquered wood and less than untreated wood:

Critical	70 per cent
Four microsecond	75 per cent
Two microsecond	80 per cent

As stated previously we are studying and have constructed a short section of a new-type 33-kv wood-pole structure which we designate as type *F*. This structure is rigid and well balanced mechanically. It is less expensive than conventional designs due to absence of braces. Our problem now is to determine whether or not modifications should be made to balance the various lightning flashover paths.

A number of points previously mentioned appear in this problem and are not covered in the paper. This is the reason for our questions. The authors' comments on the points I have raised and on the different basis of treating our practical problem will be greatly appreciated.

In conclusion I believe the number and length of my comments is a testimonial of the value of the authors' work done and of the practical results which will ensue. I believe it only needs to be expanded to cover a little more of the field, and it will become the handiest "tool" available to solve this type of transmission design problem.

W. C. Schmidt and **C. E. Waits** (The Commonwealth & Southern Corporation, Jackson, Mich.): This paper presents the findings of a very comprehensive study of the value of wood as secondary insulation. The curves and other data presented are readily applicable to actual problems of line design and we are reviewing our pole line standards in the light of this information with a view toward insuring well-balanced designs. These data should prove invaluable to designers of transmission and distribution lines.

Figure 7 gives wood-insulation values for the combination of suspension insulators and wood crossarms in series. It would be helpful to have similar values applying for the combination of air and wood in series.

The small reduction in insulation strength of lacquered crossarms under rain conditions suggests the possibility of waterproofing crossarms to recover the 15 to 25 per cent loss under wet conditions.

The authors present a good case for the use of arching horns in parallel with crossarms to avoid shattering. To be effective, however, the horn gaps must protect for the wet condition, thereby decreasing the insulation strength approximately 25 to 35 per cent. Then there is a question whether the protection afforded by the upper 25 to 35 per cent band under conditions that do not approach the severe AIEE rain test is not of greater value than the prevention of the fewer flashovers under the more severe conditions. Also a crossarm flashover is not always accompanied by dangerous shattering.

In closing we wish to again compliment the authors on making these data available in such a readily usable form.

Edgar P. Brantley (Georgia Power Company, Atlanta, Ga.): First I would like to compliment the authors on their paper which provides much needed data regarding the effect of moisture on the impulse flashover of wood as used in transmission-line construction, also, on their rather novel method of estimating impulse flashovers for combinations of porcelain and wood. This method due to its simplicity will make the data presented most useful.

That moisture decidedly reduces the impulse flashover of wood crossarms as evaluated in this paper was first established for us by a series of impulse tests on newly steam seasoned and, later, on kiln-dried creosoted pine crossarms conducted by the Ohio Brass Company in their high-voltage laboratory at Barberton, Ohio, during 1937 and early 1938 for the Georgia Power Company.

Prior to the running of these tests general observations and records extending over a number of years indicated that in general, new lines constructed of freshly steam-seasoned and creosoted southern-pine poles and crossarms suffered more lightning damage than older lines of similar construction. Lightning attacks to the new lines appeared more explosive in nature, peeled deeper into the wood of poles and crossarms than did lightning attacks to the older lines.

Many transmission line operating records also indicate a decrease in lightning damage after the first one or two lightning seasons, undoubtedly due to the gradual air drying of the crossarms while in service. This is illustrated by the record of a 61-mile 110-kv line constructed in south Georgia during 1936, on which overhead ground wires were omitted for economic reasons and insulation consisted of seven $5^3/_4$-inch by 10-inch disk insulators in series with 6.5 feet of clear wood in the double-plank crossarm. The crossarms were steam seasoned and creosoted from green stock. When installed their moisture content was approximately 40 per cent to 50 per cent based on the weight of oven-dry wood. The following is the operating record of this line:

Year	Number Months	Lightning Trip Outs	Single Planks Changed
1936	5.5	7	19
1937	12	19	17
1938	12	4	5
1939	12	16	5

Lightning storm days for 1938 were approximately 62 per cent of those recorded for the other years shown.

After considering the above tests, observations, and records, we began experimenting with kiln-dried crossarms in all transmission line sizes. The arms being dried to a maximum moisture content of 20 per cent, based on their oven dry weight, 16 per cent to 20 per cent being the average equilibrium moisture content which can be obtained by air drying for three to five years in the open in our territory.

By predrying our transmission-line crossarms, we expect to see the increased flashover reflected in the number of lightning interruptions and also to avoid much of the early damage and so justify the 10 per cent to 12 per cent increase cost due to kiln-drying. To date, unfortunately, we have no line comparable to our Americus-Tifton 110-kv line, noted above, where kiln-dried arms were used with sufficient record to indicate that this is accomplished. However, on a 44-kv pin-type triangular-spaced pole-cap line 41.72 miles long completed in south Georgia the latter part of 1938, five inches by five inches by eight feet creosoted-pine kiln-dried crossarms, having three feet clear wood paths in series with the 50-kv pin-type insulators and wood poles were used and to January 1, 1940, no arms have been replaced and only one damaged to any extent.

We believe these records to be in agreement with the results noted in Mr. Lusignan's and Mr. Miller's paper and to be the result as pointed out by them of what is to be gained by reducing the moisture content of wood transmission-line crossarms.

L. G. Smith (Consolidated Gas Electric Light and Power Company of Baltimore, Baltimore, Md.): The data included in the paper should be of considerable value to engineers designing wood-pole lines. A knowledge of the effect of wood upon impulse levels is necessary, otherwise a balanced design cannot be obtained. Several years ago the company with which I am associated had some tests made on the types of construction used on its system. However, the authors, by assembling their data in general form, have made it possible to estimate the impulse level of any type of construction. If the data are applicable for all types of construction, it will not be necessary to make laboratory tests on every design of wood-pole structure considered. It is of interest to note that the effect of such factors as creosote treatment, rain, moisture content, and cross section of wood have been studied and evaluated.

In the tests to determine the effect of creosote treatment, it is questioned whether or not the reduction of impulse strength of pine crossarms might be due to their moisture content. Frequently pine is treated green or partially seasoned. Moreover the type of treatment does not remove moisture but may actually increase the moisture content. This point is substantiated by the statement that creosote treatment has no appreciable effect upon the flashover voltages of Douglas fir. There is no apparent reason why the presence of creosote should have any different effect on the impulse flashover of pine than on fir.

The results of the impulse-strength tests made on several types of structures for the Baltimore company were checked with calculated flashovers based upon the method and the data in the paper. The tests on structures were made using a $1^1/_2$x40-microsecond wave. The values of impulse strength were the minimum crest value that would cause flashover on a 50-50 basis. It is believed that these values correspond closely to the "critical" values obtained by the authors. In comparing the results, it is interesting to note that where the feet of wood involved was from one to four feet, except in one case, the calculated values were within 20 per cent of the values obtained in the Baltimore tests. For less than one or more than four feet of wood, the differences were as much as 47 per cent. These differences may be the result of steel crossarm braces and other metal parts. As the test results were usually below the calculated values, where three or more feet of wood are involved it might be well to include an estimated correction in order to be conservative.

In the tests demonstrating the effect of moisture content of the wood, it would be of interest to know if the moisture-content determinations represented the average moisture in the entire cross section of the wood or only the moisture content of the wood near the surface. Since the impulse flashover is a surface phenomenon, might not the surface condition be the significant factor?

I. W. Gross (American Gas and Electric Service Corporation, New York, N. Y.): The authors are to be complimented on reducing to usable, workable form a mass of data obtained from extensive tests on wood insulation, wood crossarms along, and in combination with porcelain. The paper by Messrs. Lusignan and Sporn presented two years ago presented a great deal of new information on the impulse characteristics of wood, and the authors of the present paper, have carried this investigation further, particularly to more thoroughly investigate the effect of cross section of the wood, kind of wood, wood treatment, and the effect of moisture content.

The conclusion that they have reached as a result of their tests, that the impulse strength of wood under wet conditions may drop as low as 65 per cent of the dry flashover, should be of considerable interest and value to the transmission line designer.

It is interesting to note that while these tests were made on wood alone, or in combination with porcelain, somewhat similar results showing a considerable reduction in the impulse flashover of bushings and insulators alone, under wet conditions, have been reported abroad by Doctor Wanger, his figures showing a reduction in the order of 15 to 30 per cent. I would like to ask if the authors have obtained any data during their tests which seem to indicate the insulators themselves have an appreciable reduction in impulse flashover under wet conditions.

The practical application of the data is shown in typical examples in the paper. In example I, for instance, it is shown that by adding the separate impulse flashover of a 69-kv pin insulator and four feet of wood, and applying a reduction factor, a net flashover is obtained which checks closely the actually measured value of the combination. However, if only one foot of wood is used the combined insulator and this length of wood, still using the same reduction factor of 0.65—gives a combined calculated flashover of 225 kv against a flashover of the insulator alone of 260 kv.

The question therefore arises, should not this practical reduction factor be different when the flashover of the wood alone is small in comparison with the insulator alone?

Perhaps the authors can throw some light on this question.

It is particularly gratifying to find that the flashover data presented is not only in *usable* form, but also that the limits of tolerance are given, the figures being ±20 per cent as a maximum. Too often data of this type are given as *average* values *only* which introduces an element of uncertainty in its practical use.

J. T. Lusignan, Jr., and C. J. Miller, Jr.: In the preparation of this paper, the authors were constantly aware of the inherent variability of the impulse flashover of wood, both alone and in combination with insulators. No two pieces of wood behaved exactly alike and the best that could be obtained was the band in which the various flashover voltages would most probably be.

The amount of impulse testing necessary to produce even a single curve is enormous and requires considerable time. In order to cover the many different phases in the use of wood as auxiliary insulation against lightning, it became necessary to limit the amount of testing on each particular item. Accordingly, many of the curves stop short of the maximum lengths of wood which might be used in connection with insulators.

Mr. Schahfer has offered some excellent suggestions as to extension of the various curves to longer sections of wood. The authors feel that figures 6, 8, and 10 could be extrapolated conservatively to give the desired impulse information on longer sections of wood. Only the two-microsecond and critical flashover voltages were given to avoid confusion which might result from too many lines on a given curve. It is felt that if four-microsecond values are desired, an interpolation midway between the two-microsecond and critical curves would yield satisfactory values. The flashover values for the 69-kv pin-type insulator, given in figure 1, were included only for the purpose of illustration in the examples. The flashover voltage of any size pin-type insulator may be readily obtained from various sources. While figure 10 was drawn for pin-type insulators, it may be used satisfactorily with suspension insulators. In this case however, the horizontal flashover from the line conductor directly to the down-lead on the pole must be considered. This flashover voltage will be given approximately by the rod gap curves of figure 3.

The need for a curve showing the amount of impulse insulation added by air gaps to combinations of insulators and crossarms became apparent by the number of requests for such information from others besides Messrs. Schahfer, Schmidt, and Waite. Accordingly, data have been obtained from tests and the results are presented in figure 1 of this discussion. Since rain does not appreciably alter the impulse flashover voltage of an air gap, the 65 per cent reduction factor due to rain should be applied to the crossarm plus insulators before adding the air gap insulation value from figure 1 of this discussion. While this figure was drawn primarily for pin-type insulators, it may be used satisfactorily with suspension insulators. In this case it is important to consider the horizontal flashover voltage from the line conductor to the down-lead.

It would seem quite satisfactory to use the reduction factors suggested by Mr. Schahfer in comment 12 of his discussion. He is also correct in pointing out in his comment 10 of the error in example 1 due to improper reading of figure 1.

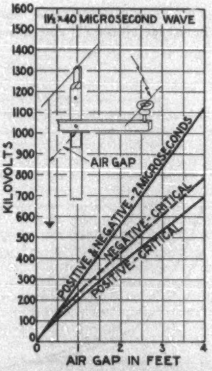

Figure 1. Impulse insulation added by air gaps to combinations of pin-type insulators and crossarms

Messrs. Schmidt and Waite bring up the question of the spacing of arcing horns in parallel with wood crossarms to prevent shattering. The usual procedure in the field has been to set the arms so that they protect the wood under average severe conditions. This practice has been quite effective in protecting crossarms and more or less indicates that the 65 per cent reduction factor due to rain gives a pessimistic flashover value. A combination of events necessary for a given crossarm to be subjected to the severe AIEE rain and a lightning voltage at the same time would seldom occur in practice. Accordingly, a factor of 65 per cent and possibly somewhat upward might apply for any given set of conditions.

Mr. Brantley's description of his company's experience with kiln-dried crossarms is most welcome. It illustrates an active design effort to gain maximum transmission line insulation strength through careful control of the moisture in the wood products purchased.

Mr. Smith's comments are very interesting, especially those comparing estimated values from the paper with his experimental values. Deviations of 47 per cent from the estimated values bear out the authors' findings of considerable inherent variations in the impulse insulation of wood. While none of the authors' tests were as much as 47 per cent away from the average, it seems quite probable that such a result might be obtained on an occasional piece of wood, especially too if metal braces and other parts are present to complicate the electrostatic fields as suggested by Mr. Smith.

In the authors' work, the moisture content determinations were made from cross-sectional blocks removed from the crossarms immediately after test. Accordingly, the values of moisture content given are an average value over the entire cross section. While flashover is a surface phenomena the voltage gradient governing it along the wood is believed to be affected greatly by the moisture within the wood, as this moisture probably has appreciable to do with the internal series impedance of the wood and its electrostatic field. The tests illustrated in figure 14 would seem to bear this out, as the lacquered specimens where only surface moisture could exist showed little change of impulse flashover under wet conditions.

In reply to Mr. Gross' question regarding the impulse flashover voltage of insulators under wet conditions, the authors have found that no appreciable change in flashover value has been observed. The application of the 65 per cent reduction factor to short sections of wood in series with insulators sometimes gives a net flashover value less than that of the insulators by itself. Obviously, such is not the case, as under no conditions would the flashover voltage be less than that of the insulator by itself. The 65 per cent rain reduction factor was deduced from tests made on a four-unit string of suspension insulators in series with a four-foot section of crossarm. Obviously, this factor will have to be increased to unity as the length of the crossarm decreases to zero. The designer can readily modify this factor to fit his conditions, being guided by the fact that the flashover voltage of the insulator itself is the limiting condition.

The flashover voltages determined with the aid of the various curves presented in this paper should be considered as indicating the most probable flashover voltage of a given structure with the actual flashover voltage of each structure of a given line falling within a plus or minus 20 or 25 per cent band.

Surge Characteristics of a Buried Bare Wire

Discussion and author's closure of paper 40-9 by E. D. Sunde, presented at the AIEE winter convention, New York, N. Y., January, 22–26, 1940, and published in AIEE TRANSACTIONS, 1940, pages 987–91.

J. H. Hagenguth (General Electric Company, Pittsfield, Mass.): The author is to be congratulated on his mathematical analysis of the impedance characteristics of counterpoises for lightning currents. The author by using the fundamental constants of resistivity, inductivity, and resistivity of the earth arrives at values of surge impedance which begin at zero at the moment the current wave arrives, reach a maximum value, and decrease to a value equal to the ground resistance of the counterpoise.

This same result had been obtained previously by experiment and by way of partly empirical calculations.[1] At that time it was believed by some that the surge impedance of a counterpoise could not be zero at the beginning of a surge but would have to be equal to that of a line in air because the effect of leakage resistance had not started. It is gratifying to see that the author by entirely independent and mathematically more correct methods arrives at values of surge impedance throughout the range of the calculations at values which are in very close agreement with the test results, even numerically.

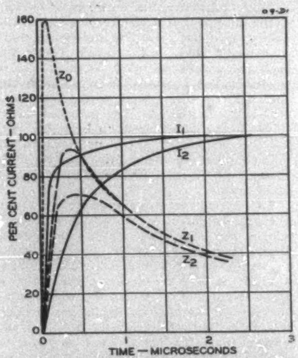

Figure 1. Counterpoise impedance as affected by front of current wave

Z_0—Calculated according to procedure outlined in previous discussion[1]

Z_1—Surge impedance when current I_1 is applied

Z_2—Surge impedance when current I_2 is applied

The author shows very little difference in maximum values of surge impedance (figure 6) between unit step current and a front of 2.5 microseconds. This is in disagreement with the test results.[1] The time functions of the current waves applied to the counterpoise in figure 2[1] are shown in figure 1 of this discussion. The first current wave has a distinctly greater rate of rise than the second one. A pronounced difference in maximum surge impedance values for the two wave fronts is evident. It should be expected, therefore, that the maximum impedance for rectangular front should be greater than is indicated by figure 6 of the paper. Perhaps the assumption made that the surge impedance of a wire buried in soil a distance d equals one-half the sum $S(a,t)$ and $S(b,t)$ is not correct. A comparison of figure 4 of the paper for $S(a,t)d=0$ and the dotted curve $R_3\times Z_3/R_3+Z_3$ on figure 4 of the previous discussion[1] show very good agreement as to the crest value, see also curve Z_0, figure 1 of this discussion. It seems reasonable to assume that considerable differences in crest values of an impedance, which is a function of time, should occur when subjected to currents of such entirely differing fronts as 0 and 2.5 microseconds.

While there still is some doubt about some of the factors, two principal points stand out.

1. The surge impedance of a buried wire rises rapidly from zero to a maximum value and decreases slowly to a value equal to the d-c resistance of the wire to the ground plane.
2. The maximum value of the surge impedance is a function of the front of the applied current wave.

The results of previous investigations[2,3] can now be used with considerably more confidence.

L. K. Swart (Bell Telephone Laboratories, New York, N. Y.): An interesting point in connection with the surge characteristic of a buried wire is that after one or two microseconds, the impulse impedance is somewhat smaller than the leakage resistance as measured with direct or low-frequency current. Other investigators through measurements with high-voltage surges have observed similar characteristics. These have usually been attributed to corona effects or breaking down of the resistance between soil particles at high voltage and at high current. Measurements recently were made on buried wires in New England using relatively low-voltage transient impulses as well as steady-state high-frequency current, also of low magnitude. The results of these measurements confirm Mr. Sunde's suggestion that it is due to contact resistance and capacitance between wire and ground.

This parallel combination of capacitance and contact resistance is considered in series with the leakage resistance in the earth. When d-c measurements are made of the leakage resistance, the latter includes the contact resistance, together with the resistance of the earth. However, under transient conditions the capacitance to ground of the conductor shunts out the contact resistance and the impedance measured, therefore, is the leakage resistance of a wire in perfect contact with the earth.

The test arrangement and the results of one of the tests mentioned previously are shown on figure 2 of this discussion. A buried wire which had a length of about 400 feet was cut in the middle and a d-c measurement was made of the leakage resistance of the two wires in series. This resistance measured 133 ohms. One terminal of a surge generator was connected to one of the buried wires and the other terminal to the other buried wire through a resistor of 133 ohms. The relation of the impulse impedance to d-c leakage resistance can be found by comparing the voltage of V_C across the

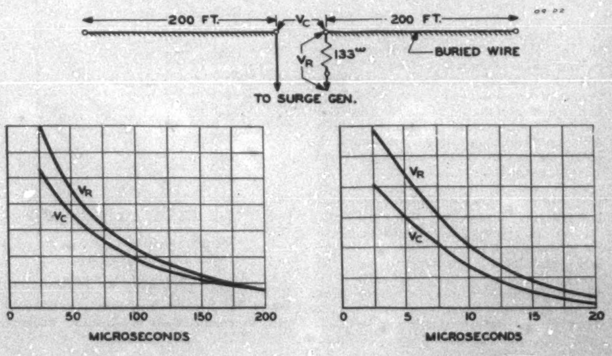

Figure 2. Comparison of impulse impedance and d-c leakage resistance of a buried bare wire

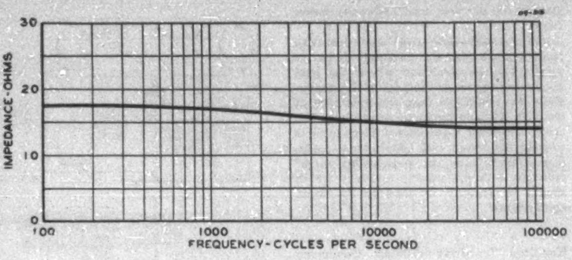

Figure 3. Impedance versus frequency of driven-rod ground system

terminals of the two buried wires with the voltage V_R across the resistor. The surge generator was discharged at about 500 volts.

As the results show, the impulse impedance is somewhat smaller than the d-c leakage resistance. No attempt was made to record the voltages during the initial one or two microseconds.

Tests have also been made on a buried wire using high-frequency steady-state currents of low magnitude and it may be of interest to note the reduction in impedance of the buried wire as the frequency is increased, as illustrated in figure 3 of this discussion. In all of the grounds tested a reduction in impedance with increase in frequency took place. For certain types of grounds, however, the reduction was greater than in others.

E. D. Sunde: In his discussion, Mr. Hagenguth questions the small difference shown in figure 6 between the maximum value of the surge impedance for unit step current and for a current of 2.5-microsecond wave front. The surge impedance for the latter current (figure 6, curve 2) is derived from the surge impedance for unit step current (figure 6, curve 1), using the superposition theorem expressed in equation 17 of the paper. It would thus seem to follow that the two impedances shown in figure 6 are mutually consistent, regardless of the assumptions on which the surge impedance for unit step current is based. The voltage in response to a unit step current is, of course, considerably larger than for a current of 2.5-microsecond wave front.

That the surge impedance for small values of time does not depend to any considerable extent on the wave front may also be concluded by inspection of the surge impedance for unit step current, as shown in figure 2 of the paper. For a wire at a depth of 0.3 meter, there is a rather small variation in the surge impedance in the interval between 0.01 and 0.1 microsecond, so that it may without serious error be regarded as constant, and somewhat larger than 50 ohms, for times less than 0.1 microsecond. On the latter assumption the surge impedance for times less than 0.1 microsecond would be the same regardless of the wave shape of the current, and somewhat larger than 50 ohms. Since the maximum surge impedance is obtained for small values of time, it would appear that the latter does not depend to any considerable extent on the wave front, when the latter is less than 2.5 microseconds, as implied by Mr. Hagenguth.

The Accuracy of Watt-Hour Meters on Intermittent Loads

Discussion and authors' closure of paper 40-40 by M. A. Faucett, C. A. Keener, and M. S. Helm, presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940, and published in AIEE TRANSACTIONS, 1940 (August section) pages 433–41.

Wm. M. Young (Ohio University, Athens): This paper indicates very interesting results on a very major problem, a problem which vitally affects the revenue received by utilities and the charges made to consumers that have loads which are not steady in character. The problem is extremely important and naturally creates wide interest.

Because of the large number of meters studied, general statements as to behavior can hardly be made, however, particularly with reference to the more modern meters, might I inquire if the authors have studied effects of change in ambient temperature on an instrument under intermittent load? Certainly it would seem that the heating effects caused by currents of short duration which produce a 200 or 300 per cent overload if checked by an indicating wattmeter might cause local heating which would aversely affect the results.

A major problem still exists in determining the effect of a complex wave of either current or voltage or both simultaneously. This problem has been partially attacked by another paper presented at this same time ["Watt-Hour Meter Performance With Power Rectifiers," C. T. Weller, H. E. Trekell, and F. O. Stebbins, AIEE TRANSACTIONS, volume 59, 1940 (August section) pages 749–57]. It would seem, however, that it is extremely important to have definite data on the behaviorism of modern meters under these highly complex conditions. Have any results been obtained for a period less than one-half cycle or for periods less than the deceleration time of the instrument?

With present meters if the load cycle changes, figure 5 is apparently of considerable importance. It indicates that each type of intermittent load of short duration should be separately studied by the utility and the meter very carefully adjusted if the intermittent load constitutes a major portion of the customer's load. In order that charges be fair and revenue just, the compensator apparently must be adjusted to the center point of its range between forward creep and reverse creep.

Has the effect of the back lash in gear trains been studied? Certainly we are dealing with a type of gear which must be produced very cheaply and one in which the torque for all angles of mesh of the gears is not constant. Other companies in other fields than electrical engineering have had considerable difficulty with variation in torque because of variation in the contact angle between gear teeth as rotation proceeded. This variation in torque may be of considerable importance, particularly for cycles of rather short duration because of the static friction effect.

It is to be assumed that the time of circuit closure was governed and controlled although this is not definitely stated as far as I could discover. There is much more interesting work to be done on this problem and I certainly hope that we will have more good subsequent reports of progress in the future.

H. E. Trekell (General Electric Company West Lynn, Mass.): This paper by Messrs. Faucett, Keener, and Helm has proved very interesting, first, because of the novel approach to the problem of determining the response of watt-hour meters to loads of short duration, and second, because of the magnitude of the errors found. In addition to finding the magnitude of errors, the method of analysis should also serve to point the way to improvement in case it is warranted.

It has not been generally believed that errors as large as those found were present in watt-hour meters of recent or modern construction. For this reason tests have just been completed on the type *I*-30 single-phase meter now being manufactured by the General Electric Company. In the first of these tests, the aid of Professor H. E. Edgerton of the Massachusetts Institute of Technology was enlisted. By the use of the high-speed stroboscopic-light camera, pictures were taken of the meter disk during acceleration and deceleration periods. Figure 1 of this discussion shows the response found at 100 per cent load and corresponds to figure 1 by the authors.

During acceleration the meter reached

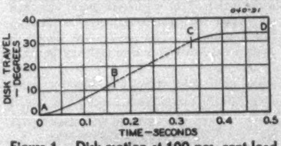

Figure 1. Disk motion at 100 per cent load unity power factor

A–B—Acceleration period—to within one per cent of steady-state speed

B–C—Steady-state period

C–D—Deceleration period—to within one per cent of steady-state speed within one per cent of the ultimate speed in about ten cycles or 0.17 seconds. Also, the time required for deceleration to within one per cent of the speed at the start of the deceleration period was found to be very close to ten cycles. The loss in displacement during acceleration and the gain during deceleration were found to be nearly equal to the steady-state displacement during two cycles. The difference between the loss in displacement during acceleration and the gain during deceleration was so small that greater accuracy in reading the displacement was needed to assign finite values to the error found. The results did show, however, that for the conditions of figure 2 of the authors' paper, the error was less than one-fifth of that shown. The displacement was read to 0.1 degree by using the teeth on the edge of the disk. In the tests the current was started and stopped at the zero of the steady-state wave and a load of constant resistance was used.

It was found that the damping and inertia constants of the meter disk were the predominant factors in determining the response as the speed-time curve was nearly a pure exponential function with an exponent of $-(D/J)t$ where D is the damping torque per unit speed and J is the polar moment of inertia. If T be the steady-state torque applied or released, it may be shown that the loss in displacement during acceleration is equal to TJ/D_1^2 for a true exponential function and that the gain during deceleration is TJ/D_2^2 where D_1 and D_2 are the respective damping constants. The value for D_2 should be less than that for D_1 and by the amount of the current-flux damping torque which is small in modern meters. This undoubtedly explains why the error is positive and small and also why the error is larger in older meters.

For loads of very short duration such as are shown by the authors in figure 3, it is thought that the above concept must be modified to include the reactance of the meter disk. It is thought that the disk reactance may keep the steady-state driving torque from being established instantaneously causing a delay of a small fraction of a cycle which effect would be difficult to evaluate or detect by means of the stroboscopic-light pictures. A second test which may be considered more straightforward was employed in finding the response for these loads of very short duration. This consisted of measuring the intermittent load by a reflecting dynamometer wattmeter which was sufficiently ballistic that the light beam did not oscillate more than one per cent of the scale reading. The registration of the watt-hour meter was then compared with the wattmeter in conventional manner. The results are shown in table I for loads of one to eight-cycle duration at 100 per cent load and unity power factor.

Table I

Time Load on (Cycles)	Time Load off (Cycles)	Error in Watt-Hour Meter Registration: Current Starting Near Zero of Steady-State Wave (Per Cent)	Error in Watt-Hour Meter Registration: Current Starting Near Peak of Steady-State Wave (Per Cent)
8	22	+0.6	−0.1
4	26	+0.7	−0.7
1	29	+0.5	−1.9

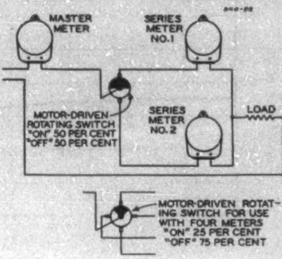
These results show errors much less than those reported by the authors. Negative results for the condition where the load begins and ends near the peak of the steady-state wave indicate that the reactance of the disk is also a factor in determining the error. However, regardless of the conditions causing the errors with intermittent loads, it is evident that the present-day meter performs with remarkable accuracy which should be entirely satisfactory for most applications.

Hamilton Treadway (Illinois Commerce Commission, Springfield): The subject of watt-hour meter accuracy is one of considerable interest and importance to engineers engaged in the regulatory field. In the past the standards of meter accuracy formulated by the state public-utility commissions have been predicated on the basis of constant load. Most of the rules were adopted when the principal use of electricity by the residential and commercial customers was for lighting and small motors. With the increase in the use of electric-welding equipment, flashing electric-light signs, X-ray machines, and other rapidly fluctuating loads the problems raised by the operation of intermittent loads on the distribution systems of the electric utilities have become of increasing importance. The authors' paper in dealing with one of the problems raised by these changes in the character of the use of electricity is particularly timely.

Many of the existing rules of the state commissions permit errors in meter registration up to 4 per cent. The authors' conclusion that the maximum error on very rapidly fluctuating loads may reach 20 per cent would therefore prove of considerable importance in the case of a customer whose load is continually transitory in nature and is metered separately. A meter serving such a load separately, though meeting the present standards of accuracy under existing methods of testing in the field, may actually be considerably in error. In such cases in the future it may be necessary to give some thought to the character of the load served by the meter when tests are conducted.

The authors do not indicate whether the tests were made under conditions of constant voltage. In the field we know that fluctuating loads and voltages go hand in hand. Since the potential flux of the meter will vary directly with the voltage the effect of the fluctuating voltage would seem to be of some importance. Except where the distribution system has been specially designed for a heavy fluctuating load the instantaneous drop in voltage when such loads come on the line is usually quite large. Information on the effect of these fluctuations in voltage on the accuracy of meters serving intermittent loads should prove of value.

A. B. Craig (Boston Edison Company, Boston, Mass.): During the fall of 1927, an investigation of the performance of watt-hour meters on intermittent loads was made by C. H. Ingalls, then meter engineer for the Boston Edison Company. The results of Mr. Ingalls' investigations have not been published. Our comments are based upon the data obtained in this original investigation.



MASTER METER
SERIES METER NO. 1
SERIES METER NO. 2
LOAD
MOTOR-DRIVEN ROTATING SWITCH "ON" 50 PER CENT "OFF" 50 PER CENT
MOTOR-DRIVEN ROTATING SWITCH FOR USE WITH FOUR METERS "ON" 25 PER CENT "OFF" 75 PER CENT

Figure 2

The fundamental approach to this problem by the authors and by Mr. Ingalls are radically different. The authors have analysed individual impulses whereas, in our test methods, the average of a large number of impulses was used. Figure 2 of this discussion shows the test methods employed by Mr. Ingalls.

A constant load registers through the master meter and, by means of a motor-driven rotating switch this load is shifted from one series meter to another. For intermittent tests with loads "on" one-half the time and "off" one-half the time, a one-half segment commutator is used with two meters. For tests with intermittent loads "on" one-quarter of the time and "off" three-quarters of the time, a one-quarter segment commutator is used with four meters. The difference between the registration of the master meter and the sum of the series meters is of course the error in registration due to intermittent loads.

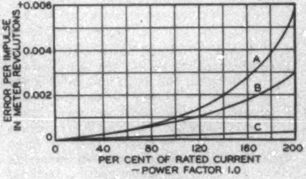


Figure 3

A—Disk constant 0.25
B—Disk constant 0.3
C—Disk constant 0.6

This method of test has the advantage that as many impulses as are necessary or desirable can be obtained. In some of the tests conducted by our company, over 100,000 impulses were used. Special registers were placed on the watt-hour meters so that the actual number of disk revolutions could be determined to one-tenth of a revolution. In all tests, loads were applied for a sufficient time so that no meter had

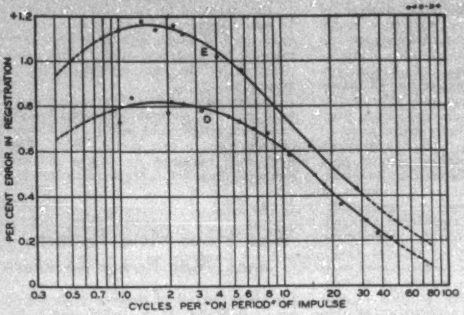

Figure 4

100 per cent load, unity power factor, disk constant 0.25

D—"On" 50 per cent, "off" 50 per cent

E—"On" 25 per cent, "off" 75 per cent

fewer than 100 revolutions of the disk. The maximum error in reading is thus one-tenth of one per cent.

We believe that this method is superior to that described by the authors, in that it is a simple, practical test method and one which can be made more nearly to simulate actual field operating conditions. Although we are in agreement with the authors as to the types of errors involved, we differ widely as to the magnitude of these errors.

From the data presented in figure 3 of this discussion, we draw the following conclusions:

1. That the error in registration is positive and is proportional to the load.
2. That for meters of the same rating the error is inversely proportional to the square of the meter test constant.

The data in figure 4 of this discussion are in close agreement with the conclusion of the authors, that the maximum error occurs when the load duration is from two to four cycles. However, in figure 3 of their paper the authors show errors from four to seven times greater than measured by us. Although they state that there may be errors as great as 20 per cent, our data leads us to the conclusion that, when the meter is subjected to full-load impulses, the maximum error will not exceed $1^1/_2$ per cent, and that for smaller loads and modern meters a much smaller error may be expected.

We are offering no discussion on various other conclusions drawn by the authors inasmuch as they are of a very general nature and our own conclusions can be considered as well within their statements.

L. A. Burckmyer, Jr. (Cornell University, Ithaca, N. Y.): This paper states that, as the duration of the "on" period of a load cycle is diminished, the watt-hour-meter error increases to a maximum and then approaches zero as the load duration approaches zero.

This statement is supported by (*a*) a brief verbal argument, (*b*) curves from direct tests, and (*c*) curves derived from measurement of acceleration and deceleration rates.

The argument reads "The registration error due to intermittent load must approach zero as the acceleration portion of the load cycle approaches zero or 100 per cent of the load cycle. At some other value of the duration of load the error must be a maximum." There is no question but that the error due to intermittent load must approach zero as the acceleration portion of the load cycle approaches zero, that is, as the load approaches a condition of not being intermittent. But the conditions stated for the other extreme are not so acceptable. Incidentally, the other extreme is not even correctly defined in the passage quoted, for it is obviously impossible for the acceleration portion of the load cycle to approach 100 per cent of the load cycle.

The meaning of the curves of figure 3 however, appears to be entirely clear. The registration error is represented as rapidly declining to zero as the duration of load is reduced from about three cycles to zero. This result, contrary to the implications of the passage quoted above, could not well have been anticipated. Let us consider a meter in which the driving torque is directly proportional to load power, the retarding torque due to the permanent magnet is directly proportional to disk speed, and the friction and potential-flux torques are exactly equal to the torque produced by the light-load compensator at all speeds. We will recognize, however, the existence of a further retarding torque proportional to the product of current and speed. The qualitative performance of such a meter agrees closely with all the characteristics observed in practice and with those described in this paper but for one exception: The percentage error on intermittent load loads *reaches a maximum as the duration of load approaches zero.* (See appendix of this discussion.) The value of the percentage error is finite, and determined by the relation between the retarding torque due to load current and that due to the permanent magnet. With torque values that make performance at low power factors and at overload acceptable, this error is small.

While this analysis disposes of the quoted argument presented by the authors, it of course cannot refute their test results. It must be borne in mind, however, that the region under dispute involves load durations of less than one cycle. There is a question of the reliability of the authors' incompletely described method of direct test under such conditions, and undoubtedly the determination and graphical application of speed-time curves for such brief load duration is subject to error. In the curves of figure 1, 0.9 of the steady-state slope is reached in about 0.2 second, so even at the end of what is called the "constant-velocity" period the slope is about one per cent less than that which would occur under continuous load. This makes it difficult to locate accurately the asymptotes to the curves. It seems that a direct test with a ballistic wattmeter would be indicated.

It is admitted that there may be little practical importance in the question raised, and that the pulsating character of most of the torque components may make the duration of load less important than the instantaneous value of voltage at the moment load is applied. Further, the nature of the transient associated with some types of intermittent load might invalidate any laboratory or analytical predictions, even those involving load durations of a number of cycles.

In regard to light-load adjustment, the authors repeatedly stress the need of making the setting with extreme "care". Since it is stated, however, that meters adjusted within the limits of commercial accuracy may show 20 per cent error under intermittent load, and that this error can be reduced by readjustment of the light-load compensator, it appears that the proper setting of this control is not a question of care but of technique. Detailed instructions for securing optimum adjustment would have formed a valuable contribution. In their absence it must be inferred that only by direct experimental study of performance under intermittent load can this be accomplished. Such procedure is, of course, impracticable in most cases.

Appendix

If a constant load is applied continuously, a speed (N) is attained, at which the driving torque (T) corresponding to load power is just equal to the retarding torque (T_m) due to the permanent magnet plus that (T_c) due to current.

During *acceleration*, at any speed n, these retarding torques are reduced to $(T_m+T_c)n/N$, or Tn/N, so the torque available for acceleration is $T-Tn/N$ or $(T/N)(N-n)$. Therefore

$$\frac{dn}{dt}=\frac{T}{4\pi^2IN}(N-n)=C(N-n) \tag{1}$$

where I is the moment of inertia of the disk and C is a constant for a given load condition. The solution of equation 1 for an initial condition of $n=0$ at $t=0$ gives

$$n=N(1-\epsilon^{-Ct}) \tag{2}$$

The number of disk revolutions completed in a time t_1 after power is applied is

$$\int_0^{t_1} n\,dt=Nt_1-\frac{N}{C}(1-\epsilon^{-Ct_1}) \tag{3}$$

During *deceleration* with zero load current, the decelerating torque becomes T_mn/N, so

$$\frac{dn}{dt}=-C'n \tag{4}$$

where

$$C' = C\frac{T_m}{T_m+T_e} \tag{5}$$

The solution of equation 4 for an initial condition of $n=N$ when $t=0$ gives

$$n = N\epsilon^{-C't} \tag{6}$$

and the number of disk revolutions completed between the time t_2 and standstill is

$$\int_{\infty}^{t_2} n\,dt = \frac{N}{C'}\epsilon^{-C't_2} \tag{7}$$

To determine the number of total revolutions, we must find the value of t_2 which corresponds to a disk speed equal to that at the end of the acceleration period. From equation 6 and equation 2,

$$t_2 = -\frac{1}{C'}\log\left(1-\epsilon^{-Ct}\right)$$

and substituting this value into equation 7, the number of revolutions during deceleration, following application of power for a time t_1 is

$$\frac{N}{C'}\left(1-\epsilon^{-Ct_1}\right) \tag{8}$$

so the total number of revolutions, from equations 3 and 8, is

$$Nt_1 - \frac{N}{C}\left(1-\epsilon^{-Ct_1}\right) + \frac{N}{C'}\left(1-\epsilon^{-Ct_1}\right)$$

It should be Nt_1, so the per cent error due to intermittent load is

$$100\left(\frac{1}{C}-\frac{1}{C'}\right)\frac{1-\epsilon^{-Ct_1}}{t_1} \tag{9}$$

As t_1 approaches 0, the quantity in brackets approaches the value C, or the meter over-registers by 100 T_e/T_m per cent.

M. A. Faucett, C. A. Keener, and **M. S. Helm:** We are pleased to note that several of those who discussed this paper have presented experimental data. Their results agree with ours in many particulars and we wish to thank them for their contributions. In the interest of brevity, we necessarily omitted many details which might have been of interest and the discussions have been valuable additions.

Many factors which might be of importance, in particular applications of meters, were omitted in this investigation. To have included such factors as voltage variation, temperature changes, and wave form, would have made the interpretation of results difficult. Such an increase in the number of variables would lead to so complex a situation that the effect of any one would be nearly impossible to evaluate. The influence of such factors as were omitted was minimized by keeping conditions involving them as nearly constant as was feasible. In answer to Mr. Young's question regarding the temperature effects of heavy loads of short duration, it might be pointed out that the thermal rating of meters is for continuous loads of such magnitudes and no errors of importance should be expected from this cause.

It is difficult to reconcile the third paragraph and appendix of Mr. Burckmeyer's discussion. The mathematical analysis of the performance of a watt-hour meter under even the simplest circumstances requires more than the assumption of simple exponential acceleration and deceleration. The component torques are not all simple functions of time or flux and differ greatly in their natures. Conclusions drawn from an analysis based on incomplete premises may be misleading. When equations fail to explain an observed natural phenomena, it is usually Nature that is correct.

In the interpretation of the curves of figure 3, only such points as represent integral cycles should be considered, although a continuous curve was used to indicate the trend of such points. Fractional cycles introduce harmonics or unidirectional components in the current waves. This complication was purposely avoided in this investigation. An investigation, by the authors, of the influence of these factors has been in progress for some time as a part of the study of the magnetic conditions in meters. It is recognized that intermittent loads, in general, need not be of integral cycles duration and that the behavior of meters on the general types of loads would probably deviate somewhat from that indicated for integral cycles.

In a like manner, under practical conditions, no guarantee can be made that the time of circuit closure will repeatedly occur at the same point on the cycle. A notable exception to this is the electronic-controlled welder. The curves of figures 1 and 3 should be considered as the average of a large number of possible cases. The experimental test curves were obtained with circuit conditions approximating the electric welder.

It is difficult to present quantitative results for meter studies without specifying all of the conditions involved, including the make, the type, or the age of the meter. For this reason, it was the intention of the authors that the study be considered more in a qualitative than a quantitative sense. For the presentation of curves, however, quantitative results are necessary. The cases chosen as illustrative are neither the best nor the worst, but are between those extremes. The quantitative results obtained on any meter were dependent upon the adjustments of that meter, especially the friction compensation.

The 20 per cent error mentioned in the paper was the greatest encountered in the investigation. This value should not be considered as the maximum possible error or that which might be expected in any particular meter. In all cases, the meters were adjusted within the limits of commercial accuracy. The meters used in the tests had no gear trains. However, it would seem probable that the gear train would not offer appreciably more opposition to disk rotation with an intermittent load than under normal operation. In a meter in good condition, this component torque is practically negligible.

The magnitude of registration errors reported by Mr. Trekell compares closely with that found by the authors in tests on that type of meter. The conclusions he has drawn check those included in the paper regarding the use of the modern meters on loads of intermittent character.

In the preliminary tests made by the authors, a switching arrangement similar to that reported by Mr. Craig was used. It was, however, put aside in favor of the other method which seemed to offer more material for analytical study. The errors observed by the two methods compared favorably.

The test data submitted in the discussions bear out the authors' observation that maximum errors occur with load durations of from two to four cycles. Since these data were obtained by widely different methods, the check is of particular interest.

Watt-Hour-Meter Performance With Power Rectifiers

Discussion and authors' closure of paper 40-42 by C. T. Weller, H. E. Trekell, and F. O. Stebbins, presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940, and published in AIEE TRANSACTIONS, 1940 (August section) pages 449–57.

Walter C. Wagner (Philadelphia Electric Company, Philadelphia, Pa.): The authors are to be sincerely congratulated upon the effective work which they have done and upon their method of presentation. All research work of a reliable character that can be done on this subject will serve to make more clear the present atmosphere of uncertainty that faces the operating companies when measuring loads of this character.

Some three years ago, when I approached some of the electrical manufacturing companies, plans were outlined for making a joint investigation, combining the work on the test floor with tests in the field in order to include all elements of the problem involved in metering six-phase rectifiers. At that time, in 1937, the General Electric Company representatives stated that, at the first opportunity, when a power rectifier was available on their test floor, they would arrange to have the necessary integrating and indicating meters installed, and tests made following the procedure proposed to their engineers. In 1938, upon their advice and invitation, we, in conference with their representatives, completed the details of the tests and co-operated in making the tests on a six-phase power rectifier on the test floor at Schenectady. During these years and later, tests were made jointly with others, and also independently, on six-phase rectifiers, in line with the original program. The data obtained from these other sources are in the course of examination, but the information so far is not uniformly in a satisfactorily close agreement with the data presented in this paper. It will probably be necessary to make additional tests to determine what factor or factors give rise to these differences.

Watt-hour meters operating on the induction principle are susceptible to inaccuracies due to departures from sine wave and changes in voltage, power-factor, frequency, and temperature to varying degrees, depending upon the design of the watt-hour meter. No reference has been made to the possible effect upon the metering current and potential transformer performance and particularly when operating under service conditions. Note also that the actual periodic field calibration of service meters is not made with the current having the wave form of the rectifier, but with a wave form derived from the voltage supply. Wave-shape characteristics of rectifiers, even when designed for the same service, apparently differ considerably and may be affected by unbalance of phase voltages, and the wave form of supply. The harmonics of voltage and current concerned are also not only affected by the reactance and capacitance in the supply circuits, but may also be influenced by inductive effects from the apparatus which the d-c circuit supplies.

It is of related interest that even the relatively small percentages of harmonics that may occur in the test circuit of a transformer loading device designed for low-power-factor tests on meters, may at times show appreciably larger deviations between the performance of two standard watt-hour meters of the same manufacture, but of different types, than are shown in this paper for rectifiers which give greater departures from sine-wave values.

In general, it is expected that the rectifier active and reactive metering inaccuracies may not be large, but just how large under service conditions is still a question.

As stated initially, test-floor data, while occupying an important part in the investigation, must be supplemented by field research. The great difficulty in the field has been in the inability to compare indicating with integrating instruments under service load conditions.

About a year ago I proposed, in writing, to the meter manufacturers of this country, the development of an energy-integrating device consisting of a wattmeter whose position would be integrated by means of the movement of mechanical parts driven by a synchronous motor. This principle of integration has for years been applied to certain fluid meters whose position of a moving element is determined by a difference of pressure across an orifice or nozzle in the pipe through which the fluid passes. The position of this moving element is integrated by means of a synchronous motor-driven mechanism and is very satisfactory where the frequency is closely controlled. As a result of my request, one manufacturer has designed and developed such an electrical integrating instrument, for general metering service and for precision measurements which is shown in figure 1 of this discussion. Note that for steady load conditions the kilowatt indication may be used. Since a wattmeter is not appreciably affected by wave form, power factor, or frequency, the integration of the wattmeter position can be directly compared with the integration of an induction-type watt-hour meter in series with it and the load. When sufficient data have been collected from such comparative measurements in service and on the test floor and such data related to results reported in this paper, then will we have a more definite knowledge of the accuracy of service meters used in the measurement of power rectifiers or other loads having considerable departures from sine waves of current or voltage.

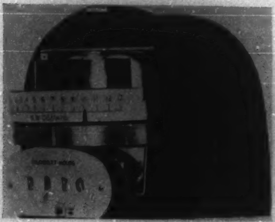

Figure 1. Dynamometer-type watt-hour meter

Wm. M. Young (Ohio University, Athens): The paper is decidedly interesting and the results gratifying because of the close agreement between calculated and experimental data. There is here one more verification of the fact that present-day watt-hour meters are capable of doing a good job of metering on unusual applications wherein the wave form of both current and voltage may be badly distorted. It is comforting to know that the many harmonics introduced by rectifiers have an insignificant effect on the reading. At first sight it would seem that the 20 per cent fifth harmonic and 14 per cent seventh harmonic would create much more disturbance; however, since these harmonics operate on small impedances, there is little error in the actual reading.

The main problem is still present with polyphase watt-hour meters and, particularly, with single-phase watt-hour meters. It seems that there should be made a careful study of the effect of the various harmonics in the voltage and current waves for various power factors on both of these meters. Numerous organizations are at present working on the various phases of the problem and the data obtained, when completely assembled, will fill in the many blanks in the complete story.

Might it not be worth-while for the committee on instruments and measurements to take under advisement the problem of co-ordinating the work being done on polyphase and single-phase watt-hour meters so that various investigators may be able to interchange ideas and proceed more rapidly to obtain a complete analysis of this very important problem?

Certainly manufacturers are to be complimented on producing metering devices at such low cost which are so vastly superior to the old measuring devices.

Everett S. Lee (General Electric Company, Schenectady, N. Y.): The paper by Messrs. Weller, Trekell, and Stebbins is another outstanding contribution to the accuracy of the watt-hour meter. It is also an outstanding contribution in measurements technique for when one must measure differences in watt-hour meter performance of a few tenths of one per cent within the accuracy which the authors believe to be within two-tenths per cent, the greatest of attention to every measurement detail is necessary. Particularly is this so when the measurements must be made in conjunction with large power apparatus together with the actual performance characteristics which apply and which must be taken into account.

Such tests are very costly because of their magnitude and it is for this reason that they may not be made to cover every conceivable case. In this particular case of the effect of wave form of mercury-arc rectifiers upon watt-hour meters, the question came up and had to be answered some years ago even without the results of actual tests, but from a knowledge of watt-hour meter performance this was done by the engineers, and the tests which Messrs. Weller, Trekell, and Stebbins have now reported in their paper confirm these earlier calculations and statements with exactness. This should be a continued assurance to the accuracy and dependability of the watt-hour meter.

As with the advance of more exacting performance requirements the microscopes of inquiry have been trained more and more upon it, the watt-hour meter has revealed itself to have the requisite characteristics demanded of its most exacting requirements. And all this in a particularly simple device produced and used by the millions.

As an example of a new method of approach to the performance of the watt-hour meter on intermittent loads, we have in the paper by Messrs. Faucett, Keener, and Helm (AIEE TRANSACTIONS, volume 59, 1940, pages 460–4) new statements of performance and these, too, as described in Mr. Trekell's discussion and in Professor Faucett's further statement, agree that differences found are so small as to be negligible in well-designed watt-hour meters. This, again, adds to the remarkableness of the performance of the watt-hour meter.

I. E. Weston (nonmember; Board of Transportation, City of New York, N. Y.): The paper gives us for the first time the results of tests on equipment comparable in size to the rectifiers used in traction work at present. This type of load is continually increasing, the Board of Transportation at the present time having some 240,000 kw capacity, all supplied under conditions discussed in the paper.

In connection with the power loss due to the various harmonics present, in a master's thesis at Brooklyn Polytechnic Institute in 1936 and in a paper in preparation, I give the following expression for this loss at light load for the delta-double wye, six-phase, six-anode connection:

$$P_{F0}=\frac{9RI^2}{2\pi^2}\left[1+\frac{1}{5^2}+\frac{1}{7^2}+\frac{1}{11^2}+\frac{1}{13^2}+\ldots\ldots\right]$$

which shows that the harmonic power loss varies inversely as the square of the order. Furthermore, the total harmonic power loss as given in this equation is about seven per cent of the fundamental power loss. If the latter is ten per cent, then the harmonic power is seven-tenths per cent which agrees with the authors' figure at light load. This harmonic power is all consumed in the feeders as I believe the authors have implied.

It would be interesting to know what transformer connections were used in the 6- and 12-phase rectifier tests as it is known that the value of harmonics varies with different transformer connections of the same number of phases. For example, the harmonic power loss in a star-connected rectifier is $33^1/_3$ per cent greater than in the double wye connection due to the different current-wave shapes.

Regarding the test results for the 6-phase rectifier, the increased meter speeds at higher loads is interesting. It may be due to one or several conditions. The effect of poorer power factor may show up at heavier loads. This tends to increase registration at the higher harmonics. Or it may be due to nonlinear effects in the iron circuit of the meter as another investigator has suggested. There seems to be some doubt in either case.

Regarding the harmonic volt-amperes in table V, why is the 11th and 13th greater than the 7th? Could these frequencies be approaching series resonance of the supply system, in which case maximum harmonic current is obtained?

Another question is why is the percentage of harmonic power greater at 156 per cent than at rated output (0.9 per cent compared with 0.6 per cent)?

Watt-hour meters on rectifier installations are tested against a rotating standard using only the voltage wave as a source of supply for both coils. This standard was previously calibrated on a sinusoidal wave at the laboratory. Thus the meter is not tested under actual operating conditions as it does not carry the current wave during the test.

Due to the fact that the feeder circuits to each rectifier installation are different, a single correction constant cannot be used for rectifiers at different locations. If the magnitude of wave distortion warrants a correction factor, it would have to be determined separately for each installation.

L. A. Burckmyer, Jr. (Cornell University Ithaca, N. Y.): The discussion of the technical aspects of this paper will be left to others, but I cannot refrain from expressing my appreciation of the presentation. It seems obvious that any paper should enable a reader quickly to discover whether its subject, method, or conclusion are of interest to him. If they are, full details must be available in order that he may form his own opinion of the validity, limitation, and application of the results.

This paper is outstanding in its *logical order of presentation*, giving the reader an immediate clear understanding of the object and scope of the work, of the results obtained, and of the authors' conclusions. Confidence in those conclusions, and facilities for checking them are provided by the *specific identification of all imporant apparatus*, with a tabular list of *complete ratings*, a concise but *complete description of connections and test procedure*, and a self-explanatory tabular presentation of detailed results. Curves, figures, and oscillograms are given *complete subtitles*, and *all test points are shown on the curves*.

Consideration of the requirements of the reader and of economy of his time often seems to receive little attention in the presentation of papers. Such a marked exception deserves special comment.

C. T. Weller, H. E. Trekell, and F. O. Stebbins: We are gratified at the interest shown in our paper and appreciate particularly L. A. Burckmyer, Jr.'s approval of its "logical order of presentation". In preparing the paper, we were somewhat uncertain as to how much rectifier theory and practice should be included, since the investigation covered primarily the performance of watt-hour meters. While the rectifier section of the paper is quite condensed, we believe measurement engineers will be able to determine from it the harmonics to be expected from 6- and 12-phase power rectifiers, both at light load and at rated output under representative conditions (see table IV, part 2, *A* and *B*).

I. E. Weston referred to the percentages of harmonic power at different outputs and to the relations between the volt-amperes at the various harmonics. It should be noted that the harmonic power values given represent the probable maxima, not the actual. These values of harmonic volt-amperes or power are based upon analyses of oscillograms; it is well known that such analyses are not accurate when the percentages of harmonics are small, as is the case with the voltage waves in these tests.

The 6-phase rectifier transformers were connected delta primary, 6-phase double-wye secondary and the 12-phase transformer was connected delta primary, 12-phase quadruple zig-zag secondary. Both of these circuits are widely used for power-rectifier railway and electrochemical installations, particularly for large kilowatt ratings. It is shown in reference 1 of the paper that for a given angle of overlap, the percentage values of harmonics of the same order in the input circuit currents for 6-phase rectifiers are independent of the transformer connections used. Thus, for a given kilowatt rating, the harmonic power loss in the supply system also is independent of the transformer connections. However, the wave shape of the currents is affected by the connections. In regard to the wave shape of the system voltages, we believe the harmonics are comparatively small in the majority of cases where rectifiers are supplied. This would indicate that watt-hour meter checking based upon such voltages is accomplished under approximately the sine-wave conditions obtained in our tests.

W. C. Wagner suggested additional tests on rectifiers, but the high cost emphasized by E. S. Lee constitutes a barrier. The work involved is indicated by the fact that over 4,000 instrument readings were taken in the 6-phase rectifier tests alone; the averaging and correction of these readings supplemented the analyses of 24 chronograph charts. Figure 5 of the paper shows part of the equipment necessary. Field tests, of course, would be very desirable and in this connection, W. C. Wagner's description of the new meter is interesting. As W. M. Young stated, numerous organizations are now working on various phases of the general problem of the effect of harmonics on watt-hour meters; this is most encouraging.

E. S. Lee also emphasized the question of accuracy. It should be noted that a change in the estimated accuracy of the present results of from 0.15 to 0.2 per cent was forced merely by rounding off the readings to the nearest 0.1 per cent. This involved shifts up to 0.05 per cent in individual values and up to 0.1 per cent in the differences between rectifier and sine-wave results shown in table II.

The var(rva)-hour and power-factor-meter results are of value chiefly in showing up certain other differences which enter the measurement picture along with harmonics, especially when these are confined largely to the current waves. Such differences have long been a source of misunderstandings. Thus in test numbers 2 and 2*a* with the 6-phase rectifier, a maximum difference of about three per cent was obtained between the power-factor-meter reading and the value calculated from the standard formula

$$\text{power factor} = P/\sqrt{3}EI \qquad (1)$$

The respective values are 0.976 and 0.946 [see formula (3)]. If the corresponding angles of about 12.5 and 19 degrees are substituted, the instrument evidently is indicating but 66 per cent of the calculated angle. A similar statement applies to the power-factor angle derived from the var-hour meter reading.

The most important result of the tests is the demonstration that the effect of 6- and 12-phase power rectifiers on the performance of typical watt-hour meters is less than 0.5 per cent. Also, the effect of a 6-phase rectifier on a var-hour meter is less than one per cent. It is concluded that limits of twice these respective values should cover all practical cases. The effect of a 6-phase rectifier on the power factor derived from the var-hour meter results or shown by the power-factor meter is about three per cent.

In table III of the paper, the performance of all usual instruments and meters is shown under conditions which are ideal, except for prominent harmonics in the line currents; the circuit voltages and currents are balanced and the harmonics in the line-to-line voltages are comparatively small. Thus the data and formulas in the paper afford an introduction to the effect of harmonics on instruments and meters and to the significance of some of the pertinent ASA definitions (ASA *C*42).

Application of and Operating Experience With Hydrogen-Cooled Synchronous Condensers and Alternators

Discussion and authors' closure of paper 40-76 by Philip Sporn and F. M. Porter, presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940, and published in AIEE TRANSACTIONS, 1940, pages 890–907.

Raymond Bailey (Philadelphia Electric Company, Philadelphia, Pa.): This paper is particularly valuable not only because it covers a subject which is of widespread interest, but also because it combines design and experience information in a way that is so useful to the engineer.

The statistics presented by the authors indicate considerable outage time for synchronous condensers on account of the water-cooling facilities and troubles with the rotors. It would seem to me that in view of the present state of design a very high proportion of outage time should not be required on account of either one of these items. Incidentally it is my belief that the design of both synchronous condensers and generators should be such that in the event of a leak in the water coolers the water cannot drain into the winding, but will be carried to the bottom of the machine.

It would appear that the authors' remarks about the use of hydrogen at pressures higher than nominally one-half pound are important and that this should receive the attention of others so that experience will be gained through the operation with hydrogen at higher pressures.

It would be interesting to learn of the viewpoint of the manufacturers' engineers on the effect of hydrogen on the design of windings for use at voltages above 13.2 kv.

It does seem to me that the auxiliaries needed for the use with hydrogen in generators are relatively complicated, but it may be that experience in the future will bring about a desirable simplification.

C. M. Gilt (Consolidated Edison Company of New York, Inc., New York): While the operating experience of the Consolidated Edison Company with hydrogen-cooled equipment is much more limited than that of the American Gas and Electric Company, its experience has likewise been generally very encouraging. There are now in operation in its Waterside plant two 53,000-kw 0.9-power-factor 13,800-volt, 3,600-rpm turbogenerators with hydrogen cooling and two 65,000-kw 0.8-power-factor units are on order for the same plant.

The first unit was put in service with air cooling on September 10, 1937. Trouble developed immediately with the shaft seals when oil was introduced for tryout purposes carrying oil into the generator. Certain changes in the design of the seals and particularly the oil drain off were made but it was agreed that the machine should be run without oil in the seals and at a somewhat reduced rating with air cooling until the bearing supports could be modified and the rotor slotted to reduce vibration. The desirability of keeping the machine in service delayed this work and hydrogen cooling was not introduced until July 6, 1939. Since then the hydrogen-cooling system and seals have given excellent service.

The second unit was put in service on June 29, 1938, and after preliminary tests hydrogen was introduced and has operated entirely successfully since. Up to January 1, 1940, the first machine had had 4,156 hours of operation in hydrogen and the second 11,762 hours.

While the distribution of losses is somewhat different in the two machines both have an appreciably higher rating in hydrogen than in air. The temperature rise of the first machine above the inlet air was 50 degrees for the stator and 100 degrees centigrade for the rotor when carrying 45 megawatts at 96 per cent power factor. The temperature rise of the stator was 35 degrees centigrade when carrying 45 megawatts at 96 per cent power factor when operated in hydrogen. The second machine when carrying 16 megawatts at 99 per cent power factor in air had a stator temperature rise of 42 degrees centigrade and a rotor temperature rise of 73 degrees centigrade. When carrying 46 megawatts at 97 per cent power factor in hydrogen, the stator temperature rise was 39 degrees centigrade and the rotor was 56 degrees centigrade.

The design of the equipment is of the low-pressure type maintaining a pressure of less than one-half pound. One of the new units will be designed for low-pressure operation but with provision so that the pressure can be raised to and maintained at 15 pounds, though with increased usage of hydrogen. The makeup of hydrogen on the two present units amounts to about 350 cubic feet of hydrogen each per week.

The hydrogen-control system of the two units, while differing in detail of equipment, performs essentially the same functions and is automatic in its operation and provided with alarms. The hydrogen in both machines is cooled by finned cooler tubes installed in the frame of the unit through which distilled water is circulated. Equipment and connections are provided for automatically turning on water from the city water mains in case of trouble in the normal water-cooling system.

The generator is scavenged with CO_2 in changing from air to hydrogen or the reverse. Three to four hours are required in the process of filling with hydrogen and about 1,900 cubic feet of hydrogen are used to fill a unit with a hydrogen volume of 1,400 cubic feet.

M. D. Ross and **C. C. Sterrett** (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): The writers are to be congratulated on their paper, which covers the field of experience with hydrogen-cooled machines from the earliest days of such apparatus and leaves little to be added in the way of comment. Such papers are of real value to both operating companies and the manufacturers as it brings out a frank discussion of problems encountered and their solution.

The earlier hydrogen-cooled condenser units were in some cases equipped with more auxiliary apparatus than was needed and there has been a gradual process of simplification in later units. As an example, one operating company dispensed with the automatic gas inlet valve and introduced gas by hand every few days. With such low gas leakage figures as indicated in the paper, this method of operation is satisfactory unless the operating procedure is such that the operator checks the unit at infrequent intervals when an automatic inlet valve would be justified. The company with which the writers are associated is also building two hydrogen-cooled condensers in which the hydrogen-purity meter is dispensed with and a portable Orsat gas analyzer being used to check the gas mixtures in filling and scavenging. As the gas pressure in the condenser is always above atmospheric pressure and gas flow is always outward, the purity meter does not seem to be a vital part of the equipment. The purity meter is desirable, however, on a turbine generator where the sealing oil may carry a certain amount of air into the hydrogen enclosure and the meter is needed to keep check on the purity and sound an alarm in case the purity drops below a certain value.

The authors mention the fact that carbon dust from the collector rings gets into the condenser. It should be noted that the New Carlisle condenser is equipped with a separate cooler and ventilating blower for the collector housing. The collector chamber forms a recirculating system in itself separate from the main enclosure so that carbon dust cannot get into the main enclosure.

The authors' data on their units certainly prove that hydrogen-cooled apparatus has progressed beyond the experimental stage and has a definite field of application in the larger high-speed equipment.

D. S. Snell (General Electric Company, Schenectady, N. Y.): The excellent and timely paper by Messrs. Sporn and Porter well illustrates the value to industry of co-operative effort between manufacturer and consumer in the development of a new product. Nineteen years ago, hydrogen cooling for electrical machinery was only an idea. Today, thanks to the willingness of the utilities to accept a radical innovation, and to the efforts of the manufacturers, hydrogen cooling is an established fact.

When this new type of cooling was first proposed, in 1921, its most desirable application was considered to be in connection with turbine generators, since this type of apparatus had the highest windage loss of any of the common types and would therefore show the greatest gain in efficiency by the use of hydrogen cooling. Accordingly, development of the hydrogen-cooled generator was early begun, and by the end of 1927 a developmental generator of 6,250-kva capacity had been in successful operation in hydrogen for nearly a year.

However, due to some reluctance on the part of the power industry to accept a hydrogen-cooled machine unless it was capable of carrying full-load rating in air, which was not an economically practicable proposition, interest in the hydrogen-cooled generator was slow in developing.

In 1928 the hydrogen-cooled synchronous condenser was introduced. This type of apparatus represented a considerably more simple application for hydrogen cooling than the turbine generator, since shaft-sealing equipment was not required. One of the first of these machines to be built was installed at the Turner station of the Appalachian Power Company and is described in the present paper. Later, several more hydrogen-cooled condensers were purchased for other companies on the same system. Experience with these machines, as reported in this paper, and with other machines of this type, was highly satisfactory and amply demonstrated the many advantages claimed for hydrogen cooling.

During the 1933–1935 industrial depression, considerable interest was developed in the superposed or "topping" turbine, as a means of increasing the efficiency of existing plants, which made desirable the construction of generators at 3,600 rpm in capacities considerably in excess of those previously considered practicable with air cooling, or which, if air cooled, would require external fans for ventilation. This made the use of hydrogen cooling for such generators highly advantageous, for the increased output per pound of material obtainable with hydrogen permits larger unit outputs and the construction of such units with internal fans. Also the saving in power with hydrogen cooling for large 3,600-rpm generators is a significant item.

As a result of the several years' successful operation of hydrogen-cooled synchronous condensers, there was little opposition, when business activity was resumed, to the adoption of hydrogen cooling for generators of the large 3,600-rpm type; hence the greater share of the generators ordered for operation with superposed turbines were hydrogen cooled. The first of these units to be ordered was the 50,000-kva Logan generator, mentioned in the present paper, and much credit is due Mr. Sporn and his organization for their foresight and courage in fostering this new product.

There have been placed in service to date, by the General Electric Company alone, a total of 14 hydrogen-cooled generators, with a combined capacity of 863,800 kva. Twenty-nine hydrogen-cooled generators are now under construction at the factory, having a total capacity of 1,578,000 kva. These figures are significant of the rapid acceptance by the power industry of this new type of generator, an acceptance which has benefited both the industry and the manufacturer and which, as has been pointed out, has been largely due to the co-operative efforts of both. Much appreciation is due the authors of the present paper and their associates for the significant contributions which they have made to this important development.

E. S. Henningsen (General Electric Company, Schenectady, N. Y.): It is seldom that a paper of so much interest and practical value to both operating and designing engineers is presented to the Institute. The authors are to be congratulated for this well-arranged record of the various developments, successes, and failures that have occurred during the little more than a decade since hydrogen cooling of rotating apparatus was initiated. It is particularly valuable in that the record covers such a large percentage of all of the hydrogen-cooled machines installed during that period.

Mr. Sporn's aversion to complacency on the part of designing engineers is evidenced by the record of changes and the number of new ideas tried out, such as: condenser speeds of 1,200 and later 3,600 rpm, 24,000-volt armature winding, electronic exciters, higher-pressure hydrogen operation, and 3,600-rpm hydrogen-cooled generators. He and his company have always been more than willing to try any suggestion that gave reasonable promise of being a step forward or a means of getting worth-while experience.

I think everyone will agree that the overall performance of these hydrogen machines has been good. Troubles experienced have largely been the same kind of troubles encountered on air-ventilated machines. The authors' figure of 29.9 per cent of the forced outages being attributable to construction for hydrogen operation is overly pessimistic in that they have included everything chargeable to this construction with no credit for the fact that many of these same outages probably would have occurred on air-ventilated machines. For example routine inspection of main shell and collector compartment account for 8.17 per cent of the forced outages. Similar inspections certainly should be made on air-ventilated machines although admittedly they would not take as long to make as with the hydrogen construction. Similarly, as the authors call attention to, collector and brush troubles are by no means confined to machines operating in hydrogen. These and other items charged lead me to express the opinion that only one-half to two-thirds of the 29.9 per cent of forced outages should be charged against the difference in construction between hydrogen and air-ventilated machines.

When one thinks back to the state of the welding art in 1927 when the first hydrogen condenser was built, it is no wonder that subsequent tests, as the authors report, showed them incapable of holding hydrogen at 15 pounds pressure. The wonder is that they held hydrogen at one pound and this was the biggest problem in the design of the first machine. The advance in knowledge in the welding art has made possible welded joints that are gastight at pressures higher than it is desired to operate.

It would be very interesting if a similar paper could be presented giving a record of operating performance over a long period of time of an equal number of air-ventilated condensers.

R. W. Wieseman (General Electric Company, Schenectady, N. Y.): The operating experience of the first eight hydrogen-cooled synchronous condensers installed on the American Gas and Electric system is a valuable contribution to the electrical industry. This experience, which covers nearly 60 machine years, shows that the machine availability factor is 96.1 per cent, but the availability factor for the hydrogen features alone is 98.8 per cent. This paper, therefore, indicates that the performance of the hydrogen features is quite satisfactory, in fact, it substantiates the claims on hydrogen-cooled rotating machines made nearly 20 years ago. The popularity of this development is indicated by the fact that in this country over four million kva of hydrogen-cooled rotating machines are in service or under construction. These machines range from 300 to 3,600 rpm, 4,150 to 24,000 volts, and 12,500 to 176,470 kva.

When hydrogen-cooled rotating machines were proposed, the explosion hazard was one of the debatable issues. To offset this, it was natural to build the first machines with an explosionproof shell which is still being used on present-day machines. This fear of explosion, however, has definitely diminished because, as stated in the paper, inert scavenging gases are no longer used when synchronous condensers are filled with hydrogen.

It is of interest to note that the first machine to be installed in 1928 has had a normal hydrogen leakage of only 4.4 cubic feet per day, or about nine cents per day. The bearing oil in this machine has never been changed. The main part of the unit including the bearings is inspected only once every five or six years. Since 1928 many improvements have been made such as in the collector compartment and seal arrangement, welding, surface-cooler construction, shell joints and gaskets, piping, and accessories, etc. Further improvements will no doubt be made especially with regard to simplifying the accessories. The hydrogen-purity indicator, for example, may be omitted on condensers since, as stated in the paper, it is of real service only in filling the machine with hydrogen.

One of the important features of a hydrogen-cooled machine which appeals to me is the excellent operating conditions provided for the winding insulation. Aging of the insulation due to oxidation no longer takes place. Corona damage on high-voltage windings is conspicuously absent. Harmful foreign matter which sometimes forms a blanket around an air-cooled winding has been eliminated and, as reported in the paper, the insulating varnish on the surface of the winding retains its high-luster finish. Obviously under these conditions insulation is at its best, and if properly maintained and protected, it will give many years of dependable service.

This is a most interesting and timely paper. The authors are to be congratulated on the thorough manner in which the subject matter is presented.

Soren H. Mortensen (Allis-Chalmers Manufacturing Company, Milwaukee, Wis.): The operating experience with hydrogen-cooled machines so ably presented in Messrs. Sporn and Porter's paper not only proves the practicability of hydrogen ventilation but also indicates paths for further developments, such as increased ratings by increased pressures as well as simplifications in the hydrogen control.

For comparison of generator outputs obtainable under various operating conditions, test results depicted in curves, figure 1 of this discussion, may serve. These tests were made some years ago upon a turbogenerator designed for hydrogen cooling. Constant loads were maintained until temperatures became constant with machine air-filled and later hydrogen-filled with pressures of one-half pound and 8.8 pounds per square inch respectively. Figure 1 shows that for 60-degree generator temperature rise, 100 per cent load was carried with air cooling, 126 per cent with hydrogen at one-half pound pressure, and

163 per cent with 8.8 pounds pressure per square inch. This test also brought out that the hydrogen leakage through generator walls, joints, and welds, increases approximately with the square root of the gas pressure. As the oil flow through the shaft seal was maintained approximately constant during the respective tests the hydrogen contamination or entrainment in oil was not appreciably affected by the test pressures.

Subsequent operating experiences indicated that shaft seals, generator materials, welds, and joints, can be made adequate to meet the requirement of higher gas pressures, thereby making possible further increases in generator outputs obtainable at 3,600 rpm.

Another of the features suggested in the authors' paper is the desirability for simplifications of the hydrogen control. One simplification made possible by the Allis-Chalmers type of generator shaft seal was described in the writer's discussion of hydrogen-cooled generators [AIEE TRANSACTIONS, volume 59, 1940 (January section), pages 48-9]. This discussion brought out the practicability of substituting vacuum scavenging for scavenging with inert gas in preparation for filling or evacuation of generator hydrogen. The elimination of scavenging with inert gas further permits simplification to the extent of omission of the piping otherwise used for this purpose.

Additional operating experience with Allis-Chalmers Company's hydrogen-cooled generators indicates the possibility of omission of the hydrogen-purity meter control. This simplification seems possible as the air volume entering the generator hydrogen with the seal oil is so small that the new hydrogen admitted to maintain pressure by making up for hydrogen leakage has been adequate to keep the hydrogen purity above the 97 per cent generally maintained by the purity meter. If further experience substantiates this, the purity meter can be omitted from the installations where vacuum scavenging is used.

In machines where the volume of the sealing oil contacting the generator hydrogen is small, special vacuum treatment of this oil becomes unnecessary and it can be taken directly from the turbine supply and returned to it through a detraining tank.

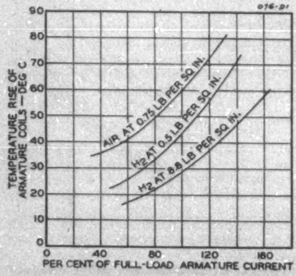

Figure 1. Comparison of air and hydrogen cooling at various pressures. Temperature rise of the armature coils in a 31,250-kva turbine generator

In conclusion I want to express my appreciation to the authors, for their very complete and constructive paper.

F. A. Lane (American Gas and Electric Service Corporation, New York, N. Y.): The Logan generator* went into service as a hydrogen-cooled machine on December 2, 1937, and from that time until September 30, 1939, the unit had run a combined total of 400 days. The running time lost during this period has not been occasioned by any trouble or maintenance in connection with the generator proper or its gas sealing system. The maximum load which has been carried over a one-hour period is 48,500 kw at 99 per cent power factor. Continuous loading of approximately 45,000 kw has been maintained without any operating difficulties, and without necessitating gas pressure above one-half pound per square inch to effect the required cooling of stator and rotor windings except for two weeks in September 1939, when the pressure was raised to approximately two pounds per square inch because of extremely high-temperature cooling water. In figure 2 of this discussion curves are shown giving the temperature rises which have been obtained for various loads and for one-half pound per square inch hydrogen gas-pressure operation. These rises are based upon the temperature of the ingoing pad liquid. Curve 2 indicates the temperature rise of the gas after it has passed through the finned-type pad coolers at the center of the machine. The maximum gas temperature reached at this point was 50 degrees centigrade. Stator temperatures are obtained by means of ten resistance temperature detectors located at various points in the coil slots and curve 3 shows the highest stator temperature rise. The highest stator temperature which has been reached at any time is 86 degrees, whereas the maximum permissible temperature is 100 degrees centigrade. The field temperature rise as given by curve 4 was obtained by means of a Leeds and Northrup recorder which indicates temperature change as measured by the rise of field resistance. The maximum field temperature which has been obtained is 108 degrees centigrade compared with the permissible maximum of 125 degrees centigrade.

PAD LIQUID SYSTEM

Plant condensate is used as make-up for the pad liquid system of the Logan generator. In order to eliminate the possibility of air pockets in the pads, it is necessary to obtain a high vacuum before filling with condensate. In this respect some difficulty was experienced initially but by circulating the pad liquid for some time and by wasting a portion from an overhead expansion tank, it was possible to remove practically all of the air still remaining in the pads. The operation of the system has been satisfactory and the pad liquid has not been changed since the initial filling. A partial inspection of the interior of the generator after a year's service gave no indication of any water leakage in the machine. Such an occurrence during operation would be detected immediately by the oil and water leakage indicator which is equipped with alarm contacts. The two heat exchangers for the pad liquid are used during the warmer months but only one exchanger is needed during most of the year.

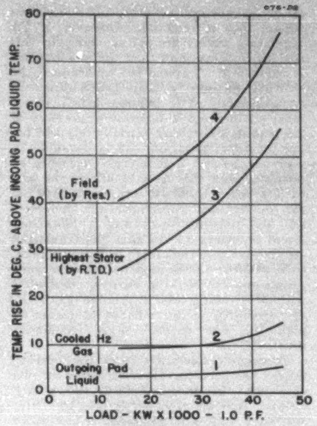

Figure 2. Load-temperature curves, Logan 50,000-kva turbogenerator

SHAFT SEALING SYSTEM

No difficulty of any great importance has been experienced with the shaft sealing system and its accessory equipment. No failure to maintain the seals has occurred at any time. This system as of September 30, 1939, had operated 500 days. The purity maintained during the first 224 days varied gradually from 99 per cent to 97 per cent but with continuous running it finally dropped as low as 93 per cent and scavenging with pure gas was necessary to bring the purity back to 95 per cent. It was determined that the difficulty was primarily because the seal-oil flow was greater than anticipated. As a result, the vacuum treatment of the oil was less than expected because of the greater amount of seal oil to be treated. Furthermore, a large quantity of air and moisture had to be removed from that portion of the seal oil which is drawn from the main oil tank to replace the oil flowing to the air side of the seals.

Changes were made in seal clearances and additional venting was provided in the bearings, which decreased the seal-oil flow 60 per cent. Since then the machine has been operated at $^1/_2$ pound per square inch gas pressure over a period of 161 days and a purity of from 98 to 99.5 per cent has been maintained. The seal oil pressure is automatically held at approximately 3 pounds per square inch above the gas pressure. With the machine stationary, the seal oil is cooler, its viscosity higher, and the differential pressure at the seals becomes approximately $3^1/_2$ pounds per square inch. At the same time, there is less liberation of air inside the generator, and the purity therefore builds up to approximately 99.5 per cent. The shaft sealing system is suitable for operation up to 15 pounds per square inch gas pressure, in which case a seal oil pressure of not less than 17.5 pounds per square inch is required. However, if the regulating valves are set to maintain this seal oil pressure, and then the gas pressure is reduced to $^1/_2$ pound per square inch the seal oil pressure automatically drops to approximately 5$^1/_2$ pounds which represents an increase in differential pressure of 2.5 pounds above that actually required for low-pressure operation. It is desirable to maintain as low a differential pressure as possible, since this directly affects the seal oil flow, which in turn determines largely the gas purity and consumption. Therefore, for high-pressure operation it has been found necessary to readjust the regulating valves to obtain the proper differential pressure desired. This adjustment is a very simple one and could be entirely eliminated without seriously affecting either gas leakage or purity, if intermittent operation at high and low pressure were frequently involved.

---

* Refer to section IX, paragraph A-5, of the paper.

Emergency operation from the bearing header has been run experimentally on two occasions. In the first case the purity dropped from 98 to 90 per cent in 15 hours, and later with a 60 per cent reduction in seal oil flow a similar purity drop occurred in 26 hours. During these operations the gas pressure actually increased slightly because of the air being released inside the generator more rapidly than the hydrogen was absorbed. With such operation it is possible that hydrogen may be released in the main oil tank, but the vapor extractor on this tank is depended upon to remove any hydrogen which might otherwise collect. During the test runs just mentioned it was not possible to detect the presence of any hydrogen in the main oil tank.

HYDROGEN CONTROL AND ACCESSORY EQUIPMENT

Experience with the gas-pressure-reducing equipment and accessories for automatically maintaining pressure in the generator has been excellent and similar to that obtained with synchronous condensers. Trouble was experienced initially with the purity indicator because of excessive vibration of the panel on which it is supported, but by the installation of springs and rubber mountings under the control cabinet reliable performance was obtained. One factor affecting the accuracy of this instrument is the possible presence of moisture in the sample of gas being circulated through the analyzing equipment which may cause inaccurate indication of two to three per cent. It has been necessary to periodically replace the calcium chloride in the dryer of the sampling circuit. This purity device has not given as accurate results as are desirable, but in general it is satisfactory for this service. However, it is believed that a more rugged and accurate device should be developed for this application.

GASTIGHT CONSTRUCTION AND HYDROGEN CONSUMPTION

In the case of a generator the gas consumption is determined not only by leakage through the outer shell joints, but also by the amount of hydrogen absorbed by the seal oil which is later evacuated from the oil and discharged to the atmosphere. Tests have indicated no appreciable gas leakage through the shell joints even at pressures as high as 15 pounds per square inch. A compound consisting of vacuum-treated triple-boiled linseed oil was initially forced into the sealing grooves and was apparently satisfactory for this service. However, in November 1938, it was found that lubricating oil from the bearings was gradually leaking into the sealing grooves and dissolving the sealing material. It was decided to replace it with a plastic sealing compound known as "Copaltite." This material which is not affected by hot lubricating oil has given satisfactory performance for the past 12 months. From the limited experience with the metal-to-metal type of joint for gastight construction, it would appear that it is preferable to the gasketed joint now in use for synchronous condensers.

The amount of hydrogen lost at the bearing seals depends upon several factors, such as oil temperature, oil flow to the gas side of the seals, and the degree of vacuum treatment. It also is affected by whether the shaft is rotating or stationary, although leakage results to date indicate no appreciable difference in gas consumption between the running and stationary conditions. Operation in hydrogen at approximately one-half pound per square inch in gas pressure, over a period of 115 days during the latter part of 1938 resulted in an average daily leakage of 48 cubic feet. Changes in the bearings as previously mentioned, decreased the seal oil flow, increased the degree of vacuum treatment, and decreased the gas consumption. Operation in hydrogen at approximately one-half pound per square inch over a period of 98 days from May to August 1939, has resulted in an average daily consumption of 38 cubic feet. The cost of delivered gas at this location is approximately two cents per cubic foot thus making the yearly cost approximately $275.

In February 1939, tests were made to determine gas consumption at several pressures up to 15 pounds per square inch for respective periods of 2$^1/_2$ or more days with the machine operating normally and with similar daily load cycles. Results obtained were as follows:

Average Gas Pressure (Pounds Per Square Inch)	Average Seal Oil Pressure (Pounds Per Square Inch)	Average Gas Consumption (Cubic Feet Per Day)	Duration of Run (Days)
0.5	3.5	40	12
4.9	7.2	115	6
10.1	12.6	221	3
15.1	17.6	351	2.5

Because of the many factors involved in determining gas leakage on a running machine with varying load and temperature, the above results cannot be considered to be extremely accurate, but for practical purposes they demonstrate conclusively that as far as gas consumption is concerned, operation up to pressures of 15 pounds per square inch can be accomplished with economy and reliability.

OPERATION AT HIGHER GAS PRESSURES

In the preceding paragraph there were mentioned the tests which were made at approximately 5, 10, and 15 pounds per square inch, respectively. During these runs various loadings were maintained for periods of sufficient duration to permit the obtaining of reasonably accurate temperature-rise data for the field and stator windings. These comparative curves are presented in figure 3 of this discussion and show clearly what may be expected from high-pressure operation. In the case of the stator winding, only the end windings of which are cooled directly by hydrogen, it will be noted that for a load of 45,000 kw 1.0 power factor the temperature rise as measured by resistance temperature detector decreased approximately 2.5 degrees centigrade for each 5 pounds per square inch increase in pressure. In the case of the rotor, as would be expected, the cooling effect is more marked, at this same loading, and indicates a decrease in temperature rise of approximately 7 degrees for the first 5 pounds pressure increase, another decrease of 6 degrees for the 5 pounds increase to 10 pounds per square inch and a further decrease of approximately 4 degrees for the 5 pounds increase to 15 pounds. Further tests will be necessary at steady loads in order to definitely and more accurately determine the shape and position of these various curves. The temperature rise of the cooled gas also decreases with increasing gas pressure, in the same manner as previously demonstrated in the case of synchronous condenser tests.

The operation of the shaft sealing equipment was entirely satisfactory at these higher pressures, although operation over longer periods will be necessary fully to demonstrate this. In the past there have been experienced at Logan, raw cooling water temperatures as high as 100 degrees Fahrenheit and for this reason, and to definitely check its feasibility, the machine was designed for higher-gas-pressure operation. Advantage can thus be taken of this additional cooling means during the extremely hot periods. In September 1939, the machine ran for several weeks with raw cooling water temperatures ranging from

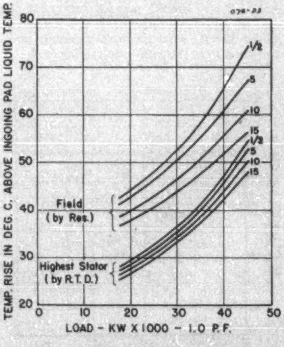

Figure 3. Load-temperature curves at various gas pressures, Logan 50,000-kva turbogenerator

Gas pressure in pounds per square inch indicated on curves

90 to 98 degrees Fahrenheit, with no difficulty whatever. The gas pressure was boosted several pounds per square inch to reduce maximum temperatures, but although loads as high as 45,000 kw unity power factor, were carried, no excessive temperature resulted.

Operating Experience With Windsor 66,667-Kva Turbogenerator*

This machine went into service as a hydrogen-cooled unit on April 21, 1939, and from that time until September 30, had run a combined total of 118 days. Running time lost has not been occasioned by any trouble or maintenance in connection with the generator proper or its shaft sealing system. The maximum load which has been carried over a one-hour period is 62,000 kw and 64,500 kva.

The shaft sealing system has been in continuous operation since April 1939, or for a total of 172 days (as of September 30, 1939). A purity of approximately 98 per cent is being maintained. At one-half pound per square inch gas pressure, the average daily leakage for a 100-day period with the machine running, from June to September 1939, was 54 cubic feet.

Since a portion of the oil for the seal system is drawn continually from the main lubricating oil tank, the vacuum-treating system for the seal oil is in effect a drying system for all the oil used by the turbogenerator. It is found, both at Windsor and Logan, that approximately one pint of water is extracted daily by the seal oil vacuum pumps.

After seven months' operation at Windsor, measurements were made to determine the amount of moisture in the hydrogen inside the generator. It was found that a typical sample of the cooled gas contained 5.5 milligrams of water per liter of gas. This corresponds to a humidity of 23 per cent at the temperature and pressure existing inside the machine at the point of sampling. No water has been collected in the leakage device at the bottom of the generator indicating that the humidity of the hydrogen is being held below the dew point. As long as any moisture is present in the lubricating oil or in the gas in the generator, it is evident that moisture will be released or absorbed by the oil at the shaft seals in a manner similar to that which causes air to be liberated or carried away at the seals. Therefore, the magnitude of the vacuum treatment and the rate of flow of the oil to the seals largely determine not only the hydrogen purity but also its humidity. Further determinations of moisture content in the gas are being made both at Windsor and Logan.

Philip Sporn and **F. M. Porter:** The general acceptance of hydrogen cooling for generators in the past few years has surprised and puzzled many engineers and operating men, to whom this modern type of cooling had just recently been introduced. The operating experience of the authors demonstrates that it is really a logical step following upon years of successful operation of many hydrogen-ventilated synchronous condensers. Quite a few papers concerning hydrogen applications have been presented, giving the results of tests, studies, and designs made by the manufacturers during the past 20 years, but little has been given regarding the practical application of hydrogen cooling. The authors have endeavored to fill this gap by presenting a fair picture, both detailed and general, of their experience with 12 machines running under all sorts of conditions.

Mr. Wieseman states that the elimination of the use of scavenging gas in the case of synchronous condensers shows that the fear of explosion has definitely diminished since the Turner unit was placed in service 11 years ago. This is undoubtedly true. Even in the case of generators the authors would not hesitate to change from air to hydrogen or vice versa without employing an inert gas, if the machine were stationary during the gassing operations. It is possible that in the future the scavenging procedures may be eliminated on all hydrogen-cooled machines except in cases where it is necessary to keep the generator in service when changing over from hydrogen to air. Mr. Wieseman agrees with the authors that the hydrogen-purity indicator, as far as condensers are concerned, is not an essential item and therefore may well be eliminated. As a matter of fact, a condenser is now being built for the Indiana General Service Company from which all devices for continuously measuring gas purity are being eliminated. A portable indicator will be employed to determine purity when gassing or degassing the machine.

Mr. Henningsen mentions that considering the state of the welding art some ten years ago, it is remarkable that the first machines hold gas as well as they do. Most of the leakage on the Turner unit during high-pressure tests was through the welds. An interesting comparison of approximate weekly gas leakage at 15 pounds per square inch on the following three units incidentally demonstrates great progress in the welding art:

Condenser	Built	Cubic Feet Per Week
Turner	1928	18,480
Scarbro	1930	1,000
Fostoria	1936	12

Mr. Henningsen believes that in table III the figure of 29.9 per cent given for outages due to construction for hydrogen is overly pessimistic. Actual work on bearings and other parts inside the machine has not been charged to hydrogen construction but the time required for removing gas and refilling is included. Inspections of air-cooled units can be carried out for the most part without shutting down the machine. It is possible that in all fairness the percentage above mentioned should be reduced slightly but the authors have felt it better to charge any questionable items against gas operation rather than otherwise. The important fact is that the availability of these machines is remarkably high and it is expected that operating results in the future will improve these figures to higher values. Similar data on air-cooled units will be necessary in order to be able to determine which type machine is more reliable and less subject to outage.

Messrs. Ross and Sterrett point out that in the case of the New Carlisle unit the collector housing is isolated from the main shell with separate coolers provided for removing heat losses in this compartment. This arrangement is provided to prevent the carrying of carbon dust into the main shell and it is undoubtedly an improvement in some respects over previous schemes. However, it does add the complication of additional coolers to be kept clean inside and out. Considering the small heat losses in this compartment, it should be possible to design the housing so that the heat can be dissipated without the use of coolers in the compartment or circulation of gas back to the main shell. As a matter of interest, for the past two years the Scranton unit has been operated almost continuously with the collector compartment closed off from the main shell and no excessively high temperatures have resulted in this housing. It is stated that two Westinghouse condensers are now being built with no permanent purity indicating equipment. The authors will be interested in following this simplification, which is likewise being adopted by them for a condenser now under construction as previously mentioned in this discussion.

Mr. Lane's description of operating experience with the Logan and Windsor generators demonstrates that the application of hydrogen to alternators gives the same satisfactory results that it does with synchronous condensers. The tests made at Logan at pressures up to 15 pounds per square inch are extremely interesting and instructive, and have contributed to the decision to have the new machines for Atlantic City and Philo designed for continuous operation at pressures up to 15 pounds per square inch in order to obtain additional economies possible with operation at this higher gas pressure. It is expected that the gas consumption at 15 pounds, on these units will be less than that which was obtained on the Logan unit. The humidity checks at Windsor over a period of months indicate that the gas is gradually becoming dryer. These tests were recently supplemented by similar checks at Logan, in which case a relative humidity of less than five per cent was obtained. As far as the generator gas is concerned, the drying action of the seal oil has thus been demonstrated on both units.

Mr. Gilt discusses briefly the experience of the Consolidated Edison Company with two hydrogen-cooled turbogenerators. Both from the standpoints of gas consumption as well as winding temperature rises, his experience has been similar to that of the authors.

Mr. Bailey points out that the auxiliaries for operation of the generator in hydrogen are too complicated. The authors are in agreement on this point but believe that after several more years' operation, existing shaft-sealing schemes will be greatly simplified or new ones developed, which will accomplish the desired results with less equipment and accessories than are now being employed. Mr. Bailey also states that the high outage attributed to rotors and water-cooling apparatus seems unnecessary in view of the present state of design of such equipment. As the authors pointed out, the rotors of the 1,200-rpm machines were of new design and this accounts largely for the high outage time chargeable to rotor trouble. As to the water-cooling equipment, there has been practically no trouble with surface coolers or piping inside the units. The breaking of a cooler vent pipe on one machine accounts for a great part of the outage chargeable to water-cooling equipment. It is believed that loss of service due to the above two causes will be greatly reduced in future operation.

---

* Refer to section IX, paragraph *B*-2 of the paper.

Mr. Mortensen states that tests which he made on a turbogenerator at various gas pressures, indicate that gas leakage varies with the square root of the gas pressure. In the case of synchronous condensers, tests made by the authors have been inconclusive but indicate that in general the leakage varies approximately with the gas pressure (above atmospheric). In the case of the tests at Logan the leakage again varied almost directly with the gas pressure (above atmospheric) with allowance being made for the approximately constant amount of gas normally absorbed by the seal oil.

The authors are grateful for the many kind remarks which have been made regarding this paper on hydrogen-cooled machinery. They are glad to have had the opportunity to present this information before the Institute, and they hope that a study of it will be of help to convince those needing light on this problem that hydrogen as a cooling medium for large electrodynamic machines offers not only many economic advantages, but, properly applied, is as safe as air or water.

Water Solution in High-Voltage Dielectric Liquids

Discussion and author's closure of paper 40-77 by F. M. Clark, presented at the AIEE winter convention, New York, N. Y., January 22-26, 1940, and published in AIEE TRANSACTIONS, 1940 (August section) pages 433-41.

T. D. Reimers (Consolidated Edison Company of New York, Inc., New York, N. Y.): This paper presents valuable data concerning the effect of moisture in liquid dielectrics and on solid dielectrics immersed in the liquid. It is evident that the data presented open a field for further research and may lead to the introduction of field service tests other than dielectric strength as a criterion of the operating condition of liquid dielectrics.

For a further understanding of the problem it would be desirable to expand figure 1 to show water solubility of transformer oil of various acidities. I would like to ask the author if any work has been done on this and if so what the data show.

In figure 2, water-solubility curves are shown for new and used Pyranol. What characteristic of Pyranol causes the increased solubility of water in used Pyranol? What are the characteristics of the used Pyranol tested as compared to new Pyranol? Can Pyranol in service obtain characteristics which will give greater water solubility than that shown for the used Pyranol curve?

Figures 1 to 6 indicate the greater solubility of water in Pyranol as compared to mineral oils. This suggests the need for exceptional care by the manufacturer in initially drying and sealing a Pyranol transformer and by operators in maintaining the unit. It suggests further development in gasket materials and gasket cements to seal adequately Pyranol equipment for long periods since there has been some indication that these materials are not as satisfactory as those developed for oil units. Perhaps the more general use of welded covers and the corresponding elimination of gaskets may be the ultimate answer to this problem.

Figure 7 indicates that wet Pyranol gives slightly more moisture to cellulose insulation than wet oil. Figure 8 indicates that wet cellulose insulation passes less moisture to Pyranol than to oil. This condition is unfavorable to Pyranol since the operator would prefer to have the moisture in the liquid where it can be more easily detected and can be more readily removed. It would be interesting to obtain similar data on used liquids.

The author uses figure 9 to illustrate the stability of the moisture in the cellulose insulation once it has entered and cautions that the moisture absorbed by the insulation is only released again by drastic treatment which involves the application of temperatures in the range of 95 to 100 degrees centigrade and even higher. To the operator this indicates a prolonged expensive process for the removal of such moisture. Apparently, mere filtering by a fullers' earth coated blotter press at room temperatures will not suffice and one gathers that it will be necessary to use loading transformers to maintain the temperature of the winding at 95 to 100 degrees centigrade to drive the moisture out of the cellulose insulation into the liquid where it can be filtered out by the fullers' earth coated blotter press. Figure 9 is for mineral oil and it would be interesting to have a similar curve for Pyranol.

Pyranol transformer conductor insulation usually consists of layers of paper and/or cotton covering which is not varnish impregnated presumably because no suitable impregnating varnish is known which would be insoluble in Pyranol. One wonders whether the impregnating varnishes generally used in oil transformers, provide a filler for the paper and cotton so as to reduce materially the amount of water they can absorb or appreciably prolong the time required to absorb moisture. Certainly, operators have had satisfactory experience in drying out flooded oil-insulated varnish-impregnated transformers without the application of heat as high as 95 to 100 degrees centigrade or higher.

Since the introduction of Pyranol transformers without varnish impregnation, similar construction has been extended to oil transformers. Perhaps it is better to continue the use of varnish impregnation on oil units until more complete data is obtained on the operation of nonvarnish-impregnated transformers.

The author mentions that the cloud-point formation temperature is a good indication of the amount of water in fluid dielectrics. However, he does not show any correlation between the temperature at which the cloud forms and dielectric strength of the sample at room temperature so that some comparison might be made between the cloud-point test and the more usual dielectric-strength test. Such a curve may be drawn from the author's data by replotting the dielectric strength values of figures 11 and 14 for 25-degree-centigrade testing temperature against the cloud points corresponding to the water content values as obtained from the author's figures 1 and 2. By this method figure 1 of this discussion is obtained.

The dielectric-strength measurements made by Mr. Clark were made with a 0.2-inch gap spacing. Plotted on this same figure is a series of tests made by the Consolidated Edison Company on 32 field and laboratory prepared samples of noninflammable insulating fluids with various cloud points and with dielectric strength tests made with 0.1-inch gap spacing. The curve obtained with the conventional 0.1-inch gap has a pronounced break not evidenced in the 0.2-inch gap curve. Admittedly more samples should be tested with the 0.1-inch gap to be certain that this curve is representative but the data indicate that further investigation should be made. It is to be noted that the change in dielectric strength with the 0.1-inch gap in the range of 35 kv to 13 kv is so rapid for relatively small changes in cloud point that any test value in this range indicates doubtful condition of the fluid. This has been confirmed by the variations obtained in successive field tests when the dielectric strength is in this range. In the past, dielectric strength values of 20 kv or better have been indicative of satisfactory insulating-fluid condition. These data would indicate that values of 35 kv or better should be used for Pyranol. No data have been accumulated for a similar transformer-

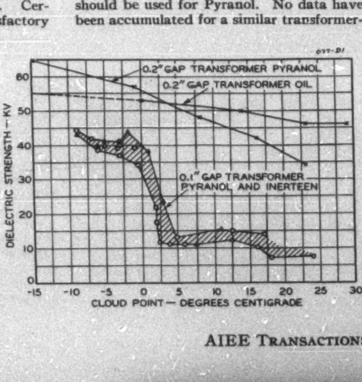

Figure 1. Dielectric strength-cloud point characteristics

X—Data from F. M. Clark's paper

△, □, ○—Data from Consolidated Edison tests

△—Field samples of Inerteen

□—Field samples of Pyranol

○—Laboratory-prepared samples of Pyranol and moisture oil curve but past experience would indicate that it does not have a similar sharp break above 20 kv.

Mr. Clark does not state what values of cloud point or dielectric strength should be considered satisfactory in service; and it is necessary to establish operating limits for these values.

Eric A. Walker (Tufts College, Medford, Mass.): In this paper Mr. Clark presents a tremendous amount of data from which all the possible conclusions are not immediately apparent. One further important conclusion might be arrived at from the data of figures 14, 17, and 18. In these figures Mr. Clark plots the dielectric strength of mineral transformer oil and transformer Pyranol as a function of temperature for various amounts of moisture. On these curves certain points are spotted with a *C*, indicating that by the presence of a cloud that some of the moisture was in suspension and some in solution. Now, because these points fall on the indicated curves it may be concluded that the dielectric strength of these two fluids is a function of the total amount of moisture present regardless of whether that moisture is in solution or in suspension. In other words, moisture in suspension is no more harmful than water in solution. Does Mr. Clark concur with this interpretation of his data?

Another surprising result of this investigation is the extreme slowness with which dry oil absorbs moisture from humid air. However, the author makes it quite clear that the test was carried out in a quiescent state. Very obviously this condition was chosen for experimental simplicity. Is it not possible that in a quiescent condition a thin layer of relatively dry air and a thin layer of relatively moist oil exists at the air-oil boundary and that the apparent slowness with which the moisture is absorbed is due to the slowness with which the moisture diffuses through the oil? It would be interesting to measure the effect of agitation or of pouring the oil over a thin lip as in passing it from one beaker to another.

Perhaps Mr. Clark might say a few words on why he chose the given method of water determination rather than other tests such as the Rodman or Grignard test. He might also comment on how accurate he believes his determination of moisture to be and also on the length of time required to test a sample.

Frank C. Doble (Doble Engineering Company, Boston, Mass.): Mr. Clark's interesting paper is a masterpiece in the preparation of curves from voluminous data that represent enormous man-hour efforts. The opening paragraphs of the paper give an accurate description of a very important problem exactly in the terms that have been recognized by the Doble client group for several years. The following comments about the rest of the paper appear to be in order:

Preceding the description of the water-extraction method, the subheading appears to be incorrect or misleading. Note that it reads: "A Laboratory Test for Quantitatively Determining the Amount of *Dissolved* Water in Insulating Oils." Apparently the method does not differentiate dissolved water from entrained or suspended water because inherently the apparatus measures the total of all kinds of water indiscriminately. Moreover, chemical authorities tell us that there is no known single method that will measure and differentiate dissolved water from suspended water in oil. Apparently the author tries to overcome this difficulty by relying upon the visible cloud test to determine saturation points on the assumption that invisible water must be in solution. Chemical authorities maintain that this is not a safe assumption because it is impossible physically to separate water in suspension and water in solution or to be sure that either form is present without the other.

"Solution" and "suspension" of water in oil are different physical states and may or may not be related directly to electrical characteristics.

We believe that a dielectric-loss measurement of oil may become a more practical criterion of its serviceability because it has a direct relation to electrical characteristics. Our use of a direct-reading meter type of dielectric-loss apparatus has allowed us to study transient conditions in the changes from water in solution to water in suspension. The direct-reading method gives indications of changes in form of water in oil which take place so rapidly that they cannot be followed by bridge measurements.

The amount of water in oil, whether in solution or suspension, is of great interest and the Doble group is working on the problem of its measurement with a method different from the one described by Mr. Clark. It is our hope that it may develop that the tolerance of oil for water in some form eventually may be a valuable criterion of its life condition from a deterioration standpoint. However, at the present time the operator of an electric-power system that is dependent upon oil as an important insulation is first concerned with the possible direct or potential hazard to operation due to the water, whatever its form may be.

From the standpoint of general utility, there is a need for some standard other than water in solution or water in suspension in oil since these two states are so difficult to differentiate and in view of the fact that both types of water may impair the electrical characteristics of the oil. This fact is emphasized by the author when he shows that the breakdown value of oil is lowered by the presence of water in solution, as well as by water in suspension.

As a supplementary standard, I would like to ask Mr. Clark why we should not give consideration to dielectric-loss measurements as criteria for good oil or for bad oil due to water whether it be in solution or in suspension. For this purpose, the terms "low loss" water and "high loss" water were suggested by me in an informal talk before the *D*-9 committee of ASTM at Atlantic City in June 1938, and again in a formal paper before the National Research Council meeting at Harvard University on November 2, 1939.

It is recognized that the dielectric loss of a sample of oil may include the effects of colloidal solution of varnishes and the products of oxidation, as well as water. However, none of these contaminants should be present in good oil. A "low loss" oil may, therefore, be considered suitable for service; a "high loss" oil obviously should be investigated to determine the nature and seriousness of its contamination.

Tentative standards for grading oil as to its serviceability by the dielectric-loss method have been in use by the Doble client group for a number of years and found to be of practical value to the operating companies.

We believe the difficulties that have been experienced in correlating dielectric loss measurements of oil with its dielectric breakdown strength and the presence of contaminants have been largely due to the presence of water in unknown quantities and unknown form. The development of a practical method for measuring the water content of oil should, therefore, facilitate further correlation of dielectric-loss measurements with the serviceability of oil.

For several years, as referred to above, the Doble company and four other laboratories have been collaborating on a general study of the oil problem from the power-company operating standpoint.

Mr. Clark and his associates have made a valuable contribution in this paper. We believe that the study of the problem should have the support of all interested parties, including oil producers, equipment manufacturers, and power-company users.

Since the work done by the Doble group, using a method different from the one described by Mr. Clark, has given results which vary somewhat from the data shown in his paper, may I suggest a symposium on the subject to be presented before the AIEE at the 1941 winter convention.

H. C. Louis (Consolidated Gas Electric Light and Power Company of Baltimore, Baltimore, Md.): The paper by F. M. Clark presents data of practical value for field as well as laboratory purposes. The indirect actions and effects in the transfer of moisture through oil to transformer insulation have not been as well understood or controlled as the more direct effects.

One special condition sometimes encountered with spare transformers on the Baltimore system is of interest in connection with this. Spare transformers of the air-breather type, after long periods of idleness, frequently show definite signs of moisture in the insulation, although the oil may show apparently excellent dielectric qualities. Such transformers are usually very difficult to dry out by ordinary methods. This indicates the advisability of occasionally exciting or loading spare transformers to avoid this condition.

A. E. Flowers (The De Laval Separator Company, Poughkeepsie, N. Y.): About 12 years ago the De Laval Separator Company made a study of the possibility of water being dissolved in oil.

Observation had shown sometimes that oil which had been centrifugally purified and had shown no visible evidence of water after purification and gave a high electric breakdown resistance, would a day or so later show low breakdown and cloud, or other evidence of water being present. Our investigation showed that water was truly dissolved in all oils, in amounts that increased markedly and increasingly with temperature, particularly at temperatures above 40 to 50 degrees centigrade.

We found further that on cooling, this water precipitated out, showing first a cloud and later droplets of water, which finally settled to the bottom of the container and during this precipitation a very low electric breakdown resulted.

We have since the time of that investigation urged users of our insulating-oil purifiers to carry out the separation at low or room temperatures.

We described this work in reports to the committee on insulating materials of the American Society for Testing Materials and in a brief paper in *Power*, February 16, 1932, "Solubility of Water in Mineral Oils" which doubtless escaped Mr. Clark's attention since it is not mentioned in the references.

Our laboratory has employed two types of tests in the measurement of the quantity of water present in insulating or other oils. One is the vacuum-distillation method and absorption and weighing in phosphorus pentoxide bulbs, substantially as described in Rodman's paper in the *Journal of Industrial and Engineering Chemistry* volume 13, December 1921, page 1149, "The Determination of Moisture in Insulating Oils".

The other method is by the use of a special high-speed test-tube centrifuge using a special type of glass test tube whose lower end is so shaped that volumes of one cubic millimeter may be read at the bottom tip, corresponding to 1/1,000 per cent or ten parts per million in a 100-cubic-centimeter sample. As this De Laval test-tube centrifuge runs at 6,000 rpm and the tube tips swing in a 20-inch circle, giving a tip force of 10,000 times gravity, a rapid and complete removal of all *free* water results.

Insulating oil from new drums or tank cars will have in solution an amount of water, depending upon the temperature, atmospheric humidity, and time of exposure. Equilibrium of large bodies of oil, such as in tank cars or large transformers may take several days, while exposure in a thin film on a watch glass may require only a few minutes. As the average atmospheric humidity is less than 100 per cent, and runs from 30 to 70 per cent such oil is generally *not saturated.*

For our investigation we carefully saturated the oil by vigorously mixing a large proportion of water to oil for periods up to 30 minutes, at or above the desired test temperature, then thoroughly centrifuged all free water out at this same temperature and decanted the *free water-free* oil to the vacuum-extraction bulb or into another test tube.

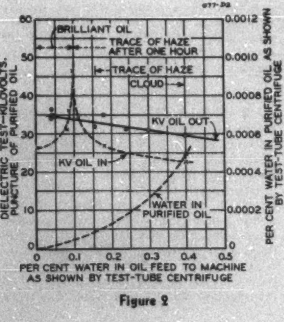

Figure 2

The procedure when using the test-tube centrifuge throughout was very simple, for if the oil is saturated at say 90 degrees centigrade then dropping the temperature in stages of 20 degrees centigrade each and holding at each level for half an hour or more, sufficient to bring about complete precipitation, allows the progressive measurement of the volume that had been dissolved in the oil at each temperature interval. An extension of this procedure below room temperature is quite feasible by refrigerant cooling of the machine and sample.

One advantage of the test tube is that it makes possible a clear distinction between *free* water and *solution* water. This is particularly important as electrical breakdown seems to be affected only by water in the *free* state. Samples can thus be prepared to enable studies of the effects of water in each state, that is, no water, dissolved water only, free plus dissolved water.

It is unfortunate that the author did not use the standard gap for electric breakdown tests nor add the breakdown values using the old standard of one-half-inch spheres separated 0.150 inch which is universally used abroad. Our laboratory has found quite erratic results with the present standard gap of one-inch disks spaced 0.100 inch when testing insulating oil with known quantities of *free* water.

Illustrative of one set of electric breakdown values, figure 2 of this discussion shows one set of such breakdown values. Another set of tests would show a generally similar shape but not identical values, as the breakdown is affected by the state of subdivision of the water and by traces of accessory contaminants that do not seem to be paper or other cellulose materials.

This whole question of the method of test for electrical breakdown is badly in need of being restudied by the Institute as well as the ASTM committee on electric breakdown.

The chemical method employed by the author is interesting and the results obtained by it should be correlated and compared with those obtained by other chemical methods such as those by

Evans, "Determination of Water in Paper-Insulated Cables and Insulating Oil," *Industrial and Engineering Chemistry*, October 15, 1939.

Larsen, *Industrial and Engineering Chemistry*, analytical edition, volume 10, 1938, pages 195–8.

Kipp, dissertation, Pennsylvania State College, 1939.

There are a number of pitfalls and difficulties in each of these methods and the volatility and reactiveness of some of the very light hydrocarbons that can come off from the best refined new insulating oils, leads to some question of these results. This is vividly brought out by the results reported by Doctor Kipp, where he found 0.03 per cent water in the most carefully prepared and carefully dried chemically pure benzene (C_6H_6).

The author is requested to add to his excellent paper an explanation of why he used the 200-mil 1½-inch-diameter disk gap; to describe how the samples were saturated and whether numerical figures could be given to the points on the curves marked *C* for the free water present.

F. M. Clark: Mr. Reimers asks concerning the relation between the solubility of water in transformer oil of varying acidity. The acidity of the oil, produced by oxidation, increases the ease of water emulsion in the oil. In general, it can be said that increased oxidation produces increased acidity and an increase in the solubility of water in the oil. To date, however, no definite relation between the oil acidity value and the water solubility in the oil has been able to be established.

Figure 2 must not be considered as a definite indication that Pyranol shows an increased ability to dissolve water as a result of commercial use. The difficulties inherent in this type of investigation caution against too fine a distinction between curves such as are shown in figure 2. In the use of Pyranol, it is desirable to eliminate all possibility of contamination by mineral oil or other soluble, oxidizable contaminants. The presence of such compounds in the Pyranol is reflected by increased acidity values and affects not only the fireproofing properties of the Pyranol but when present in sufficient quantity will lead to an increase in the ability of the Pyranol to dissolve water.

When it comes to the question of the drying of transformers in the field, it must be clearly recognized that it is necessary to carefully define the limits of the discussion. It may be that Mr. Reimers does not find it necessary to dry his flooded transformers at temperatures as high as 95–100 degrees centigrade. It is also undoubtedly true that he does not approach the degree of dryness which is originally obtained in the factory or which is under discussion in the data of figure 9. As stated in the paper, it is only when the moisture is "present in abnormally large amounts" that heating at temperatures below 95–100 degrees centigrade will be effective and then only to the degree that the "abnormally large amount" is present.

In figure 1, Mr. Reimers relates the dielectric strength of the noninflammable liquids with the cloud point and observes that there is a sharp "break" in the dielectric strength corresponding to a cloud point of 0 degrees centigrade and a dielectric strength of about 35 to 40 kv. This Mr. Reimers believes, to be different from the behavior of mineral oil and to warrant consideration of the application of more severe dielectric standards to the noninflammable liquids. This is of fundamental importance and warrants close inspection.

The measurement of cloud point is the degree centigrade. In discussing the cloud point and its correlation with the dielectric strength as Mr. Reimers has done, it must always be borne in mind that a change in the cloud point of one degree centigrade represents an increasing amount of dissolved water as the cloud-point temperature increases. This is immediately obvious from an inspection of figures 1 and 2 of the paper. This and the fact that the cloud point observed in commercial liquids may represent soluble products other than water, compels the exercise of great care in a technical inspection of such data.

In figure 1, Mr. Reimers shows a nonlinear S-shaped curve, relating the cloud and dielectric strength values for the noninflammable liquids. As indicated by Mr. Reimers, the data of the paper under discussion show a linear relation for both oil and Pyranol. This difference in behavior is attributable to the presence of secondary impurities, the effect of which is recognized to be of major importance in dielectric strength studies involving wet liquids. Of chief importance among such secondary impurities are cellulosic fibers which absorb moisture from the dielectric liquid with disastrous effect on its dielectric strength. For liquids in a condition approaching the completely dry state, the presence of these secondary impurities prevents the realization of the inherently high dielectric strength normally associated with the dry liquid, especially where the test gap used is only one-tenth inch. This gives an apparent maximum in the dielectric strength relation, as shown by Mr. Reimers. With increasing water content, the effect of water assumes increasing importance and ultimately the combined effect of the secondary impurities and the water results in a rapid fall in the dielectric strength. This Mr. Reimers has indicated would be at a dissolved water content corresponding to approximately 0 degrees centigrade cloud point (40 parts per million for Pyranol).

In the data of the paper under discussion, the presence of secondary impurities has been avoided. The relations established describe the primary effect of dissolved and suspended water on the dielectric strength of the liquid. At 25 degrees centigrade, the effect of increasing water content gives a linear decrease in the dielectric strength of the liquid. If however, fibers are incorporated in the wet liquid, the dielectric strength falls precipitously when the cloud point of the liquid is increased from −10 to +10 degrees centigrade. This is illustrated in figure 3 of this discussion. In obtaining the data on which figure 3 is based, the Pyranol is stirred with wet linen tape, thereby incorporating wet fibers in the wet liquid. The dielectric strength-cloud point relation of Pyranol treated in this manner closely duplicates the data submitted by Mr. Reimers. When, however, this same wet-fiber-containing Pyranol is filtered through a sintered glass filter, thereby removing the wet fibers, the dielectric strength of the wet-fiber-free liquid falls more slowly and in a linear relation to its cloud point, greatly resembling the relation presented in the data of the paper under discussion. A similar effect is illustrated in the relation illustrated on figure 4 of this discussion which describes the measured water content of the Pyranol before and after glass filtration. Tests on mineral transformer oil, similarly treated, have yielded similar results and relationships. From such data it is concluded that the relation presented by Mr. Reimers does not describe the effect of water, per se, on the dielectric strength of the Pyranol but describes the combined effect of water and wet secondary impurities. Since the consideration of the effect of secondary impurities is beyond the scope of the present paper, complete discussion is reserved for a later paper which the author hopes to present to the Institute.

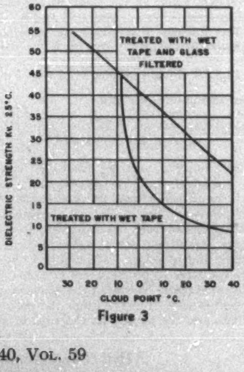

Figure 3

Complete consideration as to whether water in suspension is more harmful than water in solution involves many factors. Figures 14, 17, and 18 referred to by Mr. Walker indicate the effect of the total water present on the dielectric strength. Increased water content leads to decreased dielectric strength Since water in suspension is normally indicative of the presence of larger total amounts of water than are present in clear liquids, suspended water in insulating liquids can only be considered as presenting a more dangerous condition.

The method of test described was selected for use in order to avoid the many pitfalls inherent in a test such as that described by Rodman. The accuracy of the test method selected is approximately plus or minus 2 parts per million at a water content of 30 parts per million. The length of testing time and other details are given in the paper.

Mr. Doble draws attention to the well-known fact that solutions may consist of true solutions or colloidal solutions. In the paper the terms water in solution or suspension are used in the general sense. Water in suspension is distinguished from the general class of water in solution on the basis of visibility and ability to settle under gravity. No distinction is drawn between water in true or colloidal solution.

Mr. Doble is correct in his statement that the operator of an electric-power system that is dependent on oil is concerned with the direct and potential hazard to operation due to water whatever its form may be. In the paper under discussion, therefore, only the total water present and its effect on the dielectric properties of the liquid have been considered. Good dielectric strength has always been looked upon as an indispensable requirement. Recently the dielectric loss has been suggested as of equal importance. Mr. Doble's belief that this type of measurement may become a more practical criterion of oil serviceability is worthy of consideration. Whether this gives justification for a distinction between two dielectric types of water as suggested by him may be seriously questioned when the whole question of the water hazard is reviewed with respect to its effect on the oil and its effect on the cellulosic insulation.

Doctor Flowers asks why a 0.2-inch test gap was used in place of the more common 0.1-inch gap. The 0.2-inch gap was used merely to reduce the possibility of a complete bridging of the electrode gap by a single water droplet held in liquid suspension. It was believed that the use of a larger test gap would allow a more reliable study of the effect of water on the dielectric strength of the liquids.

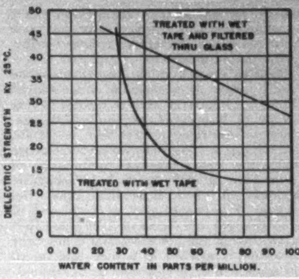

Figure 4

Determination of Short-Circuit Torques in Turbine Generators by Test

Discussion and authors' closure of paper 40-78 by E. C. Whitney and H. E. Criner, presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940, and published in AIEE TRANSACTIONS, 1940, pages 885–9.

S. B. Crary (General Electric Company, Schenectady, N. Y.): This paper is a valuable contribution in two respects. First, the instantaneous calculated short-circuit torques for three types of faults are confirmed within practical accuracy by actual test. Second, equations are developed for the unidirectional torques which influence the machine and system stability characteristics.

The torques developed by terminal short circuits as shown in the paper result in high instantaneous values of fundamental-frequency and twice normal-frequency torques. In some respects this makes them less severe than if they were at a lower frequency, depending of course on the physical construction of the machine and foundation under consideration.

If a machine is accidentally synchronized considerably out of phase to a system which has electrically a lower reactance than the machines being synchronized, the fundamental and twice normal frequency torques may be larger than that for a terminal short circuit and the low-frequency or unidirectional component may have a magnitude approaching as a limit the maximum instantaneous value of torque for a terminal short circuit. The amount of this high unidirectional torque due to bad synchronizing which is transmitted through the shaft is a function of the relative inertias of the generator rotor and the driving machine. The shaft torque would be higher in times normal for a frequency changer set and a condensing-steam-turbine-driven generator than for a water-wheel or noncondensing-steam-driven generator.

Another possible cause for high unidirectional torque is a terminal short circuit through a relatively high resistance having a value of the order of magnitude of the machine subtransient or transient reactance. For the case of a high-resistance three-phase fault, the high-frequency components of torque are quickly damped and may be critically damped depending upon the amount of resistance and, as is the case of synchronizing out of phase, the maximum magnitude of the unidirectional component of torque is reached in a time interval of the order of a cycle or less of the fundamental electrical frequency.

A third cause for high torques of low frequency, although in general of less magnitude than that for extremely bad synchronizing, and for a high-resistance fault, are the torque swings due to system faults, switching, and possible running out of synchronism. Running out of synchronism may be particularly serious if the relatively low-frequency torque pulsation so produced approaches the natural frequency of any of the mechanical parts of the machine.

Accordingly, in order to relieve the stress on an electrical machine, particularly with a relatively large driving machine WR^2, it is advisable to insure against bad synchronizing and of running out of synchronism.

The equations which the authors have presented are applicable only to low-resistance faults. This is not a criticism, for to include completely the effect of resistance is necessarily difficult. However, there appears to be some advantage, if only to confirm the physical understanding of this effect, to consider some of the additional effects produced by resistance. If this is done considering constant rotor flux linkages, to show the effect of armature-circuit resistance, the expression for the torque resulting from a three-phase short-circuit, assuming $x_d''=x_q''$, is,

$$T=\frac{re_0^2}{x_d''^2+r^2}-\frac{re_0^2\epsilon^{-\frac{r}{x_d''}t}}{x_d''^2+r^2}+\frac{x_d''e_0^2\epsilon^{-\frac{r}{x_d''}t}}{x_d''^2+r^2}\sin t$$

This expression shows that the unidirectional component of torque due to armature circuit resistance increases at a rate determined by the armature-circuit time constant, that the maximum magnitude of unidirectional torque is obtained when $x=r$, and also the manner in which the fundamental-frequency component of torque is affected by armature-circuit resistance.

The authors show in their equations a torque component, that due to the rotor resistance caused by the d-c component of armature current, which is ordinarily neglected in the usual stability study. This effect is of greatest importance for a solid fault at the terminals of a solid-rotor low-reactance machine and should not be neglected for this case. Otherwise if the fault is on the high-voltage system, the rate of decay of the d-c component of short-circuit current is usually sufficiently rapid to render this component of torque unimportant. For water-wheel-driven generators the effect is small even for terminal faults.

From a stability standpoint the three-phase and double-line-to-ground faults are the most severe, the line-to-ground being comparatively insevere and the line-to-line fault usually involves ground. Accordingly, it would seem worth while if the authors would include in their table I the expression for the torque produced by the double-line-to-ground fault as well.

It would be of interest to know if the authors were able to determine the value of R_2 for the machine they tested and how well it compared with their formula

$$R_2=\sqrt{2}R_{rs}+R_1$$

Also whether they were able to confirm by their tests that the rotor-loss component of torque varies as the 1.8 power of the current. In this respect, it would be of interest if the authors could show the numerical equations for the calculated torques presented in the paper so that the relative importance of the different components of torque could be readily evaluated.

Ernst Weber (Polytechnic Institute of Brooklyn, Brooklyn, N. Y.): The authors claim that "as far as is known the test results of this paper constitute the first experimental check . . . as applied to a turbine generator." I should like to point to the treatise by H. Rikli on, "An Experimental Investigation of the Sudden Short Circuit," published in the *Bulletin* des Schweizer Elektrotechnischen Vereins (of the Swiss Electrical Association), volume 16, 1925, page 217.

In that paper, oscillograms of currents, voltages, and speed are reproduced for various short-circuit conditions of a turbine generator for 2,500 kw at 3,000 rpm. The speed oscillograms are rather clear and permit, by differentiation, the evaluation of the torque variation. True, the accuracy in finding the slope of oscillograms is not as high as desirable, but the accelerometer utilized by the authors has a most annoying natural frequency which in turn impairs the accuracy of their results.

It might also be of value to refer to the series of books, "Electrical Machines", by R. Richter (successor to E. Arnold), published by J. Springer, Berlin. Volume 2 (1930) of this series devotes about 500 pages to synchronous machines, of which 74 pages deal with short-circuit phenomena.

Finally, would it not be more accurate to refer to all the formulas used by the authors in computing torque values as semi-empirical? One would be somewhat relieved to know that the remarkable agreement in certain cases between calculation and test is due to a compromise between theory and experience, rather than a unique feat of theory alone. After all, as the authors admit themselves, many factors have been disregarded from the start in formulating the expressions for the torques.

H. D. Taylor (General Electric Company, Schenectady, N. Y.): The authors' experimental check of the theoretical equations for short-circuit torques in turbine generators is a very interesting and valuable piece of work. The confirmation of the analytical work of Nickle, Pierce, and Henderson on the *alternating components* of torque is particularly gratifying. With regard to the unidirectional or *loss components*, it appears that in the absence of considerable external resistance, these are generally not large enough to have much effect on the torque peaks. If I have interpreted the authors' numerical results correctly, the loss components apparently add about 12 to 15 per cent to the peak torque values for three-phase and line-to-line short circuits on their 12,500-kva machine. In order to bring out the relative size of the various components, I would like to suggest that the authors give the numerical values of 60-cycle, 120-cycle, and loss components, as shown by their equations, for the cases given in table II.

E. C. Whitney and H. E. Criner: The authors wish to thank the various discussers for their very pertinent and interesting discussions.

In line with several suggestions concerning table I, the authors have revised the table to include a calculation for the double-line-to-ground fault. The table as printed in the paper is the revised edition which includes several corrective suggestions made by S. B. Crary and C. Concordia which did not affect the calculations of the tests shown in the paper as well as the torque calculation for a double-line-to-neutral fault. In the double-line-to-neutral fault several items in the nomenclature were added as shown in the table. X_1, X_2, and X_0 are used to indicate the total reactance in the positive, negative, and zero sequence networks respectively. Also there are several terms which involve larger approximations than in the other formulas due to the difficulty in determining the d-c component for this type of short circuit.

With respect to the comment concerning the factor R_{rs}, it is probably true that from the purely theoretical standpoint R_{rs} should be more nearly equal $\sqrt{2}(R_2-R_1)$ than $(R_2-R_1)/\sqrt{2}$. However, this portion of the unidirectional torque is a fairly large percentage and it would appear from the tests that the value given in the paper will yield better results and in this sense must be considered somewhat empirical. Since it was impossible in the time allotted to test R_2 accurately, this presents an additional possibility for error from this source.

To compare the relative magnitude of the various components of torque the per-unit torque coefficients of the various terms are shown below for the machine in question. When decay factors F and A for specific times are applied the results will add up to the values given at the peak of the calculated torque curves of figures 5 and 6. For the test machine $R_1=0.0064$ and $R_2=0.036$.

Three phase case:

$$T=11.5FA\sin\omega t+.85F^2+1.7A^{1.8}$$

For the line-to-line case:

$$T=11.5FA\sin\omega t-5.75\sin 2\omega t+1.77\times(1-\cos 2\omega t)F^2+1.69A^{1.8}+2.2F^{1.8}$$

The electrical torques resulting from a line-to-neutral and double-line-to-ground short circuit will always be smaller than the three-phase and line-to-line short circuits.

Mention has been made of the electrical torques resulting from synchronizing a machine out of phase. This subject is entirely too large to be discussed here as it depends on the relative size of the machine and the system as well as the angle between the machine and the system at the time of synchronizing. Also the natural frequency of oscillation of the machine with the system must be considered. However, as a limit of the rated-frequency torque pulsation, consider the case of synchronizing 180 degrees out of phase with an infinite system. This case resolves into the equivalent of a three-phase short circuit from twice rated voltage. This is, of course, a condition of very, very bad operation and should never be permitted to exist since dire results are possible.

With reference to the earlier paper presenting experimental data on the subject of short-circuit torques, the authors are sorry that they missed the earlier Swiss paper. However, upon reviewing this paper it appears it would be very difficult to differentiate the speed curves to get the torque accurately in the first place, and in the second place, the construction of European turbine generators of that vintage differs considerably from present-day American machines which partially nullifies the benefits of the test. In the third place this paper was written before any of the present-day reactance concepts were invented and thus there is little possibility of correlating the information with modern data. With respect to the textbook by Richter, there is practically nothing presented dealing specifically with this problem except part of the theoretical background of this paper.

While it is true that this paper necessarily presents some empirical data most of the factors involved were derived directly from theoretical consideration. All work done previously applying to turbine generators, except the work mentioned by Professor Weber, was entirely theoretical in character.

Basic Impulse Insulation Levels

Discussion and authors' closure of paper 40-83 by Philip Sporn and C. A. Powel, presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940, and published in AIEE TRANSACTIONS, 1940 (October section) pages 596–8.

J. E. Clem (General Electric Company, Schenectady, N. Y.): This report is another step in the advance of the industry toward the establishment of a uniform and orderly array of insulation levels to be used for the application of electrical equipment. Because the report affects all the major lines of equipment, it should be considered very, very carefully before the values suggested are definitely adopted.

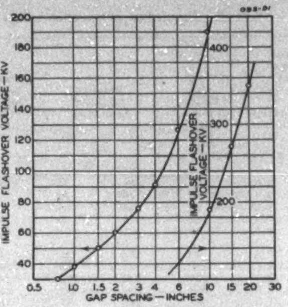

Figure 1. Impulse flashover, rod gaps

The report states: "Some of the porcelain insulators in bus and switch assemblies do not meet the basic impulse level proposed for the system voltage on which they are commonly used". This is rather disconcerting because the flashover data available a few years ago indicated that these same insulators were comfortably above the insulation levels being considered at that time and even above those proposed in the report. Accordingly, I have retraced some of the steps in the development of the proposed levels in an effort to discover the cause of the difficulty in which certain bus insulators now find themselves.

The initial report of the committee on basic insulation levels was adopted in January 1937 and was presented at the 1937 summer convention, and appears on page 711 of the June 1937 issue of ELECTRICAL ENGINEERING. In table I, "Basic Impulse Insulation Levels", a set of impulse insulation values, together with the corresponding gap spacing in inches, are given for the various voltage classifications. In the footnote the following statement appears: "Gap spacings are those giving 50 per cent flashover and 50 per cent full wave when subjected to 1.5x40 positive impulses with crest values given in column 2 under standard conditions of air density and humidity". With but one exception (345 kv, 106 inches instead of 105.6 inches), the gap spacings given are identical with the test gap for transformers appearing in table I, page 750, of the same issue of ELECTRICAL ENGINEERING.

Since we had gaps with us for impulse testing before we had kilovolts, it seems reasonable to recheck the kilovolt values corresponding to the given gap spacings. In the same issue of ELECTRICAL ENGINEERING, on page 712, there is a report of the laboratory committee, "Flashover Characteristics of Rod Gaps and Insulators". Table II of this report, page 713, gives average impulse flashover voltages for rod gap spacings.

Table I. Comparison of Flashover Values

Gap Spacing	Flashover Voltage*	Flashover Voltage†
20	350	346
30	505	504
40	650	656
50	800	807
60	945	956
70	1,095	1,103
80	1,240	1,297
90	1,385	1,390
100	1,530	1,536

* Values from table II, page 713, ELECTRICAL ENGINEERING, June 1937.

† Read from curve corresponding to empirical expression

$$\text{Flashover} = 182.1\left(\frac{S}{10}\right)^{0.926}$$

The data in table II of the report, for gap spacings up to 20 inches, were plotted on semilogarithmic paper, using the minimum values (for obvious reasons) over the unstable range. This gives a very smooth curve, as indicated in figure 1 of this discussion. Above this point the curve is a straight line on log-log paper and the values correspond very closely to those calculated from the empirical equation given in table I of this discussion, which table also compares the tabular values with the empirical values. Using the curve in figure 1, and the empirical equation in table I, the average flashover values for the various test gaps, or gap spacings, have been determined and are listed in column 6 of table II of this discussion.

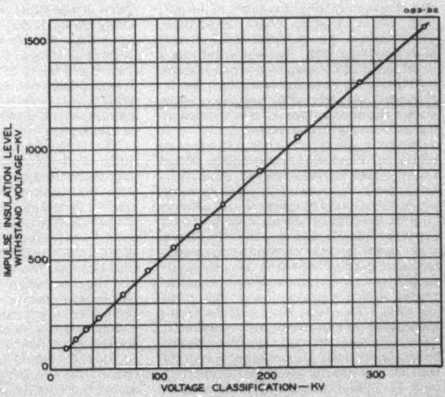

Figure 2. Required insulation level

Table II. Comparison of Insulation Levels

			Distribution Transformer Test Gap			Required Insulation Level (Kv)					Standard Insulation Levels (Kv)		
Insulation Class (1)	Gap Spacing (Inches) (2)	B.I.L. 1937 Kv (3)	Flash-over Kv (4)	Spacing (Inches) (5)	Test Gap Flash-over Kv (6)	(7)	(8)	Power Transformer Test Kv (9)	Proposed B.I.L. Kv (10)	Proposed B.I.L. Kv (11)	(12)	(13)	(14)
0.6										30			
1.2	0.8	32	32	0.8	32	29	30	60		45	60	30	
2.5	1.6	53	53	1.6	53	49	50			60		45	30
5	2.2	63	63	2.2	63	58	60	76	75	75	75	60	45

345	106.0	1,620	1,620	105.6	1,617	1,488	1,537	1,540	1,550	1,550	1,550		

1. Same as column 1, table I, page 711, June 1937, ELECTRICAL ENGINEERING report "Basic Insulation Levels", with values 0.6, 7.5, and 23 added.

2. Same as column 3, table I, page 711, June 1937, ELECTRICAL ENGINEERING.

3. Same as column 2, table I, page 711, June 1937, ELECTRICAL ENGINEERING.

2–3. Footnote to table I quoted reads "Gap spacings are those giving 50 per cent flashover and 50 per cent full wave when subjected to 1.5x40 positive impulse with crest values given in column 2 under standard conditions of air density and humidity". Actually there are average flashover values based on data in table II, page 713, June 1937, ELECTRICAL ENGINEERING report "Flashover Characteristics of Rod Gaps and Insulators", and so are subject to the same deviation of plus or minus 8 per cent.

4–5. These values taken from columns 10–11, table I, page 750, June 1937, ELECTRICAL ENGINEERING report "Insulation Strength of Transformers". Although not specifically stated these test gaps apply only to distribution transformers over part of the voltage range, because power transformers received a higher test on account of the larger bushings used.

6. Values read from figure 1 and calculated from equations in table I of this discussion. Based on data in table II, page 713, June 1937, ELECTRICAL ENGINEERING report of subcommittee on correlation of laboratory data "Flashover Characteristics of Rod Gaps and Insulators" and therefore subject to a plus or minus deviation of 8 per cent. Check on columns 3 and 4.

7. Obtained from column 6 by multiplying by 0.92 to obtain minimum values in consideration of the deviation in test results of the data on which values in column 6 are based.

8. Obtained from column 6 using multiplying factor of 0.95 on account full-wave test on transformer is 5 per cent less than test-gap flashover.

9. These values taken from table II, page 752, June 1937, ELECTRICAL ENGINEERING and are the full-wave test values for power transformers.

10. From report by Powel and Sporn with values 60 kv and below omitted.

11. Proposed value of basic insulation level based on columns 3–6–8 and curve 2 of this discussion. It is understood that the implied allocation applies only to power transformers and large outdoor circuit breakers for insulation classes 15 kv and below and 34.5 kv and below respectively.

12. Application of insulation levels to power transformers for all entries and to outdoor circuit breakers 15 kv and up.

13. Application of insulation levels to distribution transformers, instrument transformers, indoor circuit breakers.

14. Application of insulation levels to some instrument transformers and indoor circuit breakers.

Columns 1, 2, 3 of table II are taken from table I, page 711, of ELECTRICAL ENGINEERING, June 1937, of the report of the joint committee on basic impulse insulation levels. The same numerical values throughout, except one at 345 kv, appear in the report of the transformer subcommittee on "Insulation Strength of Transformers", in table I, page 750, of the same issue of ELECTRICAL ENGINEERING, see columns 4 and 5 of table II of this discussion. The numerical values in column 6 and in column 3 are so close together that the situation as it affects bus insulators is not affected by variations in the results obtained by the process of translating gap spacing to kilovolts.

In the report of the laboratory subcommittee on "Flashover Characteristics of Rod Gaps" appearing on page 712, June 1937, ELECTRICAL ENGINEERING, the deviation in the test results of impulse flashover voltages is given as plus or minus eight per cent. Since the kilovolt values of basic insulation levels in the report of the insulation co-ordination committee are based upon the average flashover voltage of a rod gap, their deviation obviously is the same as that of the gap data. Therefore, when it is desired to translate them into withstand, or minimum, values it is necessary that they be multiplied by the factor 0.92. The result of this arithmetical operation is given in column 7 of table II. The values in this column represent the minimum withstand test values justifiable from the initial report of the Joint NEMA-EEI Committee on Co-ordination of Insulation.

However, established practice for transformers permitted a full wave test at a value five per cent lower than the average values given in the initial report. Because of this established practice, the change in the average values, already published, to proposed withstand values, was made by multiplying by the factor of 0.95 and the result of this multiplication is given in column 8 of table II. It should be noted that both multiplications were made upon the values given in column 6.

The values in column 9 are taken from table II of the report of the transformer subcommittee, appearing on page 752 of the June 1937 issue of ELECTRICAL ENGINEERING. The values represent full-wave test voltages for power transformers and it should be noted that they are higher than those for distribution transformers (which are five per cent less than the values in column 4 or 3) and that the values for distribution transformers correspond to the values of the basic insulation levels proposed in 1937.

The reason the values for the power transformers are higher is as follows: Initially, one of the required impulse tests on transformers was a flashover of the bushings with an applied overvoltage of not less than a specified amount. Bushings for power transformers had already become quite well standardized and were higher than the values proposed in 1937 for basic insulation levels for voltage classifications 69 kv and below and were also higher than the flashover characteristics for bushings as used in distribution transformers. It was thought to be inadvisable to reduce the bushing flashover and, consequently, the practice of giving power transformers an impulse test higher than the basic insulation levels in those voltage classes 69 kv and below became established.

In column 10 of table II are given the proposed values appearing in the paper by Sporn and Powel. These figures are identical with those appearing in the report of the joint committee on standardization of bushings. Comparing columns 9 and 10 it is quite apparent that the proposed basic-insulation-level values for voltage classifications 69 kv and below correspond closely to existing practice for power transformers, which, in turn, was based upon existing design of bushings, and this resulted in a definite increase above the 1937 proposals in the insulation levels required for voltage classifications 23, 34.5, and 46 kv.

It is in these three voltage classifications that the insulator and air-switch group find it most difficult to accept the values proposed in the paper by Sporn and Powel. The curve in figure 2 of this discussion has been plotted from the values in column 8 and shows that these values for 15-kv voltage class and up all fall upon a smooth curve, indicating that they are all consistent with one another. Inasmuch as the three troublesome values were increased because of power-transformer practice, which should not affect the insulation level required for bus supports and air switches, it seems only reasonable to expect that these values could be modified to a value not lower than the values in column 8, so that genera' acceptance of a consistent array of basic insulation values could be adopted.

Such a compromise proposal is listed in column 11. The values in column 11 are identical with those in the report of the committee on co-ordination of insulation, with the exception of five values. It appears that the extra value (inserted because of power-transformer practice) would line up more consistently with the others if it were 115 instead of 110. The other changes are for the 23, 34.5, 46, and 69 voltage classifications, where the values have been reduced a very small amount; namely 5, 10, 10, and 5 kv respectively. The acceptance of these figures will relieve considerably the difficulties of the insulator and air-switch group and the modified values would still represent an appreciable increase on a withstand basis over the values proposed by the committee in 1937.

I wish to make a definite recommendation that the subcommittee on insulation levels reconsider its action and give careful and serious consideration to the adoption of the array of numbers listed in column 11 of table II of this discussion.

M. S. Oldacre (Commonwealth Edison Company, Chicago, Ill.): The three papers on "Basic Impulse Insulation Levels," "Co-ordination of Electrical Equipment With Basic Insulation Levels," and "Rationalization of Transmission-System Insulation Strength" should assist very materially in giving a clear understanding of insulation co-ordination that will help all in the industry to either co-ordinate or rationalize the insulation of their installations.

We now have a proposal for a series of impulse insulation values that seem entirely logical and consistent for the different classes of service. They are stated on a withstand basis instead of flashover, thus corresponding to other insulation testing practices.

Therefore, it seems that they should be adopted, at least tentatively, as the standard for the industry. If some pieces of equipment do not comply with these proposed values, a policy of gradual change should be adopted and the new designs made to conform.

It should be clearly understood that in adopting the proposed basic insulation levels no hardship or economic waste is being imposed on the industry but, instead, a definite system of insulation strengths is being established, so that all will know the characteristics of the equipment and be able to select the equipment to meet their needs. Full rating information should be given on the name plate of the apparatus.

As now proposed, the basic impulse insulation levels are not directly and definitely associated with the usual insulation classes that have some reference to operating voltages. It seems that it would be of definite assistance to the ordinary user if such direct association was made. Thus a standard insulation class would mean that the equipment and its insulation would withstand certain low-frequency and impulse tests. The user could select standard apparatus or higher or lower classes as desired.

I should like to suggest that the term "basic impulse insulation level" be replaced by one that is more descriptive of the purpose when referring to equipment. It seems to refer more to a curve drawn when "rationalizing" the insulation strength for a particular installation or service.

The 95-kv basic insulation level now proposed should be associated with a standard insulation class, probably a specially designated 15-kv class to be used for the smaller or so-called distribution class of equipment.

To make the insulation co-ordination fully effective, definite test procedures should be incorporated in the standards for each kind of equipment at an early date as suggested in the paper "Recommendations for High-Voltage Testing."

R. L. Whitney (Westinghouse Electric and Manufacturing Company, Derry, Pa.): There is no doubt but that the work of the joint committee on co-ordination of insulation has done a fine piece of work and they deserve the commendation of the Institute.

As a manufacturer of insulators we have, of course, followed the work of the committee actively. Our test work in connection with the investigation has shown that with the exception of four standard ratings the industry now produces a complete line of standard units that meet the proposed basic insulation levels. Even these four ratings taken as a whole are not more than five per cent below the proposed levels. That deficiency can hardly be deemed a serious one since it lies within the variations encountered in a given test laboratory and well within the variation between laboratories.

The establishment of the proposed basic insulation level as an industry standard carries with it certain specific responsibilities that warrant examination. Necessarily it involves a major investment in new designs on the part of the insulator manufacturer and a duplication of stocks all along the line. Economically every user of apparatus insulators is directly interested in such points as the doubling of the cost due to tool maintenance, natural deterioration of moulds, and stock duplication. All of these are increments in the purchase price. Duplication of field stocks means added cost of and a certain confusion in maintenance work.

Field experience with present standard insulators indicates quite conclusively, we believe, that those units offer no particular impulse hazard. Furthermore, the servicing of equipment involving those units is readily carried out with little loss of time and at low cost.

In this respect the problems differ from those encountered on apparatus using bushings. The number of apparatus insulators involved is large. The number of bushings is comparatively small. Relatively the cost of a given apparatus insulator is low while that of a bushing is high. The flashover of an apparatus insulator seldom results in any system disturbance beyond the operation of a reclosing beaker while damage to a bushing from a flashover may, and usually does, result in a major outage. The replacement of an apparatus insulator is quickly accomplished while the replacement of an apparatus bushing is a major operation.

This comparison of an apparatus insulator to an apparatus bushing would seem to justify some differential between the two types of insulation in so far as hazard and required basic insulation level are concerned.

Messrs. Sporn and Powel's paper indicates that it may not be detrimental to the co-ordination program if apparatus insulators do not meet the proposed levels until the need for conformity has been more conclusively proved in the field.

It is believed that this statement was wisely included. The new levels are set forth as proposed levels. It is felt that users must indicate the extent to which these proposed levels will ultimately be used. Will they be limited to the more important portions of a system? Will their adoption depend on lightning conditions or switching practices of the particular system? Will there be a general replacement of insulation now in service which is below the proposed levels? The answers to these questions have a direct bearing on the economics of the proposed change.

L. G. Smith (Consolidated Gas Electric Light and Power Company of Baltimore, Md.): In the Sporn and Powel paper the culmination of the work of a number of years is presented as a table of basic impulse levels. The entire electrical industry is indebted to those who have been engaged in the work of correlating service requirements with practical manufacturing capabilities to derive some degree of standardization out of the variety of impulse levels that has existed in the past. In standardization of this type the problems are of a commercial as well as an engineering nature. Those of us who are operating engineers naturally desire the highest possible impulse level. On the other hand, sometimes the cost of high levels cannot be justified whereas at other times the operating results may warrant higher costs. Therefore, commercial and economical considerations must be included in the evaluation of engineering factors.

As stated by several representatives of the manufacturers of insulators, the effect of the proposed levels on bus and switch insulators requires consideration. For the four reference classes 23, 34.5, 46, and 69, the switch and bus insulators have withstanding impulse levels $3^1/_3$ per cent to $8^3/_3$ per cent below the proposed levels as shown in table III of this discussion. Except for the 350-kv basic insulation level these represent differences of five to ten kv. Therefore, if the proposed levels are adopted, the manufacturers must either redesign or derate the insulators in these four reference classes. As shown in column 4, derating will result in insulators having levels of 20 to 28 per cent above those required; the elimination of an insulator having a level between 110 and 190 kv; and the introduction of a new design for the 350-kv level. Attention is called to the fact that the points developed in this discussion are independent of the reference classes. Column 1 in the table can be deleted.

Table III

(1) Reference Class	(2) Proposed Basic Insulation Level	(3) Withstanding Test Level of Present Insulators	(4) Withstanding Test Levels of Present Insulators if Derated
15	110	110	110
23	150	145	190
34.5	200	190	240
46	250	240	320
69	350	320	350*

* New design insulator.

Operating companies have many bus and switch insulators in service. As these are broken they must be replaced with new units that are interchangeable with the old ones. Should the proposed levels be adopted and if insulators can be redesigned for the high withstanding tests so that the new insulators are interchangeable with the old ones, no difficulty should result. However, it is understood that this is not possible. Therefore, two lines of insulators will have to be manufactured. As this will increase manufacturing costs, the users can expect to pay this cost. If compliance with the proposed levels is obtained by derating, interchangeability with present standard units can be obtained by retaining the present 145-kv-level insulator as a special unit. However, the user will be penalized by using units 20 to 28 per cent above the required levels. Actually the effect of the small differences between the values in columns 2 and 3 upon operation should be insignificant. It is realized that in so far as bus and switch insulators are concerned, it is the practice to overinsulate. However, this does not solve the problem introduced. No change should be made that will result in the mounting dimensions of insulators being changed so that thousands of insulators now in use become nonstandard.

Elias Cornell (Delta Star Electric Company, Chicago, Ill.): I would like to congratulate the joint committee on co-ordination of insulation upon the fine work done, and the results accomplished.

As manufacturer of high-voltage switch insulator assemblies and switching equipment, we have taken great interest in this work. Recent tests on switch insulators indicate that all but four ratings now meet the proposed basic insulation levels. The four exceptions are the 23, 34.5, 46, and 69-kv ratings. The actual withstand impulse voltage for these four units runs approximately five per cent below the proposed basic insulation level.

It is with satisfaction that we note that the authors do not deem these nonconformities a serious detriment, when considering the general subject. It is, however, important at this time to weigh carefully several solutions that are possible.

1. If the proposed basic insulation level values are adopted and adhered to rigidly one of two things must be done:

(*a*). Use the present standard insulators as far as possible by derating them so they will meet the proposed basic-insulation-level values. This would eliminate the present 23-kv unit, derate the present 34.5-, 46-, and 69-kv units to the next lower rating, and introduce a new 69-kv unit.

Certain disadvantages appear at once to the above mentioned scheme. If users of equipment desire to maintain their present standard insulation on new equipment, the new name-plate ratings might cause confusion or embarrassment since in some cases these ratings might be considerably lower than actual operating voltage. If on the other hand the higher-voltage units were selected for new equipment it would naturally result in increased cost, greater spacings, larger structures, and stocking difficulties.

(*b*). A second solution would be to redesign the four insulators in question. From preliminary information we have from porcelain manufacturers it appears almost impossible to secure new designs that would be interchangeable with the present units. This of course would result in more types of insulators on the system, and stocking difficulties of spare equipment. We can also be sure that there would continue to be a demand for the present standard units for new equipment to match existing installations or replacements. The net result would be more items to manufacture and stock, with no increase in total number of units. Needless to say this would decidedly increase costs.

It is felt that neither of the above schemes can seem very satisfactory to many operators.

There are two other possible solutions that have been discussed:

1. Allow a 5 per cent tolerance factor for all switch and bus insulators below the proposed basic-insulation-level values. This can be justified because of the difficulties of securing consistent impulse test results; admittedly plus or minus 5 per cent within any given laboratory, and even greater for interlaboratory comparisons.

2. Accept the present standard units with the maximum withstand impulse ratings that manufacturers can now guarantee. This scheme could be given a trial period until we have gained further experience with co-ordination or until such time when a more definite demand for a change is evident.

It is my opinion that this last scheme is fully within the spirit of the author's paper as well as the two fine companion papers by Messrs. Sporn and Gross, and Messrs. Foote and North.

H. K. Sels (Public Service and Gas Company, Newark, N. J.): Knowing that the committees working on the subject of basic insulation levels would want a broad expression of opinion, I should like to present a few points for their consideration.

The committees have proposed quite an orderly array of figures arranged in practically arithmetic progression. Maybe they are not what some would like to see but at least they are consistent and orderly. I am pleased to note that they have raised the levels for the 15-kv to 69-kv classes, inclusive. In applying insulation we have for many years been using 23-kv and 25-kv insulation for 15-kv service and 46-kv for 34.5-kv service. Why not call a spade a spade and rerate the insulators in these classes? I like Mr. Cornell's suggestion that a new insulator be developed for the 69-kv class, the other classes be reduced one step, and the present 15-kv insulator be eliminated.

Like Mr. Montsinger, I have been trying to co-ordinate insulation since 1925 but just when I think that we have something under our thumb it slips away from us. Co-ordination seems to be a slippery subject. We started out trying to insulate our bus equipment—oil circuit breakers, air-break switches, and bus supports—at least ten per cent higher than the line and the transformers ten per cent above the bus. However, by the time the bus insulation started to deteriorate, particularly that of the oil circuit breakers, and transformers were rerated in the light of present-day knowledge, the steps were down from the line instead of up, leading I know not where.

Rounded off to the next even hundreds the basic insulation levels proposed require an equivalent number of standard ten-inch disk insulators; that is, starting with the 34.5-kv class, the basic insulation levels of 200, 300, 400, 500, 600, 700 up to and including the 161-kv class of 800 requires 2, 3, 4, 5, 6, 7, and 8 units. However, the 196-kv class with a basic insulation level of 900 takes 10 units and the 230-kv class with 1,100 takes 12 units, the 287-kv class with 1,300, 15 units, and the 345-kv class with 1,600, 18 units. If you will look over the table of transmission lines published periodically by the *Electrical World* I don't believe that you will find a single line operating in any class insulated with so few units For example, our 138-kv lines are insulated with 9 suspension units and our 220-kv lines with 16 units. This means that all lines are considerably overinsulated compared to the proposed insulation levels. Therefore we must depend entirely upon co-ordinating gaps or lightning arresters to protect the terminal equipment.

Messrs. Sporn and Gross' paper entitled "Rationalization of System Insulation" shows only a 10 per cent margin in the higher classes and 25 per cent margin in the lower classes between the basic insulation level of equipment and the protective level of arresters passing a mere 5,000 amperes. Mr. Smith says the average for all classes is 20 per cent. Therefore, with such a narrow margin as this, I want to sound two notes of warning for the manufacturers.

First, better arresters are necessary. I think placing dependence entirely on arresters is like leaning on a weak crutch. About every five years it has been necessary for us to hold an anniversary year of rebuilding or replacing our arresters. Second, it is all right to establish basic insulation levels which the transformers and other equipment will meet when new; but can they hold it? Our experience has been that transformers purchased in the roaring 20's for 132-kv operation but insulated for 161-kv class are now only considered equivalent to the 138-kv class and transformers insulated for 138-kv class have been derated to 90 kv. We have had internal flashovers with the latter units and I can only hope that lightning arresters which we are now installing will afford sufficient protection.

In other words, it is not only necessary to lower the protective level and improve the discharge capacity of arresters but also to improve the terminal equipment so that it will maintain its basic insulation level. We do not want to have to pay a premium to purchase equipment with a higher basic insulation level and operate it in a correspondingly lower-voltage class to improve this margin. It appears that the basic insulation levels proposed are a minimum that should be considered in every class.

Philip Sporn and **C. A. Powel:** It is particularly significant to find that none of the discussers on this paper have taken exception to any of the proposed basic-impulse-insulation values on the basis that they are ir-rational, unsound, or predicated on an analysis and line of reasoning which is in the least fallacious.

Several discussers have elaborated on the point that certain apparatus insulators notably in the 23-, 34.5-, 46-, and 69-kv classes, will not at the present time meet certain values in the proposed basic-insulation-level grouping, the deficiency being in the general order of five to ten per cent. This situation was briefly noted in the paper, and we are glad to see the situation more fully presented by Messrs. Whitney and Cornell. Several procedures for taking care of this situation have been mentioned. The four outlined by Mr. Cornell are:

1. Derate the present insulators.
2. Make new insulators where deficiencies now exist.
3. Allow insulators to fall five per cent below the proposed basic insulation levels (by allowing five per cent tolerances).
4. Accept present insulators as now used.

Mr. Clem has offered a fifth suggestion which is a new group of basic insulation levels which he has arrived at by applying correction values to test values of transformers which were set some years back.

Mr. Sels has pointed out his belief that the proposed basic insulation levels are minimum values which should not be reduced. Mr. Henry likewise voices the same sentiment in his statement that "... the principles involved in their (basic insulation levels) determination are sound and the proposal should receive very careful consideration."

Thus we have the general points of view, first, that the proposed basic insulation levels have been established on sound principles and that they should not in general be reduced and second, the point of view of insulator manufacturers, who find that certain equipment does not meet the proposed levels without derating its impulse rating. To effect a remedy they propose changing the basic insulation levels on that account alone regardless of the principles involved.

The final determination of what values can be most satisfactorily accepted can be determined only after joint committee action by the triple joint committee. It should be pointed out, however, that while considerable time has elapsed since the work was first started on this subject of insulation co-ordination, up to the present time each step has been a progressive one forward. Considerable care should be exercised at the present time to make certain that no action is now taken which is detrimental to the general forward progress and development in the art.

Several comments have been made in regard to the slight labor expense involved in replacing apparatus insulators should they fail in service. This is a point of view which is not at all consistent with the operating performance of a high-grade system. The failure of even one bus insulator in a station may result and has in the past resulted, in a complete station outage, while the cost of replacing the one insulator which failed may be only a few dollars, the consequential damage to other equipment and service may be relatively enormous. The fact that in a great many cases operating companies are today using the next higher class of insulation above system rating is convincing proof that the flashover of insulators in the medium-voltage class is in general not considered adequate at the present time for many systems where high-grade service is required.

The point raised by several discussers that to change apparatus insulator designs in several of the insulation classes would result in an economic burden requires careful consideration. Since on a sound engineering basis it appears that the basic insulation levels proposed are required, it should lessen the economic burden, if appreciable, by permitting such changes to be made over a period of time, as has been suggested, or even derating equipment. This procedure would seem at the moment to be preferable over attempting to adopt as a standard, impulse strength of equipment which had been initially designed on a 60-cycle basis only without consideration of how its impulse strength fits into the insulation co-ordination system.

All the discussions offered on this paper and the various suggestions made will be helpful in acquainting the electrical industry with the problems confronting insulation co-ordination, and is welcomed as an aid in carrying on the work to a conclusion.

Rationalization of Transmission-System Insulation Strength—III

Discussion and authors' closure of paper 40-36 by Philip Sporn and I. W. Gross, presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940, and published in AIEE TRANSACTIONS, 1940 (October section) pages 591–5.

M. S. Oldacre: See discussion, page 1199.

J. T. Lusignan, Jr.: See discussion, page 1205.

C. A. Powel (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): This paper by Messrs. Sporn and Gross, dealing with the margin between the levels to be protected and the levels held by the protective devices, is very important, because on these margins depends the entire justification for the basic levels to be submitted for consideration by the joint committee on insulation co-ordination, as proposed in the Sporn-Powel paper. It must be recognized that a proper choice of basic levels is of great economic importance to the industry. The margins shown in the paper are very moderate and might be considered in some cases inadequate except for the fact that other factors, such as rapid decay of the lightning surge and the small probability factor of heavy surges, come into the picture and help the situation.

Because of limitations imposed by the necessity of retaining assurance that the arrester will maintain its integrity at operating frequency, it would seem that the protective ratio now obtainable in good lightning arresters is about as low as we can expect. Certainly no major reduction is to be expected, and this being the case and some margin being recognized as necessary, the likelihood of a reduction in basic levels in the future is quite remote.

R. T. Henry (Buffalo, Niagara and Eastern Power Corporation, Buffalo, N. Y.): The problem of co-ordination of insulation has been one of the major problems before the industry for many years. A great deal of effort has been directed toward its solution, particularly since the formation of the EEI-NEMA Joint Committee on Co-ordination of Insulation nearly ten years ago.

Careful consideration of masses of data and a great many different ideas on the subject have finally developed a logical proposal based on sound engineering analysis of the problem.

This proposal involves establishing "basic insulation levels" which can be used to determine the insulation strength required for apparatus in the various voltage classes. The values proposed are based on the assumption that, in each voltage class, a reasonable margin of insulation strength should be provided above the voltage to which apparatus may be subjected in service, up to the level of protection which can be provided with modern lightning-protective equipment.

This proposal represents the concensus of opinion and judgment of a large number of the outstanding engineers of many of the utilities and manufacturers. Whether the values proposed are exactly right or not, the principles involved in their determination are sound and the proposal should receive very careful consideration.

There are differences between some of the values proposed and the characteristics of present-day apparatus. The next step in the solution of this problem is to adjust these differences. Fortunately, the situation in regard to lightning protection has improved through the years to such an extent that it is now possible to protect the insulation for any given service voltage at lower levels than could be done some years ago. Otherwise, it would have been necessary to propose values considerably higher than those now proposed. As it is, most of the differences are small and can probably be eliminated by minor adjustments, either in the values proposed or in the design or rating of certain apparatus. In a few cases where the difference is appreciable it may be necessary to modify the design or the rating of certain apparatus. In considering these adjustments, it should be kept in mind that most major apparatus such as transformers, circuit breakers, etc., will meet the proposed values and that most of the present-day insulators which will not meet them are commonly used, not at their present rated voltage but at voltages below their present rating.

It seems to me in this connection that we should avoid establishing tolerances in any case and we certainly should not establish lower levels for some apparatus as compared with other apparatus in the same voltage class. The basic idea behind this proposal is to select insulation for each device such that all of the apparatus in a given station can be protected and on this basis there should be no lightning flashover on any of the apparatus. This would seem to eliminate any consideration of the relative seriousness of failures in one device as compared with other devices and any justification for different values for different devices in any voltage class.

There is some tendency in certain quarters to withhold agreement to this proposal because some present-day apparatus would not meet the proposed requirements. In order to avoid any undue burden which might result from the adoption of this proposal, I would suggest that the "effective date" might be postponed, several years if necessary, in order that agreement may be reached without further delay. Meantime the industry could have the benefit of a definite objective to work toward. This would permit the completion of a number of standardizing activities which are held up pending such agreement.

It seems to me that the time has come to eliminate petty considerations, make adjustments in the values where possible, modify designs or ratings where necessary, and reach agreement in order that the industry may realize the benefits which will result from a logical solution of this problem.

W. J. Rudge, Jr. (General Electric Company, Pittsfield, Mass.): Messrs. Sporn and Gross, and Foote and North, have presented excellent treatment of the subject of insulation levels. The procedure of establishing levels outlined in these papers appears rational and well thought out. Both papers have recognized that the protective levels established by modern arresters are determined by the system operating voltage line to ground.

Modern lightning arresters are classified into two general classes: those suitable for grounded-neutral circuits and those suitable for nongrounded or isolated neutral circuits. For circuit voltages above 15 kv the factor between the arrester's maximum line-to-ground voltage rating and the circuit's normal line to neutral volts is approximately 140 per cent for grounded-neutral circuits and 180 per cent for isolated-neutral circuits. These values have been arrived at largely through experience in the past with numerous systems.

With the advent of the transient analyzer, the a-c calculating board and improved methods of checking up system operating voltages, it should be possible to examine the various system conditions and establish the normal and maximum voltages existing on systems today and to evaluate the magnitude of overvoltages which may occur under the various operating conditions.

The analyzer and calculating-board studies are all given in percentage of the normal operating system voltage. It is as vital to know the actual operating voltage as it is to know the percentage system overvoltages occurring under abnormal conditions, as the actual operating voltage is one of the essential factors which determines the proper arrester to be used at a given location. We note that Messrs. Sporn and Gross propose a factor of 130 per cent for grounded-neutral arresters. This undoubtedly will be satisfactory for a well-grounded system, that is, where the ratio of X_0 to X_1 is equal to or less than 2 and for a value of R_0 to R_1 not greater than 1. Our experience over a great many systems has indicated that there are a number of grounded-neutral higher-voltage systems which have a higher ratio of X_0 to X_1 than 2 and which do not have as close voltage regulation as the six per cent mentioned in Messrs. Sporn and Gross' paper.

Likewise, in the case of the ungrounded systems, the studies on the network and transient analyzers and measurements on some of the actual systems indicate that 180 per cent is below the voltage which may be found on these systems in the event of a single-line-to-ground fault. Yet as far as can be determined at present, there has not been an excessive number of arrester failures on this type of system.

We feel that to set up the final values for the basic insulation levels a survey should be made of the operating voltage of the various companies to find out the maximum operating voltage in each voltage class with the ultimate goal of setting levels which will cover the majority of systems, as any standard lines must be so set up to be of greatest value to the industry.

In addition to the determination of actual operating voltages, there should also be a determination of the results of X_0 to X_1 found on the various systems so that the factor selected for both grounded and isolated neutral arresters can be chosen to cover most systems.

The importance of such a study cannot be overemphasized, particularly in view of the trend toward arresters of higher discharge capacity and lower protective ratios. It becomes obvious that modern arresters which have low impulse ratios will be more sensitive to overvoltages because they are designed to pass higher current for a given overvoltage, whether it be from lightning or system power-frequency voltage. This makes it all the more important to select arrester ratings which will fit the system operating conditions, as by so doing a premium will be realized on both the prevention of equipment failures from lightning and the probabilities of damaging the protective device.

It is of particular interest to note that Messrs. Sporn and Gross propose 5,000 amperes as the current to be used for establishing basic insulation levels. This seems a rather low current when compared to the discharge currents being considered by the lightning-arrester subcommittee which is rewriting lightning-arrester standards. However, it is to be noted that when comparing the arrester levels with the basic insulation levels that arrester maximum values were used to compare with basic insulation levels which are minimum, or with standard values. Actually, to demonstrate basic insulation levels it will be necessary to set the impulse generator so that the voltage will not come below the basic insulation levels which means that the actual values demonstrated will be between the basic insulation level and some value perhaps in the order of ten per cent higher. The average demonstrated value will be about five per cent higher.

The average arrester performance value is 15 per cent lower than the value used. Hence, there will be approximately 20 per cent factor between the average apparatus test and the average arrester level which does not appear in the table.

This could be considered as a factor to maintain a margin below the basic insulation levels when the discharge current is greater than 5,000 amperes and if we refer to the arrester values presented in the lightning-arrester subcommittee report [AIEE TRANSACTIONS, volume 59, 1940 (June section) pages 345–6] it may be found that when the arrester voltage increases 20 per cent above the discharge voltage at 5,000 amperes, the current increases to approximately 20,000 amperes.

We are particularly interested in the procedure used by Messrs. Sporn and Gross when selecting the rod-gap setting given in line *n*. It is stated that the gap spacings are taken as $3^1/_4$ times the maximum expected line-to-ground voltage. It appears from the values used that this assumption must have also been that the gaps were dry. It appears that this gap should have been based on the wet flashover, as there is usually rain at the same time that lightning occurs. If this were done, it would require a 10 to 20 per cent increase in gap spacing with a corresponding increase in flashover voltages.

V. M. Montsinger (General Electric Company, Pittsfield, Mass.): As one who has been associated with the problem of co-ordination of transformers since the inception of co-ordination in 1926–27, I am glad to see the progress that is being made on the broader subject of co-ordination, and the sound foundation on which it is being built, namely the available protective devices like lightning arresters. As pointed out in these papers, the arrester level of protection is dependent primarily on the low-frequency voltage of the system.

For many years, up until the time of the co-ordination movement, the insulation level of transformers was determined solely by the system voltage. For example: for isolated-neutral systems, transformers were generally insulated for twice line-to-line voltage. When the neutrals of high-voltage systems were solidly grounded, it was common practice to insulate the transformers for an induced voltage test of 2.73 times leg voltage to ground, without regard to whether protective devices capable of protecting the lower level of insulation were installed on the system. Where lightning was prevalent, it was found impractical in many cases to provide sufficient protection to apparatus with such low insulation levels, and as a result the 2.73 transformer is rarely used today.

The next and most logical thing to say was that the insulation requirement of apparatus was dependent only on the protective levels of protective devices. This might lead one to conclude that the system voltage was no longer the controlling factor in the selection of apparatus insulation levels. This, of course, is not true because the protective level of the protective devices themselves is dependent on the system voltage, that is, the maximum dynamic line to ground voltage. In other words, while it can be said that the insulation level of apparatus is dependent on protective devices, yet the system line-to-ground voltage still remains the principal factor that determines the co-ordination of insulation. This is evidenced by the fact that it is proposed to use one level lower of insulation on solidly grounded-neutral systems where the lower-rated arrester can safely be used.

As to the system dynamic overvoltages, I note that Messrs. Sporn and Gross suggest a 20 per cent increase in voltage for circuits up to 8.3, a 15 per cent between 8.3 and 15 kv, and a 6 per cent increase above 15 kv.

While these values might be met on an exceptionally well-regulated and well-grounded system, it is doubtful if such a small tolerance on dynamic overvoltage should be used as standard.

Our experience indicates that many systems are outside of these limits. Therefore, if we are to set up basic insulation levels which will cover the requirements of the majority of systems, it seems in order to suggest that a program be set up by the operating companies to obtain factual data which will include the maximum continuous line-to-line operating voltage as well as the maximum line-to-ground voltage under both normal and abnormal operating conditions. If this data were submitted to the EEI-NEMA committee, it would serve as a sound basis for setting up firm values for the basic insulation levels.

Considered from the standpoint of the assignment of apparatus to the proposed basic insulation levels, so far as transformers are involved there will be no trouble in meeting the new basic insulation levels with the exception of distribution transformers rated 12.5–15 kv and intended for connection line to line which have been assigned in table I of the Sporn-Gross paper to the 110 basic insulation level. Transformers of this rating have previously been built for a full wave test (or basic insulation level) of 95 kv. This 110-kv level, if adopted, means that the insulation of these ratings must be increased to a point between the present 15-kv and the 25-kv insulation classes, obviously at higher costs especially for the smaller pole-type transformers. Some operators who use transformers of these voltage classes may object on this basis.

With reference to the definition of basic insulation level in the paper by Sporn and Powel, I feel that the word "suitable" is subject to misinterpretation. "Suitable" was criticized by some of the members of the NEMA group on the ground that what is suitable to one may not be suitable to someone else. It really means "apparatus insulation as demonstrated by standard tests". So why not add the word "standard" and say, "suitable standard tests . . . ."

L. G. Smith (Consolidated Gas Electric Light and Power Company of Baltimore, Md.): The two papers by Sporn and Gross, and Foote and North, present a logical engineering approach to station lightning protection. The authors of both papers emphasize that adequate lightning protection depends upon the proper correlation of the voltages permitted by surge protective devices and the impulse insulation strength of station equipment. While the data presented on specific protection problems are the best available at present, a warning against their too literal use is believed necessary. As this warning is predicated on the lack of statistical data concerning lightning, no criticism of the tabulated data is implied.

While reasonably accurate information is available concerning impulse strength of electrical equipment, probability factors of the magnitude of voltage permitted by surge protective devices have not been established, because of the lack of statistics concerning lightning such as rates of rise of currents and voltages and magnitude of surge voltages and currents. In the Sporn and Gross paper, the protected levels are based upon surge currents of 5,000 amperes. While this assumption is confirmed by the data in the paper by Gross and McMorris, it is believed that the data on which it is based are insufficient. Moreover, if only a small percentage of the surges exceed 5,000 amperes, we cannot afford to permit such a small margin that equipment failures may occur, causing loss of electric service to large numbers of customers.

The basing of the equipment insulation levels upon the lightning arrester applied should make it necessary to use different levels for grounded- and ungrounded-neutral systems. In the Foote and North paper attention is called to the withstanding impulse level of current potential transformers on feeders in table I. Since current and potential transformers may be essential elements of feeder relay protection, the wisdom of a level of 50 kv for instrument transformers as compared with a general level of 60 kv is questioned. A failure of an instrument transformer associated with the relay protection of a feeder may prevent the feeder from tripping, which may result in the loss of service from an entire substation.

S. B. Crary (General Electric Company, Schenectady, N. Y.): As pointed out in the paper by Messrs. Sporn and Gross the voltage rating of an arrester is influenced by the maximum dynamic voltage that may be obtained at the arrester location, and this in turn is an important factor in determining the protectable level. During the last few years, the subject of power-system overvoltage has been given considerable attention so that it may be in order to review briefly some of the factors which influence the maximum voltage on systems and which may be controlled by giving attention to the system design.

1. Line-to-ground faults, in general, result in the highest dynamic voltages on the unfaulted phases and are practically completely controlled by the method, number, and arrangement of system grounding points.
2. High dynamic voltages due to sudden loss of load and overspeeding, particularly of waterwheel generators may be reduced in magnitude by modern regulators and excitation systems which act quickly to reduce the excitation under such conditions.
3. High dynamic overvoltages may result due to unbalanced faults on lines to which are connected salient-pole generators, particularly under the condition when a line or lines having appreciable capacitance, is left connected to the generators but disconnected from the load. These overvoltages may be minimized by properly designed amortisseur windings in the generators and operation of the system so this condition is not likely to occur.
4. Use of single-phase switching devices, fuses, etc., in three-phase systems may, in some circumstances, result in high dynamic voltages. Edith Clarke, H. A. Peterson, and P. H. Light have submitted to the Institute a paper treating this subject (40-105, 1940 AIEE summer convention; scheduled for inclusion in 1941 Transactions). They show the conditions under which high voltages may occur. By proper application of such devices, the probability of obtaining these overvoltages may be reduced or eliminated.
5. Switching surges may under some circumstances result in severe overvoltages. Again by giving attention to the method of system grounding arrangement, and employing circuit-interrupting means which have a minimum tendency to restrike, such effects may be minimized.

A. C. Monteith (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): With reference to the example in the paper by Messrs. Sporn and Gross, it is noted that a factor of 30 per cent was added to the phase-to-neutral voltage to determine the dynamic voltage rating of the lightning arrester for application on an effectively grounded-neutral system. This factor is satisfactory for a large percentage of the cases where the arresters are applied on the larger systems but there are a number of systems where this might not be an adequate factor. This brings up the age-old question of the definition of an effectively grounded system.

In an attempt to put this application on a simplified engineering basis, consideration has been given to the use of ratios of zero-sequence resistance and reactance to positive-sequence reactance as viewed from the lightning-arrester location and it has been found that a fairly simple set of curves can be plotted. The methods of calculation and some of the curves are presented in references 4 and 5 of the paper by Messrs. Sporn and Gross. As a result of this work and a review of the number of systems, it was concluded that a lightning arrester with a rating of 80 per cent of the maximum line-to-line voltage can be used in the majority of cases when all points of power supply are solidly grounded. Incidentally, in the past the selection of 80 per cent has been associated with a grounded-neutral lightning arrester. The application on the basis of the limiting ratios of X_0/X_1 of $3R_0/X_1$ of 1 for the 80 per cent arrester allows a ready check with breakers closed and open, whether the arrester is applied on the transformer side or the line side of the line circuit breakers. The curves referred to above are such that as soon as the ratios are determined the limiting voltages are immediately available.

The example cited in table III of the paper by Messrs. Foote and North is of interest in this connection. They have selected a station with the transformers solidly grounded, yet the 30 per cent rule would not apply for the lightning arresters on the bus, nor would the 80 per cent rule apply for the arresters on the line side of the breakers when the breaker is open. It is therefore felt that before using lightning arresters with reduced ratings, a check should be made for the particular application and then a corresponding basic insulation level selected as outlined in Messrs. Foote and North's paper.

In connection with the paper "Recommendations for High-Voltage Testing" it should be noted that although the different laboratories are not in agreement on the short-time values for volt-time curves the disagreement being as much as plus or minus 20 per cent, nevertheless volt-time curves can be used in co-ordination work. This statement is true provided that any comparison is made with data originating in the same laboratory.

Philip Sporn and I. W. Gross: Both Messrs. Rudge and Monteith have brought up the point that the basis used in our paper for the application of lightning arresters on grounded-neutral systems, based on 1.3 times the normal line-to-ground voltage gave too low 60-cycle voltage values for some systems. This factor of 1.3 is one which in our experience based on calculated voltages has never been exceeded on our 132-kv solidly grounded-neutral system, except on one part of the system close to large hydro generation. A rough survey of conditions on our 12,000-volt systems indicates that here too the 1.3 factor is adequate. We appreciate, however, that there are grounded-neutral systems in the country where the voltage may go higher and thus justify a higher maximum rated arrester.

Likewise Messrs. Rudge and Montsinger believe there are many systems in the country where the regulation exceeds 20 per cent, 15 per cent, and 6 per cent for the circuit voltage ranges of 8.3, 8.3–15, and above 15 kv. In justification for these values as well as the 1.3 factor for grounded-neutral lightning-arrester application, we wish to point out that we attempted to select values which would be conservative from the point of view of justifying a low basic impulse insulation level. Should extensive further study of the situation and general experience indicate that the values used are too low, it means that the lightning arrester will require a higher 60-cycle rating, and in turn the protective level permitted by this arrester would likewise be higher. This then, will result in one of two things: either less margin between the arrester level and the basic insulation level or raising the proposed basic insulation level.

It has been pointed out by Mr. Powel that the margins shown between the arrester characteristics and basic insulation levels "are moderate" and in this we heartily agree. With a factor of safety of 10 per cent over the arrester characteristic, even with 25 kv added for added benefit in the lower-voltage classes, we certainly cannot feel that the calculated margins are excessive. Further, as Mr. Powel points out, since there is very little possibility of lightning arresters having appreciably lower protective characteristics in the future, greater margins between the arrester and basic insulation level cannot be expected from this source.

Several discussers have pointed out the desirability of calculating overvoltages on grounded-neutral systems in the application of arresters to determine the proper arrester 60-cycle rating. We have always done this in recent years on our 132-kv system and have reached the conclusion that the 109-kv arrester is suitable in most applications on our system. This has been borne out by some eight years of actual experience. In any important installations where arresters are to be applied, we always calculate the expected maximum overvoltages and use these as a basis for applying arresters.

Both Messrs. Smith and Rudge have questioned the 5,000-ampere lightning-arrester discharge current as a basis for the arrester characteristic. Here again, we appreciate that occasionally discharge currents through arresters may exceed this value, and if so, protection of equipment theoretically at least may be questioned. In the case of transformers, however, it is possible to rely on the factor of safety in the transformer to supply the necessary insulation for protection against such higher-voltage surges. To have taken a higher arrester current such as 10,000 amperes would again have raised the arrester characteristic and cut down the margin between the arrester and the proposed basic insulation levels; or viewed from another point of view, would have required the basic insulation levels to be higher if the same relative margins were to be retained.

In all cases where assumptions were necessary such as system voltage regulation, lightning currents through the arrester, and application of arresters on grounded-neutral systems, we used those assumptions which, while staying within the limits of test and experience, still would tend to justify the lowest basic insulation levels. For this reason, we believe that our analysis as shown in the paper indicates clearly that the proposed basic insulation levels are none too high in any of the insulation classes, and if any change at all is warranted, on the basis of protection only, it would justify a raise of levels rather than a reduction.

The Co-ordination of Electrical Equipment With Basic Insulation Levels

Discussion and authors' closure of paper 40-35 by J. H. Foote and J. R. North, presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940, and published in AIEE TRANSACTIONS, 1940 (October section) pages 585–9.

W. H. Cooney (General Electric Company, Pittsfield, Mass.): Since the principles of co-ordination were started more than ten years ago, the units of measurement have changed from insulators, to rod gaps, to kilovolts, as the knowledge of impulse voltages was increased by work in laboratory and field, but the fundamental ideas have been retained. Now we are thinking in terms of basic insulation levels, and Messrs. Foote and North have shown by three excellent examples how the insulation strengths of the component pieces of equipment of a station can be properly related.

The method of determining first the protectable level and then selecting the indicated basic insulation levels seems logical. Whether the proposed protectable level of (1.10×arrester maximum performance)+25 kv is about right should be determined by further study and experience. On the one hand, it should be high enough to allow for the variable conditions of service, and on the other hand, it should not be so high as to require unnecessarily expensive insulation. It does demonstrate the value of a protective device which holds impulse voltages to a low level.

Obviously for the sake of brevity, the authors did not repeat the method of calculating protectable levels outlined by Messrs. Sporn and Gross. If this paper is to be reprinted, I would suggest for completeness of the three examples that the arrester levels selected and the calculations of the protectable levels be shown in each case.

The examples of selecting insulation for three substations demonstrate the flexibility of this method, since the particular operating conditions, the importance of each type of apparatus, and the importance of the substation itself can all be factored. Caution should, however, be exercised by selecting standard insulation so far as possible, for special insulation may prove quite expensive. As the authors emphasize, the economics involved are of equal importance with the low-frequency and surge-voltage requirements.

J. B. MacNeill (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): Messrs. Foote and North cover in their paper the type of reasoning which will be generally used in the future in co-ordinating the insulation of equipment in stations and substations. I agree that the impulse characteristics of equipment are equally important with the low-frequency characteristics.

It is desirable, of course, that impulse and 60-cycle characteristics of a given piece of apparatus bear a definite relation to each other so that it may find general use and its cost be kept to a minimum.

In the past many customers have brought overvoltage equipment because of their knowledge that standard apparatus tests did not insure them trouble-free operation. Several factors have contributed to this difficulty, one of which has been improper relationship between impulse characteristics and low-frequency test values. In the future the improved methods of test and greater information on the subject should allow rational applications.

There are, however, some factors which are not adequately covered by any statement of either low-frequency voltage test or impulse test. For instance,

1. A device such as a switch which generates a large volume of gas on circuit interruption may have adequate structure spacing for any type of voltage test but the momentary presence of gas within the structure may vitiate these spacings.

2. Gas-forming devices without adequate means for exhausting the gas away from live terminals may also have their insulation values momentarily reduced to negligible amounts.

3. Horizontal insulation surfaces on which moisture may collect in service may on new apparatus tests appear entirely adequate but give trouble in operation.

4. Structures which may absorb water through breathing or leakage may have adequate test values as new equipment but not be trouble-free in service.

The point I wish to make is that there are several factors entering into the subject of adequate insulation, some of which are not necessarily covered by test, but which an experienced manufacturer intends to cover when he says "This apparatus is good for use on . . . . service voltage." Taking all factors into consideration, it appears then that service voltage should be the bench mark of application and both 60-cycle and impulse tests be related to it.

F. J. Vogel (Westinghouse Electric and Manufacturing Company, Sharon, Pa.): Messrs. Foote and North are to be congratulated on giving an engineering approach to a difficult problem. It might be more easily described as the familiar method by which we determine the stresses which apparatus is required to stand, and design it accordingly. This seems simple, but when it is complicated by past usage, lack of information as to the strengths of various parts, and similar matters, the problem becomes very difficult indeed.

There are some difficulties to which I would like to call attention. The basic insulation impulse levels specified in both this and the Sporn and Powel paper do not exist for all lines of apparatus. One of these is the 110-kv impulse level which does not now exist for circuit breakers or several lines of transformer apparatus. The same difficulty exists in other lines of apparatus, for other voltage classes, I believe. The examples given by the authors show the effect of past and present standardization and usage in this regard. It is unsafe to prophesy, but possibly as time goes on both the proposed basic impulse insulation levels and apparatus levels will be modified and agreement on all types of apparatus will be reached.

The procedure of determining arrester applications by the method of determining the maximum low-frequency voltage which can be applied seem unassailable. This leads to the only weakness in the proposal, that of determining what surge voltages are possible on apparatus in service. The margin described may not always protect the apparatus. Two possibilities should be recognized:

(*a*). If there is any appreciable distance between the protective device and transformers, it is possible to have a higher voltage on the transformer than at the protective device. In the case of extremely high and steep-fronted surges, obtained by nearly direct strokes of lightning, this failure to furnish complete protection is possible. As a matter of opinion, trouble from this source will probably be rare on high-voltage systems of customary design, using ground wires and other methods of protection and relief from direct strokes. I think it can however occur, and some transformer failures from this cause will happen.

(*b*). If high discharge currents in the protective devices result in high voltages across them, the surge voltage may exceed the basic impulse level and result in flashovers at transformer bushings, pillar insulators, etc. No remedy for this is suggested, but if in practice, this occurrence is rare, the proposed scheme will be justified. It is my opinion that this will be true.

In the closing part of the "Procedure for Selection of a Particular Basic Insulation Level", an important statement is made, namely, that "In the final analysis, the insulation suitable for a given situation will be that which fulfills the low-frequency requirements, the surge-voltage requirements, and the economics involved." At the present time, the impulse levels are still relatively new, and correspond to low-frequency test levels established by long practice. The low-frequency tests now specified are not required by service. This is recognized by the fact that users often find that they can use an arrester rated one voltage class lower than the rated voltage of the line, and then specify lower 60-cycle test voltages. The facts are that there is no necessary correlation between impulse strength and 60-cycle strength in apparatus of different designs, and also that the low-frequency service requirements (including switching surges, etc.) are independent of the arrester used. The internal insulation of transformers might be given present impulse tests, and somewhat lower 60-cycle tests than we now use, and meet the service requirements. This might lead to some economies, but is contrary to established usage, and would lead to confusion at the present time. There may at some future time be a trend in this direction, based on the possibilities mentioned above.

D. C. Prince (General Electric Company, Philadelphia, Pa.): A study of this paper and the other splendid papers on the subject fails to give any idea of the thousands of man-hours which have been expended in considering the subject or the extreme complications of the subject matter involved.

The material to be co-ordinated includes bushings; transformers, large and small; circuit breakers, large and small, indoor and outdoor; fuses; air disconnecting switches and bus supports, and finally line insulation. Nature has established certain relations between effects of 60-cycle voltage and impulse voltage on these various types of equipment. The oil-immersion insulation in transformers and circuit breakers brings a high impulse ratio of the order of two (for one-minute 60-cycle crest and for standard 1.5x40 wave) or more for short-time applications of voltage. At the other extreme, certain forms of bus insulators flashover at the same crest voltage both at 60 cycles and under impulse. Other forms of insulation have varying impulse ratios between these limits.

Not only is the nature of the behavior of the different insulations under impulse different, but the cost of providing different impulse levels may vary greatly. On account of those high inherent ratios the impulse strength of a transformer can be made quite high by equipping it with what might be considered an oversized bushing, which has a considerably higher 60-cycle strength than the transformer winding. Since the cost of bushings is only from five to ten per cent of the total cost of the transformer, the high impulse level is obtained with relatively little cost. In an oil circuit breaker, the cost of bushings is roughly a third of the total cost. High impulse levels are, therefore, obtained at somewhat greater relative expense in circuit breakers than in transformers. In air switches and bus supports, all of the parts have inherently low impulse ratios so that a change in impulse ratio affects the cost of the total device.

Transformers are relatively expensive pieces of equipment. An impulse breakdown of a transformer may put it out of service for a considerable period and involves a high cost of repair. Small transformers involve much less cost in repair and their loss involves less interruption to service. There is some question, therefore, whether the criteria for the selection of impulse levels might not indicate a higher level for large power transformers and circuit breakers than for small circuit breakers, disconnecting switches, and bus supports. On the other hand, insulators when flashed over may not be damaged and even if they are, a replacement can be made quickly and at relatively small cost.

Again, transformers normally receive the best possible lightning-arrester protection, whereas the other pieces of apparatus are progressively further from the lightning arresters and correspondingly are not so well protected. Following this line of reasoning one might conclude that transformers might economically be built for a lower impulse level than other pieces of equipment, the impulse level being increased as the distance from the arrester increases.

Another type of question involved in this selection of impulse level is the question of need of allocation of impulse levels to operating voltages. In a transformer, the operating voltage fixes such important design elements as turns and iron sections. It is, therefore, practically essential that there be a definite allocation of impulse levels to correspond with line voltage for transformers. Circuit breakers, on the other hand, are regularly designed for a standard voltage step and are frequently used on circuits considerably below this standard rated voltage. The reason for the tie between impulse levels and operating voltages is, therefore, much less imperative. In the case of current transformers and bus supports, there is no necessary relation between the operating voltage and the impulse level. At the present time, the effort is being made to assign standards of insulation for all these kinds of equipment.

The difficulty in reaching an agreement in regard to such standards is primarily due to a lack of an agreed philosophy to govern the situation. If it were agreed that the different types of apparatus should not necessarily have the same relationship between the operating voltage and impulse level as suggested to some extent in this paper, it would be possible for the different standardizing bodies to proceed with little difficulty, each to standardize the apparatus in which he is most interested. On the other hand, if it is considered that all of these pieces of apparatus should not only be co-ordinated but should meet the same impulse levels relative to operating voltage levels, then the standards could be worked out on the basis of the limiting pieces of apparatus with due regard to past operating experience and economic considerations. It seems, therefore, that a major effort should be made to agree upon the broad policy to be followed in working out this co-ordination. If the fundamental principles could be agreed upon an acceptable solution for the whole problem should be obtainable.

J. T. Lusignan, Jr. (Ohio Brass Company, Mansfield): I believe these papers on insulation co-ordination give a complete picture of all phases involved. Messrs. Sporn and Gross tell us of the methods of setting up protective levels in order to guard equipment in the various voltage classes. Messrs. Foote and North tell us more of the assigning of equipment to the proper levels for protection. I like particularly well their examples for showing how these assignments should be made for several typical insulation classes.

In the section "Procedure for Selection of a Particular Basic Insulation Level" of the paper by Foote and North two statements appear. The first reads: "In stations accommodating many connecting lines and in stations of considerable extent, it may be that different types of protective devices are used at different locations; also, the operation of switching equipment may isolate certain apparatus from some of the protective devices." The second statement reads: "If a gap type of protective device such as a protector tube or a plain rod gap is to be used, the protection afforded is based entirely on the time to break down and should not be considered as a level, but rather a volt-time curve. In this case, a comparison of the apparatus chopped wave impulse voltage test with the gap breakdown at a comparable time plus suitable tolerance and margin would more accurately represent co-ordination for apparatus on which complete volt-time curves are not available."

I believe the first statement suggests the need for a protective device other than an expensive arrester which might be counted upon to guard oil breakers, bushings, and other station equipment which might be separated through switching from the arresters, protecting transformers. The second statement intimates that protecting devices should have flat "volt-time" characteristics. A device which we feel would serve all these needs is the so-called "control gap", described in a paper given before this convention two years ago. ["The Control Gap for Lightning Protection", Higgins and Rorden, ELECTRICAL ENGINEERING (AIEE TRANSACTIONS,) September 1936, pages 1029–34.] This gap has been suggested and used at station entrances, where the highest lightning currents may be expected, as well as near the transformers. Its flashover and discharge characteristics are unchanged for any current magnitude or polarity.

I particularly approve of conclusion number 3 of the Foote-North paper suggesting the addition of "withstand" ratings to equipment name plates. This will make it easier to buy equipments and associate them together on the proper insulation voltage levels. Indirectly this will help to promote the general idea of better insulation co-ordination. This is with the thought that sometime in the near future all in the industry can see the wisdom of co-ordinating on specific insulation levels, and agreeing on final values for the various levels so that values somewhat like those of the Sporn-Powel paper may be tabulated as final and no longer as proposed or tentative. If assurance can be given at that time that these values, and only these, will hold for an appreciable period, then both manufacturers and users should have much more peace of mind than they have now with so many ideas prevalent as to station insulation arrangements, and with a mass of so-called "standard" size devices needed to fit all of these arrangements.

J. H. Foote and **J. R. North:** Naturally we are very much pleased at the wide interest shown in the problem of application of the proposed basic insulation levels to situations actually to be met in apparatus selection and station design, as evidenced by the large number of discussions which have been submitted. The encouraging tenor of practically all of these discussions is heartening and makes us feel that progress is being made in the solution of this rather difficult problem. Constructive criticisms and suggestions are given by Messrs. Cooney, Lusignan, MacNeill, Monteith, Montsinger, Oldacre, Rudge, and Smith. Their comments indicate not only interest in the problem, but serious study of the method of attack presented in the paper.

We especially value the very clear and fundamental presentation of the general problem by Mr. Prince. His discussion warrants careful consideration by all who are preparing studies or schedules of application of the basic insulation levels to actual practice. Other discussers have called attention to the necessity for the determination of a proper appraisal of the reliability of service as related to apparatus hazards, and also as related to the costs involved. Some are prone to look at the situation as it affects the apparatus itself and say, for instance that because a piece of apparatus is of small, unit cost and easy to replace, its failure is of small moment. Others, particularly those who live close to the operating problems involved in the maintenance of service to customers, are perhaps a little more conscious of the effect of the failure of a piece of equipment on continuity of service. Mr. Prince brings out the necessity for a proper evaluation of these factors.

We are glad to have Mr. Vogel, who has had a great deal of experience in matters relating to insulation co-ordination, emphasize and amplify some of the points in the paper. Proposals (*a*) and (*b*) were given consideration in setting up the marginal allowances. He points out that the basis for co-ordination of protective-device performance and apparatus impulse strength involves a nice balance between the surges reasonably to be expected and the assuredness of protection by the protective device. Our illustrative examples were intended to show that the basic-insulation-level applications indicated were such as to insure reasonable security without going to extremes one way or the other. The necessity for consideration of low-frequency as well as surge-voltage requirements is again brought to the reader's attention.

Mr. Henry's discussion is worthy of a second reading. He has done a great deal of work in connection with insulation co-ordination and its application, and his study of the problem and experience in the practical application of basic insulation levels to apparatus makes his contribution of more than ordinary value.

Mr. Crary's and Mr. Monteith's discussions emphasize the importance of properly determining the voltages which may be expected to occur under fault conditions.

Mr. MacNeill has very nicely enumerated factors which are particularly applicable to oil-circuit-breaker design where transients and low-frequency voltages, as well as surge voltages, are of great importance. We are sorry, however, that we cannot feel that the manufacturer's name-plate voltage rating, indicating the service voltage for which the apparatus is designed, is necessarily sufficient in actual practice. We appreciate Mr. MacNeill's position and are quite sure that he intends to convey that such certification would be adequate only after the principles set forth in the paper had been applied to the situation by those designing and selecting the apparatus.

Mr. Montsinger makes a very worth-while suggestion, which we endorse—that the definition of basic insulation level be modified to incorporate the word "standard", that is, "suitable standard tests". His suggestion that a factual survey of maximum line-to-line and line-to-ground operating voltages actually existing on operating systems be made is also voiced by Mr. Smith. It is believed that several of the operating companies are already conducting new surveys of these factors to supplement ones previously available and to extend the scope of these investigations.

We welcome Mr. Lusignan's endorsement of conclusion number 3 of the paper that name plates should definitely indicate the insulation strength of apparatus.

In connection with the thought expressed in the discussion by Mr. Rudge that a considerable additional margin between arrester performance and insulation strength may be available in the actual application of arresters, we believe that the correlation of rather moderate surge currents (as compared with the maximum surges which may sometimes occur) with slightly pessimistic arrester performance characteristics afford a reasonable compromise. If average arrester performances were to be taken as suggested by Mr. Rudge, it might be logical to assume a larger margin between arrester performance and the protected level.

Mr. Cooney's suggestion that the characteristics of lightning-surge protective devices and the derivation of the protected level be added to the illustrative examples has been carefully considered, and we realize that the paper would be more complete with this additional information. However, it has been our thought that the companion paper by Messrs. Sporn and Gross on "Rationalization of System Insulation—III" provides these data in their table I and in their formula for a margin of (protective device performance $\times 0.10$) $+25$ kv. The determination of the maximum voltage to ground is in accordance with the methods commonly used as set forth in reference 7 covering symmetrical components. It was felt unnecessary to duplicate this presentation.

Mr. Cooney mentions a point which we hope will not be misunderstood, which is—no "special insulation" has been contemplated, but insulation of a higher or lower standard level is supposed to be selected if a particular strength does not seem to be most economical or entirely suitable.

On the basis of the very general interest exhibited in the practical application of these principles, we believe that many engineers are studying in a logical manner the selection of the basic insulation levels suitable to their systems and preparing studies illustrated by the examples in the paper. This should hasten the general application and adoption of common principles of insulation co-ordination.

Proposed Standards for Outdoor Bushings

Discussion of paper 40-37 by the AIEE joint committee on bushings, presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940, and published in AIEE TRANSACTIONS, 1940 (October section) pages 590–1.

R. T. Henry: See discussion, page 1201.

L. Wetherill (General Electric Company, Pittsfield, Mass.): Anyone who has followed the development of the proposed bushing standards from the study of the various conflicting and inaccurately defined practices used in the past through to the development of the consistent and rational requirements which have been proposed will agree that Mr. Henry is to be congratulated on the accomplishments of his committee.

Perhaps the widest departure from former practices is the complete adoption of the hold or withstand test as a means of demonstrating the external electrical strength of bushings. This type of test has advantages not only in simplicity of definition and interpretation of test results, but also in that it tends to eliminate some of the variation in results which are obtained in making flashover tests and which makes any single flashover test subject to erratic variations.

The variability of the external electrical strength of bushings is illustrated in figure 1 of this discussion, which shows the probability of withstanding a voltage application without flashover as a function of the magnitude of the voltage. The middle curve is based upon data involving both 60-cycle and impulse voltages applied to a considerable number of bushings of various ratings. Occasional flashovers can be expected at 15 per cent above or below normal. The upper and lower curves show that although single tests may deviate as much as 15 per cent, no group of tests would be expected to deviate more than 9 or 10 per cent.

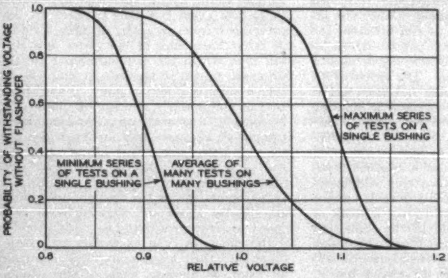

Figure 1. Variation in flashover strength of bushings

Bushing designs should contain margin for some variation in external electrical strength regardless of whether standard tests are of the "flashover" or "withstand" type, but the "withstand" type of test has the advantage that it demonstrates more definitely the presence of excess strength above the standard requirement.

Examination of figure 1 serves to explain why the standards for external electrical strength of bushings have apparently been decreasing in recent years. In past years flashover performance of bushings was expressed in terms of the average flashover strength; corresponding to unity on the scale in figure 1. Any given bushing is as likely to come below the average as above. It was felt necessary to place some restriction on the deviation of individual bushings on the low side and a minus-five-per-cent tolerance was used for this purpose. In recent years, a minimum value five per cent lower than the former average value has been widely used as the basis of specifications. It is seen from the curve that the minimum value should perhaps have been nine or ten per cent lower in order to constitute a more comparable requirement. However, the majority of bushings apparently had insufficient margin of safety to meet the more stringent requirement of a minimum value only five per cent below the former average value.

The introduction of withstand tests is a further increase in the severity of the requirement. At a voltage 15 per cent less than the normal flashover, figure 1 shows that a bushing can be expected to withstand voltage application without flashover in practically all cases. Introduction of "withstand" requirements in place of average flashover specifications is equivalent to 15 per cent increase in severity of test requirement. The kilovolt values have been decreased, in general, by a lesser amount so that the actual requirement is somewhat more severe.

The proposed standards specify test performance on the basis of bushings without gap electrodes. Now that established transformer test procedure no longer requires the use of gap electrodes to adjust the flashover strength of transformer bushings downward to standard values, it is possible to give more consideration to the possible injurious effects of the use of gap electrodes on bushings in service. The presence of gap electrodes on a bushing increases the probability that a flashover will occur adjacent to the bushing porcelain with possible injurious effects. Even in cases where it may be deemed advisable to provide gap electrodes, it would be the part of wisdom that they should be placed several feet away from the bushing, in order to avoid injury to the bushing.

The requirement stated in the proposed standards that bushings shall be suitable for operation at their standard ratings when and where the temperature of the cooling medium does not exceed 40 degrees centigrade should probably have some modification or amplification to cover applications, such as water-cooled transformers, which have different standard ambient conditions. Doubtless this can be accomplished in a subsequent revision.

Some points will not be settled until the proposed test code becomes available. The standard rate of precipitation and water resistivity for low-frequency wet tests are not stated in the proposed standards. The data on which the proposed standards are based were obtained with a precipitation of 0.1 inch per minute and a resistivity of 12,000 ohms per cubic centimeter. These conditions have been standard in testing bushings for a considerable number of years.

There has been discussion of changing the standard conditions to agree with those established for insulator testing which involve a precipitation of 0.2 inch per minute and a resistivity in the order of 18,000 ohms per cubic centimeter. The test performance of bushings would be affected by such a change and a careful study of the data will be required to determine the modifications in kilovolt values necessary to permit such a change and maintain the same degree of severity of requirement. Probably a small decrease in the kilovolt values would be in order.

The question will arise as to what extent the proposed standards should be placed in use at this time. There appears to be no reason why they cannot be used in specifications at this time, when it is desired to do so.

Recommendations for High-Voltage Testing

Discussion of paper 40-38 by the EEI-NEMA subcommittee on correlation of laboratory data, presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940, and published in AIEE TRANSACTIONS, 1940 (October section) pages 598–602.

Theory of Hysteresis-Motor Torque

Discussion of paper 40-80 by B. R. Teare, Jr., presented at the AIEE winter convention, New York, N. Y., and published in AIEE TRANSACTIONS, 1940, pages 907–12.

Wayne J. Morrill (General Electric Company, Fort Wayne, Ind.): Professor Teare has made an important contribution to the theory of hysteresis motors. His work outlines a method for approaching the problem of predetermining hysteresis-motor torque, and the data and conclusions given in his paper should be of considerable value to those actually designing such motors. I think it is no discredit to Professor Teare's work to say that a thorough analysis of all the aspects of hysteresis-motor performance has merely received a good start and Professor Teare's paper leaves open considerable opportunity for further investigation. It is to be hoped that further efforts, extending Professor Teare's work, will be forthcoming at future meetings of the Institute.

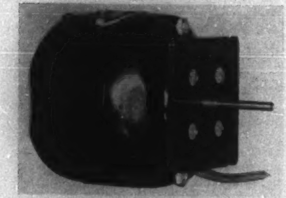

Figure 1. Hysteresis synchronous motor for horizontal operation; three watts (0.004 horsepower), 1,800 rpm, 110 volts, 60 cycles

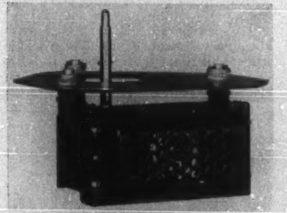

Figure 2. Hysteresis phonograph motor, 0.75 watt, 78.26 rpm, 110 volts, 60 cycles

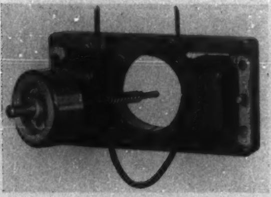

Figure 3. Armature and field of hysteresis phonograph motor

While Steinmetz mentioned and discussed the characteristics of hysteresis motors at the beginning of the century and Telechron and others have produced *modified* hysteresis motors, we are the only ones I am aware of who have produced true hysteresis motors in production quantities. For this reason it might be of interest to show several illustrations of production hysteresis motors. Two of those shown have been produced to the extent of approximately 75,000 units each.

Our experience agrees with that of Professor Teare in that the hysteresis motor is not a competitor of the induction motor in the general fields of motors. General statements are likely to be misleading unless carefully limited but it seems that, in the same size, a hysteresis motor will have from one-fourth to one-tenth the output of an induction motor. This means that the hysteresis motor will, as a rule, be somewhat more expensive than the induction motor.

The hysteresis motor has two outstanding characteristics which cause it to be attractive for certain types of work. Having, as it does, no slots in the rotor, it is not subject to the high-pitch harmonic noises of induction motors. It is, therefore, probably the quietest of all motors. Where extreme quietness is required and cost is not of primary consideration, a hysteresis motor may be used in place of an induction motor.

The hysteresis motor is not merely synchronous but it differs from other synchronous motors in that it has inherently good "pull-in" characteristics. A normal synchronous motor comes up to speed on the induction torque characteristic furnished by its amortisseur winding. Since the induction torque is zero at synchronism, the speed to which the motor can be driven by its induction characteristic is somewhat less than synchronous speed. The synchronous torque characteristic does not exist below synchronism except as transient alternating torques. It follows, therefore, that a normal synchronous motor must be "snapped" into synchronism from its highest induction speed by a single impulse of transient synchronizing torque as the rotating field passes the rotor poles. The ability of such a motor to synchronize is limited by the amount of inertia in the rotor and in the connected load. If this inertia exceeds a certain value the motor will fail to synchronize at all. This is not true of the hysteresis motor, since it has a constant synchronizing torque all the way up to synchronism. For this reason, the hysteresis motor will accelerate all the load that it can carry regardless of the inertia involved. This characteristic of a hysteresis motor might cause it to be used where otherwise a synchronous induction motor would be employed.

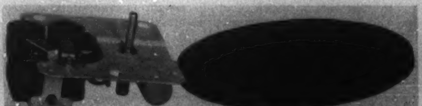

Figure 4. Hysteresis synchronous motor for rim-drive phonograph application

Induction-Motor Characteristics at High Slip

Discussion and authors' closure of paper 40-12 by Theodore H. Morgan, William E. Brown, and Arthur J. Schumer, presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940, and published in AIEE TRANSACTIONS, 1940 (August section) pages 464–8.

Quentin Graham (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): This paper deals with aspects of induction-motor operation which usually have been omitted from elementary textbooks and have had rather infrequent attention in the technical journals. For that reason the authors probably are justified in their references to what they have considered as the conventional methods. I believe, however, that the paper may give a false idea of the actual methods of practicing engineers. In particular the following items may be noted as representative of present-day design practice:

1. The rotor resistance is treated as a variable and appropriate values are taken depending on the slip.

2. The rotor reactance is varied with the slip.

3. The effect of saturation of the leakage paths is calculated so that the correct values are used for locked current and for full-load current.

4. The effects of flux harmonics on losses and torques are considered.

5. When motors are tested actual speed-torque curves are measured over the complete range of positive and negative speeds and at oversynchronous speeds rather than being constructed from no-load and locked-rotor test data.

The method of separating the losses and torques shown by the authors is dependable in certain cases but fails if there are appreciable torques set up by the fifth, seventh, or other harmonics of low order and may fail even where the slot harmonics are the principal source of parisitic torque. If we take a slightly different point of view from that of the authors, the torque curve may be considered as made up of the component torques of all harmonics among which are the slot harmonics. In relating torque to watts loss we must use the appropriate slip for each separate harmonic. Since the synchronous speeds for the slot harmonics are slightly above and slightly below zero speed no great error would be made, usually, if the effects of both harmonics were combined and their losses converted to torque by using an average value of slip. Since their average synchronous speed is nearly zero the average slip becomes the actual motor speed. This is what the authors have done. Suppose, however, that there is a large seventh-harmonic torque present. Obviously this will be overlooked as the loss which it represents will have been referred to the wrong slip. Even in the case of slot harmonics alone, if there are low-resistance rotor circuits available in which the harmonic currents may circulate, the torque curve may have important cusps which would not be detected by the method which has been used in the paper. A torque curve of the latter type is shown in figure 1 of this discussion. This curve was taken on a motor built especially to study such characteristics and is of course an extreme case.

It is true that there are many cases, perhaps most well-designed motors, where the principal torques aside from the fundamental are caused by the slot harmonic currents flowing in relatively high-resistance circuits. These motors will lend themselves to analysis similar to that in the paper. Thus the paper is useful in that it illustrates a rather common characteristic of motors. One of the points to be emphasized is that any appreciable amount of these harmonic torques seriously affects the heating of a motor during the accelerating period. They decrease the acceleration and at the same time add losses. For that reason it is essential to have a speed-kilowatt curve as well as a speed-torque curve in applying motors for frequent starting.

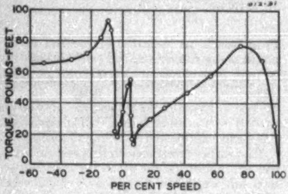

Figure 1

M. M. Liwschitz (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): The paper by Morgan, Brown, and Schumer is a very noteworthy addition to the paper "Reverse-Rotation Test" presented one year earlier by the same authors, because it discloses the possibility of determining in a relatively simple manner the curve representing the actual torque at the shaft of an induction motor.

It is the purpose of the present discussion to point out the necessity of supplementing by additional tests the tests on the four-pole machine described in the paper.

The stray load losses, occurring in an induction machine, consist of five components; two of these loss-components are iron losses, and the other three are copper losses in the rotor bars.

The two components covering the iron losses are:

1. The eddy current and hysteresis losses at the surfaces of the tooth crowns
2. The eddy current and hysteresis losses in the tooth bodies

The three loss-components occurring in the rotor bars are due

3. To the slot openings of the stator
4. To the step harmonics of the stator flux
5. To the phase belt harmonics

If the skin effect can be neglected, the iron losses follow the square of the speed. The copper losses do not follow the square of the speed.

The phase belt harmonics can be especially disturbing. This can be seen from figure 4 of the paper. This figure has a dip at positive speed values in the vicinity of the standstill point, for which the authors' method cannot account. This discrepancy between calculation and experiment is due to the phase belt harmonics, and it is a matter of fact that these harmonics may produce dips of considerable magnitude in the speed-torque curve, especially in the vicinity of the standstill point. Each one of the phase belt harmonics has the same operational effect as the fundamental wave; it should be considered, however, that the slip has different values for the various harmonics. In the vicinity of their synchronous speeds, said harmonics can produce torques of considerable magnitude without appreciable losses.

In Figure 2 of this discussion is shown the speed-torque curve of a two-pole three-phase 60-cycle 20-horsepower experimental motor, having 24 stator slots and 31 rotor slots. The application of the authors' method to this particular motor would not lead to satisfactory results.

I have checked by calculation said speed-torque curve, which was obtained experimentally with the aid of a dynamometer, and have indicated in the diagram the calculated points by crosses. The calculation involved the separate computation of the torque components, produced by the fundamental and by each one of the phase belt harmonics; in these computations, the increase in resistance and the decrease in reactance, due to the skin effect, were properly taken into account. In making the calculation, certain assumptions, concerning the temperature of the rotor winding, had to be made. Taking this into consideration, it can be said that the calculated values check reasonably with the experimental ones.

The effect of the various harmonics on the speed-torque curve is clearly visible in the figure. In the case of this particular motor, the fifth and the seventh harmonics have the greatest influence, while the slot harmonics, the 23d and the 25th, are without effect.

All harmonics produce positive torques at negative speeds; that means torques that have to be added to the torque produced by the fundamental. At the standstill point, the torques produced by the inversely rotating harmonics are all negative, and those produced by the forward rotating harmonics are all positive. At positive speeds the torques produced by all harmonics are negative; that is, they cause the resultant torque to be lower than the torque produced by the fundamental.

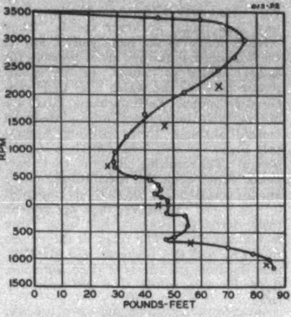

Figure 2. Speed-torque curve (see table I)

The phase belt harmonics may have a harmful effect especially in two-pole machines, although the high torque components that may be produced by these harmonics are not necessarily accompanied by high losses.

For example, at the speed of 1,080 rpm, the slip with respect to the fundamental is 1.3 and with respect to the fifth harmonic −0.5. The torque produced by the fifth harmonic at the slip −0.5 is equal to 30.7 pounds-feet and the corresponding losses are 1,580 watts. Even if we could find the real value of this loss by the method given in the paper, we would calculate a torque of only 11.2 pounds-feet instead of the real value of 30.7 pounds-feet.

On the basis of the foregoing, I recommend the making of supplementary tests, preferably on two-pole machines.

Theodore H. Morgan: From the discussion it would appear that there is some question as to the extent of the harmonic effects which are included in the method set forth in this paper. At the outset it should be understood that, while the effects of harmonics under one general classification are included, the torque which may result from harmonics of a somewhat different nature is omitted. For purposes of explanation and simplicity harmonic effects in induction motors may be divided into two main classifications. First, there are harmonic air-gap fluxes originating in the stator, which remain uniform in magnitude and rotate at constant speed in the air gap. These are excitation fluxes and are of the same nature as the fundamental air-gap

Table I. Twenty-Horsepower Two-Pole 60-Cycle Three-Phase Motor

n(RPM)	S_1	T_1 (Pounds-Feet)	T_5 (Pounds-Feet)	T_7 (Pounds-Feet)	T_{11} (Pounds-Feet)	T_{13} (Pounds-Feet)	$\sum_5^{13} T$	$\sum_1^{13} T$
−1,080	1.3	46.0	30.7	4.3	1.6	0.59	37.2	83.2
− 720	1.2	47.0	0	5.1	2.9	0.62	8.6	55.6
0	1.0	50.0	−14.5	10.3	−3.2	1.6	− 5.8	44.2
720	0.8	54.5	− 8.1	−17.6	−1.2	−1.8	−28.7	25.8
1,440	0.6	62.0	− 5.7	− 6.6	−0.91	−0.56	−13.8	48.2
2,160	0.4	76.0	− 4.0	− 3.1	−0.67	−0.39	− 8.2	67.8

flux. However, they are smaller in magnitude and rotate at lower speeds. They produce torque in the same general way as the fundamental flux and are responsible for sharp changes or "cusps" in the speed-torque curve in the region near their synchronous speeds. Such harmonic fluxes are of negligible importance in well-designed motors although their resulting torques may prove seriously large for those of poor design. The resulting effects of these harmonic fluxes upon the speed-torque curve are not considered in the methods employed in this paper. Whenever they are present their effects are superimposed upon those herein described. The cusps in the curves shown by both Mr. Liwschitz and Mr. Graham illustrate the effects of these harmonic fluxes for cases where they are unusually large.

There is a second family of harmonics which produces a distinctly different type of reaction. Due to rotation the relative position of the teeth and slots of the rotor and stator is constantly changing. The results produced by this change in the configuration of the magnetic path may be quite complex and varied in the production of harmonics. However, in order to understand the over-all effects of such harmonics it is only necessary to remember that they are caused by rotation. Thus all losses associated with such harmonics must necessarily be produced by rotation and result in a retarding torque upon the rotor. This group of losses forms the major component of stray load loss. They are taken into account fully by the methods of the paper and are the cause of torque production of major importance at high values of slip, even in the best designed machines.

Heating of a D-C Armature

Discussion and author's closure of paper 40-79 by Carl J. Fechheimer, presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940, and published in AIEE TRANSACTIONS, 1940, pages 920–6.

T. M. Linville (General Electric Company, Schenectady, N. Y.): The paper suggests the use of the contact thermocouple for measuring surface temperatures. The thermometer has the advantage of simplicity since any number of them can be placed in position rapidly and read repeatedly in succession with little chance of error. It is conceivable that a number of thermocouples could be attached to the rotor after shutdown and read repeatedly in succession without disturbing them. However, it has always appeared more satisfactory to use thermometers. Therefore, in connection with data relating internal and surface temperatures, it is recommended that thermometers be used to determine the latter. Other methods of measuring surface temperatures include the use of alloys having melting points about ten degrees apart, fastened to the armature in inaccessible spots and covered with thermal insulation, pyrometers, and (for commutators) thermocouples placed in a hole drilled in the face of brushes which are electrically and thermally insulated. In connection with the use of thermocouples, the leads may be brought out through copper and "copnic" slip rings without difficulty, using leaf brushes of the same material.

The paper concludes that average temperature rise can be measured on d-c armatures by resistance. This method has been used many times and gives accurate and valuable results. It can be measured by using a bridge and also by measuring the millivolt drop between two marked commutator bars when current is supplied through the brushes. Either method requires laboratory technique and has not been found to be a practical procedure which can be relied upon as a shop test.

J. F. Calvert (Northwestern University, Evanston, Ill.): Reference to author's figures 9, 10, and 11 shows that it was impracticable to get test data all the way back to time zero. The slope of this curve at time zero if known would be of assistance in extrapolating the curves. In cases where the loss is known (such as in the copper) the slope can be computed. In other cases if the slope at time zero can be taken as approximately correct, then the loss per unit-volume can be computed for the point at which the temperature measurement is made. This latter procedure can be of particular value to the designer when he is interested in the magnitude of high local losses in solid parts.

The mathematical relations which are involved are shown below. Choose the x, y, z rectangular co-ordinates. Then equate for any elemental section $\Delta x\cdot\Delta y\cdot\Delta z$ for any increment of time Δt that

heat generated in the incremental volume = heat stored + heat flowing out − heat flowing in

Or

$$W\cdot\Delta x\cdot\Delta y\cdot\Delta z\cdot\Delta t = C\cdot\Delta x\cdot\Delta y\cdot\Delta z\cdot\Delta t - K\left\{\left.\frac{\partial T}{\partial x}\right|_{x+\Delta x}\cdot\Delta y\cdot\Delta z\cdot\Delta t - \left.\frac{\partial T}{\partial X}\right|_{x}\cdot\Delta y\cdot\Delta z\cdot\Delta t + \left.\frac{\partial T}{\partial y}\right|_{y+\Delta y}\cdot\Delta x\cdot\Delta z\cdot\Delta t - \left.\frac{\partial T}{\partial y}\right|_{y}\cdot\Delta x\cdot\Delta z\cdot\Delta t + \left.\frac{\partial T}{\partial z}\right|_{z+\Delta z}\cdot\Delta x\cdot\Delta y\cdot\Delta t - \left.\frac{\partial T}{\partial z}\right|_{z}\cdot\Delta x\cdot\Delta y\cdot\Delta t\right\} \qquad (1)$$

From which,

$$W = C\frac{\partial T}{\partial t} - K\left(\frac{\partial^2 T}{\partial x^2}+\frac{\partial^2 T}{\partial y^2}+\frac{\partial^2 T}{\partial z^2}\right) \qquad (2)$$

where

W = watts generated per cubic inch at x,
C = heat storage capacity in watt seconds per cubic inch per degree centigrade
T = degrees centigrade (at x, y, z)
t = time in seconds

x, y, and z are the arbitrarily chosen rectangular co-ordinates in inch units.

Assume that steady-state conditions have been attained so that the rate of change of temperature with respect to time is zero. This is represented by equation 4. Then assume that the loss per unit volume is suddenly changed from the steady-state value of W_0, either up or down, to another constant value W_1, and write the expression for the conditions at $t=\Delta t$, where time is measured from the instant when the sudden change in loss occurred. This is shown in equation 3.

$$W_1 = C\left.\frac{\partial T}{\partial t}\right|_{\Delta t} - K\left\{\left.\frac{\partial^2 T}{\partial x^2}\right|_{\Delta t} + \left.\frac{\partial^2 T}{\partial y^2}\right|_{\Delta t} + \left.\frac{\partial^2 T}{\partial z^2}\right|_{\Delta t}\right\} \qquad (3)$$

$$W_0 = -K\left\{\left.\frac{\partial^2 T}{\partial x^2}\right|_{0} + \left.\frac{\partial^2 T}{\partial y^2}\right|_{0} + \left.\frac{\partial^2 T}{\partial z^2}\right|_{0}\right\} \qquad (4)$$

Subtracting (4) from (3) and rewriting the last expression:

$$W_1 - W_0 = C\left.\frac{\partial T}{\partial t}\right|_{\Delta t} - K\frac{\partial}{\partial t}\left\{\left.\frac{\partial^2 T}{\partial x^2}\right|_{0} + \left.\frac{\partial^2 T}{\partial y^2}\right|_{0} + \left.\frac{\partial^2 T}{\partial z^2}\right|_{0}\right\}\cdot\Delta t \qquad (5)$$

Since $\frac{\partial}{\partial t}\left(\frac{\partial^2 T}{\partial x^2}\right)$, $\frac{\partial}{\partial t}\left(\frac{\partial^2 T}{\partial y^2}\right)$, etc., are finite, then as Δt is allowed to approach zero it is found that

$$W_1 - W_0 = C\left.\frac{\partial T}{\partial t}\right|_{0}$$

From which, as indicated in the first paragraph of this discussion, if $W_1 - W_0$ is known, $\left.\frac{\partial T}{\partial t}\right|_{0}$ can be computed; or if $\left.\frac{\partial T}{\partial t}\right|_{0}$ as obtained by test is regarded as sufficiently accurate, then $W_1 - W_0$ can be found. (The constant C is easily established from handbook data.)

Two earlier references on this general subject which indicate the use of the above relation but which do not entirely justify its validity are as follows: "Additional Losses in Synchronous Machines," C. M. Laffoon and J. F. Calvert, AIEE TRANSACTIONS, volume 46, 1927, pages 84–96, and "Time-Temperature Tests to Determine Machine Losses," M. D. Ross, ELECTRICAL ENGINEERING (AIEE TRANSACTIONS), volume 54, 1935, pages 512–15.

C. Lynn (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): Mr. Fechheimer has presented a very interesting paper, particularly to the designer. The user of electrical machinery is interested in operating temperatures only in so far as these temperatures affect the performance and useful life of his machine.

The relatively low temperature limits that have been and are at present specified for the insulating materials used in industrial d-c machines have been justified by the long trouble-free life the insulating materials have given in the past in these types of d-c machines.

The abandonment, approximately ten years ago, of cast construction for armature spiders as used in the machine of Mr. Fechheimer's experiment and the substitution of fabricated steel permitting better ventilation and the use of stranded conductors, as mentioned in the conclusion of Mr. Fechheimer's paper, has materially reduced the spread between thermometer measured temperatures and actual hot-spot temperatures. These improvements over the past decade will permit industry using smaller and more economical higher-temperature-rated machines in the future without any untoward results. The tendency among users of electrical machines has already been in this direction for the past year or so as indicated by the application of d-c equipment with 60-

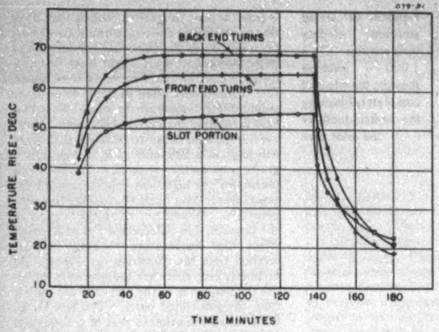

Figure 1. Temperature-time curve of the armature winding on a 1,500-kw d-c machine showing the relative temperatures of end turns and slot portion

degree temperature rise for marine application and for machines with class *B* insulation in some steel-mill installations.

W. E. Jacobsen (General Electric Company, Schenectady, N. Y.): Because of the inherent difficulty of measuring temperatures in d-c armatures, there is little accurate comprehensive data available. Mr. Fechheimer's paper shows one method of overcoming this difficulty and obtaining what is unquestionably accurate information on the magnitude and variation of armature temperatures as they exist in a running machine. His paper, therefore, is a welcome one.

As Mr. Fechheimer points out, the investigated machine was unsatisfactory from a ventilation standpoint and consequently the test results are not representative of a normal machine. It is somewhat unfortunate that this is the case and care should be used in interpreting the results obtained so as to avoid false generalizations.

There are three items in this paper to which I would briefly direct attention. The first concerns the iron-surface time-temperature curve taken with the contact thermocouple and shown in figure 12. Since the temperature difference between the armature core surface and the copper is a maximum at the instant of shutdown, and since this difference grows steadily smaller with passage of time, the resulting heat flow from copper to iron also becomes less with passage of time. Now, at any time after the instant when this flow becomes equal to the rate of dissipation by the external surface, the surface must be cooling and can never again regain temperature because of heat flow from the copper since that flow grows steadily smaller as time goes on. The only method by which the iron temperature could be raised by heat flow from the copper to the iron after it had once started to cool, would be to have the copper temperature itself raised again by the dissipation of more energy. As the curve of figure 12 indicates that the surface had begun to cool after about 4 minutes time, heat flow from the copper to the iron could not produce the rise obtained at 11 minutes time.

The second comment concerns figure 17. The information here presented is interesting because it indicates rather well the difference or gradient in temperature that exists in the copper of a commutator while running. The more rapid response of the contact thermocouple enables more of this temperature gradient to be measured since with it readings can be obtained much more quickly than with thermometers. This is essential since the temperature difference between commutator ends will act quickly to even the temperature throughout the length of the material as soon as the cause of that gradient is removed. The cause is very largely removed by the shutting down of the machine. In extreme cases commutator end temperature differences as high as 30 degrees centigrade have been observed by measuring commutator temperatures at various axial positions while running under load. These measurements were made by arranging thermocouples close to the commutator surface in small air pockets cut out in the faces of insulated brushes. It has been found that the differences between thermometer readings on commutators after shutdown and contact-thermocouple readings or running temperature readings is a maximum for small high-speed commutators and a minimum for large slow-speed units.

The third and last comment concerns figure 19. The curves in that figure show rises in the center of the core portion of the armature winding that are more than twice as high as those occurring at the ends of the coils. This tendency toward high copper temperatures in the core section is aggravated by the faulty ventilation and it is expected that a normal machine would show this tendency to a lesser degree. Since in general the hot-spot temperature exceeds the average or mean winding temperature determined by resistance by an amount approximately proportional to the difference between maximum and minimum temperatures, this difference as observed on the machine investigated by Mr. Fechheimer is larger than would normally be expected. In some d-c armatures where because of high speeds or other considerations it becomes necessary to cover rather completely the end turns with insulation and binding wire, an entirely different heating situation is produced. In this case, the end turns of the armature tend to be considerably hotter than the portion embedded in the core and the transverse heat flow in the copper is from the end turns to the core portion. A part of the test results recently obtained on a 1,500-kw machine equipped with temperature detectors is shown in figure 1 of this discussion. The average indicated rise of the copper of the core section was 54 degrees centigrade, while the front end turns indicated a rise of 64 degrees and the back end turns a rise of 69 degrees. It is interesting to observe that after shutdown the end turns cool at a faster rate than the portion embedded in the core and soon after shutdown are cooler than the core portion. This is to be expected since the larger mass of the core iron cools relatively slowly compared to the copper and is eventually aided in its cooling process by passing heat to the core portion of the winding for dissipation by the cooler end-turn sections.

Most calculation methods for armatures assume that there is no transverse heat flow at some position in the core section, usually the middle. This is not necessarily the case. Certain high-speed d-c armatures for which fairly complete temperature calculations have been made show curves as in figure 2 of this discussion. The mean ordinate of each of these curves was closely checked by test resistance results after rapid shutdown and projection of the cooling curve back to the instant of shutdown. The curves of figure 3 of this discussion, taken on the same machine with changed ventilation arrangements, show the result of shutting off the air to the radial ducts. The average ordinates of these curves were also checked by test results. The similarity of the curve with the ducts blocked to those obtained by Mr. Fechheimer is perhaps interesting. If the end turns on this machine had been more

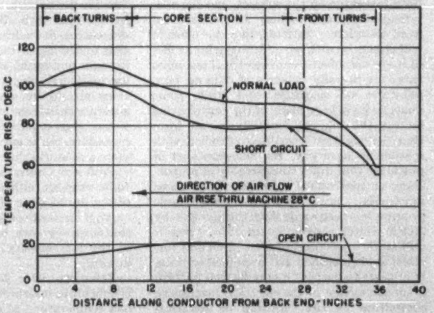

Figure 2. Calculated armature winding temperatures of a 1,000-kw totally enclosed fan-cooled d-c machine

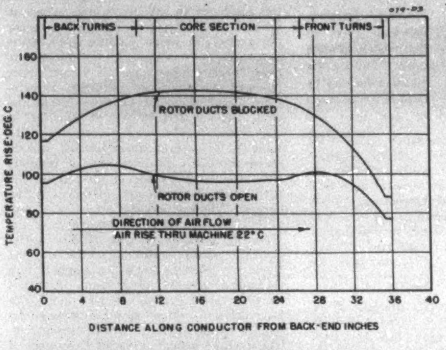

Figure 3. Calculated armature winding temperatures of a 1,000-kw machine showing the effect of completely blocking the radial ducts of the rotor core

exposed making them more similar to those of the machine employed in Mr. Fechheimer's tests, the similarity of the results would have been even more striking.

The machine on which the data of figure 1 were obtained is an open-type medium-frequency machine with moderately heavy overload capacity. The machine on which the data of figures 2 and 3 were obtained is a totally enclosed fan-cooled short-time-duty machine.

In conclusion, it might be well to emphasize the fact that temperature-rise characteristics are not the result of total losses and ventilation only, but are materially affected by the distribution of those losses as well. In a low-frequency unit, the ratio of copper to iron loss might be in the approximate ratio of ten to one while in a high frequency unit this ratio might be one to one. This, together with the construction changes necessary because of changes in speed, make it possible to obtain a wide variety of temperature patterns, and it is difficult, if not impossible, to make satisfactory generalizations on so complicated a problem without having first thoroughly investigated a number of machines covering a wide range of ratings and speeds.

Carl J. Fechheimer: It has been my firm belief for many years that no problem concerned with electrical machines is more intricate and of more importance than heating. Yet comparatively few papers have been presented on the subject, and the analytical and experimental studies are far from complete. Perhaps, like the poor, it will always be with us. Although in the files of every manufacturer of electrical machines there are literally volumes of data on temperatures of machines, and while some analyses have been made of the contributing factors, the data are generally in such form that the engineer is unable to predict, with reasonable accuracy, the temperatures of machines that differ considerably in proportions or mechanical structure from those previously built. Whereas considerable progress has been made since the noteworthy AIEE winter convention in 1913, there is still much opportunity for research and correlation of published and unpublished data. It appears to me that it may be well to form a subcommittee of the electrical machinery committee on the "heating of electrical apparatus". It was my especial purpose in presenting this paper to call attention to a few things associated with d-c machines, in order to try to arouse interest in the important subject of heating. To those who are inclined to be impatient may I call attention to the claim that the great Kepler devoted ten years to the study of Tycho Brahe's astronomical data, and his interpretation led to the enunciation of the three famous Kepler's laws.

Replying to Mr. Linville, at the historic winter convention of the AIEE in 1913 there was much controversial discussion on the use of embedded detectors in stators of a-c machines; but, notwithstanding the opposition, their use in large a-c stators has become standard. During the many years that have elapsed since then, comparatively little attention has been paid to methods of surface temperature measurements, and the thermometer is used today as it was then. In general, the thermometer takes considerably longer time to attain its maximum than does the contact thermocouple, and the surface will have cooled appreciably more before the maximum is reached with thermometer than with contact couple. Perhaps the subject could be discussed to advantage in meetings of the committees on test codes. Alloys having various melting points and color-changing paints have been considered frequently for temperature measurements but I was not aware that either had been placed on a practical basis for application to armatures. It would be of value for Mr. Linville to publish some results of his investigations with alloys having ten-degree differences in melting points. One objection to the use of thermocouples with leads brought out to slip rings is that many rings are needed if temperatures at various locations are to be measured. I agree that accurate measurement of d-c armature resistance has so far been almost a laboratory procedure, but it may be possible to place it upon a practical shop basis.

Professor Calvert's suggestion may prove to be valuable, either for the determination of the initial slope of the temperature-time curve if the loss per unit volume just before shutdown is known, or for the determination of the loss density if the initial slope is known.

Referring to Mr. Jacobsen's discussion, it is difficult to interpret the second rise in surface temperature, as shown in figure 12. It is possible that the rate of cooling may have decreased during the test without its having been noted; as the tests were conducted in a large building, a draft might have been reduced while the measurements were made. It is undoubtedly more valuable to measure commutator temperatures while the armature is running than after shutdown. However, it does not seem to be likely that there was as great a difference as 30 degrees centigrade between the two ends, as Mr. Jacobsen found, for the high heat conductivity of the commutator bars tends to equalize the temperatures. Would not the local heating in the brushes, due to localized I^2R or friction, affect the temperature reading, by the method that Mr. Jacobsen employed? As he points out, there are armatures in which the temperatures of the coil ends are higher than the embedded parts. The late G. E. Luke called attention to that in a discussion of a paper that I presented some years ago (AIEE TRANSACTIONS, 1921, page 653, figure 2). The irregular forms of the curves shown in Mr. Jacobsen's figures 2 and 3 are interesting, and they indicate how ventilation can affect materially the distribution of temperatures.

There is no doubt that the difference between the bare copper and surface temperatures has been materially reduced, as stated by Mr. Lynn, by improving ventilation and by better stranding of the armature conductors.

Electric Couplings

Discussion and authors' closure of paper 40-46 by M. R. Lory, L. A. Kilgore, and R. A. Baudry, presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940, and published in AIEE TRANSACTIONS, 1940 (August section) pages 423–8.

C. C. Hutchins (Elliott Company, Pittsburgh, Pa.): The authors' paper on electric couplings is very timely and several points in connection with the design are very interestingly treated.

As a matter of general information it might be of interest to call attention to certain earlier work on electric couplings which is referred to in a general way in the author's paper. Prior to 1919, a considerable amount of work was carried on in an experimental way by M. E. Thompson of the Elliott Company and later two patents were issued to him, one of them particularly interesting, number 1,481,655 granted in January 1924. In 1920, 1922, and 1925 three couplings of the type being investigated were built, one was 750 horsepower at 400 rpm, another 1,000 horsepower at 425 rpm, and the third 2,500 horsepower at 375 rpm. It is interesting to note that these were being considered for the purpose of ship propulsion. While the greater emphasis was at that time placed on synchronous locking features, yet the equipments were (according to the records of tests conducted at the Brooklyn Navy Yard) capable of developing sufficient torque at high slips to start the Diesel engines used in connection with them. It is interesting that much of this earlier work covered a surprising number of the ideas being intensively developed at the present time.

In the last paragraph of the section "Other Types of Electric Couplings," the statement is made that a synchronous coupling can be built by using salient poles and d-c excitation on both members. Several couplings of this type have been built and were the subject of a large amount of experimental work by Mr. Thompson and a considerable amount of valuable and interesting information was developed from the shop tests.

Anyone who has worked out designs for slip couplings of the more recent type will agree with the authors' statement regarding the difficulty of the design problem. While the photograph, figure 4, of the paper is too reduced in size to show the squirrel-cage winding in detail, yet having seen the rotor itself, it appeared that the cage winding being used was somewhat more elaborate than an ordinary double-deck design. Possibly it could be described as being a combination of a double-deck squirrel-cage winding with the lower layer of bars proportioned to secure the benefit of what is normally considered a deep-bar rotor.

Elliott Company electric couplings employ double cages in some designs and triple cages in others, depending upon the torque characteristics desired.

The computation of the slip-torque curve, particularly over the unstable range, that is, at slip values beyond the breakdown point, is quite complicated, especially as it is necessary to treat the demagnetizing and cross-magnetizing effect of the squirrel-cage winding on the field which requires the development of some means for taking into account saturation effects.

In appendix *A* of the authors' paper there is a rather interesting idea presented, the analysis being based upon electrical considerations alone. It is of interest to compare this method of analysis and the solution on the basis of the assumptions included with an analysis based on an entirely different set of assumptions published in the *Transactions* of the British Institute of Marine Engineers, volume 49, 1937, entitled "Electromagnetic Slip Couplings for Use With Geared Diesel Engines for Ship Propulsion", by G. L. E. Metz and Nils Erickson. Possibly this paper could profitably be included in the authors' list of references.

That the coupling has a very slight spring action due to its electrical characteristics has been observed during the test of some units when the inertia of the members and the frictions in the test setup have been sufficiently low so as not to mask the effect completely. We would like to ask the authors if, in their opinion, when the effects of inertia, bearing frictions, etc., are taken into account whether the combination of these effects is not so much larger as to make the particular electrical effect described in appendix *A* comparatively of not very great significance.

The Elliott Company's experience in this connection has been that when dealing with a coupling of the synchronous locking type, the spring action is of sufficient magnitude as to be of considerable importance, but when dealing with a slip coupling the amount of spring action which can be observed is so small in comparison with the amount of torque transmitted that in the usual cases little attention need be given to it. This is not to say that torque variations will not be transmitted through the coupling, for experience shows that they will, however, in so passing, the magnitude is generally reduced to a value seldom in excess of two to three per cent for comparatively low frequencies. It would be of interest to hear the authors express a further opinion upon this point.

The paper would be somewhat more readable if a collected list of symbols and definitions were included.

M. M. Liwschitz (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): The spring torque of the electric coupling is something remarkable in the paper of Lory, Kilgore, and Baudry, because it means a synchronizing torque in an induction motor, but it is not so surprising if we consider more exactly the synchronizing torque of the synchronous machine. In a paper published in 1933 (*Wissenschaftliche Veröffentlichungen aus dem Siemens-Konzern*, volume 12), I derived for the synchronizing torque of the synchronous machine the equation given at the bottom of figure 1 of this discussion. It consists of four terms. Some symbols are not usual and must be explained:

N is the number of turns (of the field winding or of the primary winding per phase)
τ is the leakage-coefficient

$$\tau_{1d}=\frac{X_1}{X_{ad}} \qquad \tau_{1q}=\frac{X_1}{X_{aq}}$$

ω is equal to 2π times the line frequency
z is equal to 2π times the frequency of the oscillation
X_L reactance between machine and line

The curves relate to a synchronous motor with a rating 2,660 kva, $\cos\phi=0.9$ leading, 50 cycles, 125 rpm.

The curve T_s is the synchronizing torque of this machine, representing the sum of the four terms of the equation. It is plotted over $\cos\phi$, for leading current on the right, for lagging current on the left.*

The curve $\frac{n_{nat}}{n}$ represents the ratio between the natural frequency expressed in revolutions per minute and the normal revolutions per minute of the machine. The crosses are tested values. The calculation checks well with the test.

We consider now separately each of the four terms of the synchronizing torque. The first and the second terms are well known. Professor Arnold derived them more than 30 years ago. Both of these terms are connected with the angle θ_{av} between the line vector and the vector of the induced electromotive force. They are independent from the frequency of the oscillations.

The third and the fourth terms are proportional to $\sin^2\theta_{av}$ and $\cos^2\theta_{av}$ and depend on the leakage reactances of the primary and secondary windings. Both of these terms depend also on the frequency of the oscillations and are equal to zero when the frequency of the oscillations is zero. For reasons which I will give, I use for the sum of the first two terms the sign T_{syn} and for the sum of the last two terms the sign T_{asyn}.

The distribution of the synchronizing torque between these two parts is shown on the slide. The asynchronous part of the torque increases with decreasing field current and becomes very important for lagging power factors. At a lagging power factor equal 0.9, the asynchronous part of the torque has the same value as the synchronous part.

In order to see better the meaning of the third and the fourth terms, we assume that the machine is symmetrical with respect to both axes. Then the third and fourth terms can be combined and expressed by one term only, which will be independent from the angle θ_{av}. This term will not have anything of the properties of the synchronous machine. I wrote in the paper mentioned above:

> "The synchronous machine has a synchronizing torque only, when the angle θ_{av} which corresponds to a fixed load is being changed. If this change of the angle θ_{av} goes on very slowly, this means, if the frequency of the pulsations is very small, the synchronizing torque will be expressed by the first two terms given in the equation on the figure. If the pulsations are not slow, then to the synchronous state of the machine will be superimposed an asynchronous state and the synchronizing torque will be increased by the wattless power, which corresponds to the leakage reactances of all windings. To the stabilizing effect of the main flux will be added the stabilizing effect of the leakage flux of the stator winding and of the rotor winding."

There is no reason why the synchronizing torque that corresponds to the third and fourth terms, that means the asynchronous part of the synchronizing torque, cannot exist in the induction motor. Indeed it is possible to derive a general equation for the synchronizing torque of the induction motor. This equation with sufficient accuracy is

$$T_s^{watt}=\frac{m_1E_L^2}{4}\times$$

$$\left\{\frac{[X_1+(1+\tau_{1d})X_{2d}]\frac{1}{1+\tau_{1d}}}{\left[(1+\tau_{1d})r_{2d}\frac{\omega}{\alpha}\right]^2+[X_1+(1+\tau_{1d})X_{2d}]^2}+\right.$$

$$\frac{[X_1+(1+\tau_{1d})X_{2d}]\frac{1}{1+\tau_{1d}}}{\left[(1+\tau_{1d})r_{2d}\frac{\omega}{\beta}\right]^2+[X_1+(1+\tau_{1d})X_{2d}]^2}-$$

$$\frac{2[X_1+(1+\tau_{1d})X_{2d}]\frac{1}{1+\tau_{1d}}}{\left[(1+\tau_{1d})\frac{r_{2d}}{s}\right]^2+[X_1+(1+\tau_{1d})X_{2d}]^2}+$$

$$\frac{[X_1+(1+\tau_{1q})X_{2q}]\frac{1}{1+\tau_{1q}}}{\left[(1+\tau_{1q})r_{2q}\frac{\omega}{\alpha}\right]^2+[X_1+(1+\tau_{1q})X_{2q}]^2}+$$

$$\frac{[X_1+(1+\tau_{1q})X_{2q}]\frac{1}{1+\tau_{1q}}}{\left[(1+\tau_{1q})r_{2q}\frac{\omega}{\beta}\right]^2+[X_1+(1+\tau_{1q})X_{2q}]^2}-$$

$$\left.\frac{2[X_1+(1+\tau_{1q})X_{2q}]\frac{1}{1+\tau_{1q}}}{\left[(1+\tau_{1q})\frac{r_{2q}}{s}\right]^2+[X_1+(1+\tau_{1q})X_{2q}]^2}\right\}$$

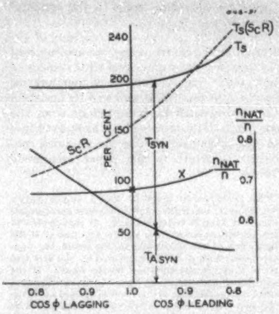
s is the slip of the machine. Furthermore,

$$\alpha=s\omega+z \qquad \beta=s\omega-z$$

---

* The curve $T_s(ScR)$ is the product of the short-circuit ratio and the normal output of the machine. This product is sometimes used as synchronizing torque.

For the derivation of this equation, the assumption was made that the rotor is not symmetrical with regard to both axes (synchronous motor running with the slip *s*).



$$T_s^{\text{watt}} = \sqrt{2}E_L I_f \frac{N_f}{N_1 K_d K_p} \frac{X_{ad}}{X_d + X_L} \cos\theta_{av} + m_1 \frac{E_L^2}{X_d}\left(\frac{X_d}{X_q} - 1\right)\cos 2\theta_{av} + m_1 E_L^2 \times$$

$$\frac{[X_1 + (1+\tau_{1d})X_{2d}]\dfrac{1}{1+\tau_{1d}}}{\left[(1+\tau_{1d})r_{2d}\dfrac{\omega}{z}\right]^2 + [X_1 + (1+\tau_{1d})X_{2d}]^2} \times \sin^2\theta_{av} + m_1 E_L^2 \times$$

$$\frac{[X_1 + (1+\tau_{1q})X_{2q}]\dfrac{1}{1+\tau_{1q}}}{\left[(1+\tau_{1q})r_{2q}\dfrac{\omega}{z}\right]^2 + [X_1 + (1+\tau_{1q})X_{2q}]^2} \times \cos^2\theta_{av} = T_{\text{syn}} + T_{\text{asyn}}$$

Figure 1

2,660 kva, cos $\phi = 0.9$, 50 cycles, 125 rpm
100 per cent $T_s = 2{,}660$ kw

For the normal asynchronous machine, $X_{2d} = X_{2q}$, $\tau_{1d} = \tau_{1q}$ and only three terms will be between the brackets.

For the symmetrical synchronous machine, $X_{2d} = X_{2q}$, $\tau_{1d} = \tau_{1q}$, $s = 0$, $\alpha = -\beta = z$ and the synchronizing torque will be

$$T_s^{\text{watt}} = m_1 E_L^2 \times \frac{[X_1 + (1+\tau_1)X_2]\dfrac{1}{1+\tau_1}}{\left[(1+\tau_1)r_2\dfrac{\omega}{z}\right]^2 + [X_1 + (1+\tau_1)X_2]^2}$$

This is exactly the same value that we will find for the symmetrical synchronous machine from the equation given on the figure.

Frank M. Lewis (nonmember; Massachusetts Institute of Technology, Cambridge): The electric slip coupling is a very effective device for isolating a gear reduction from the vibratory torques of a Diesel engine. For all practical purposes it can be assumed that such isolation is complete. Their action in this respect is very similar to that of the Foettinger hydraulic couplings, and in any given installation the question will arise as to which is the most suitable device.

With the gears isolated from the engine there will remain critical vibration of the system comprising the engine and the attached member of the coupling. If the engine-attached member of the coupling, either electric or hydraulic, can be given an appreciable amplitude of vibration relative to that of the engine cranks, that is, if the nodal point can be moved up into the engine, then the couplings are effective in damping criticals of the engine coupling system, and an arrangement entirely free of criticals can be constructed.

It has been possible to build hydraulic couplings of sufficient lightness to accomplish this. The requirement is that the polar inertia of the engine-attached coupling member be of the same order of magnitude as the total polar inertia in the engine. Information as to how nearly the electric couplings can meet this condition would be of interest.

The authors mention synchronous couplings. Several of this type were constructed by the Sperry Gyroscope Company and the Elliott Company about 15 years ago, but were not successful. One great difficulty is that a low-speed critical develops due to the elasticity of the coupling. In passing through this, vibration torque may build up to such an extent that the breakaway torque is exceeded, resulting in a runaway.

B. C. Seaman (Elliott Company, Ridgway, Pa.): The following points may prove of interest to those making a study of electric couplings.

It should be noted that the method of operation proposed on the more recent couplings mentioned by the authors is somewhat different than that employed on earlier ships. The Maritime Commission's requirement of 75 per cent torque for any slip up to 140 per cent is based on de-energizing the couplings, reversing the engines, and then re-energizing the coupling to pick up the propeller.

Published data on the Swedish couplings show that these couplings developed torques as low as 20 per cent at a slip of 100 per cent and could pick up the propeller from standstill only after the engine had been reduced to a very low speed. These couplings were left energized after the propeller had been picked up and all maneuvering done with the engine.

Even when designed for the maximum torques there is, of course, a certain lapse of time between energizing the coupling and the time the propeller is reversed and brought up to the engine speed. With certain types of Diesel engines, the manufacturers state that considerably greater than full-load torque is available when reversing on the air and that a quicker reversal despite the inertia effects may be effected by having the coupling energized.

Prolonged operation at high slips and comparatively high torques results in considerable heating of the squirrel-cage member. However, it has been demonstrated that with a properly designed squirrel cage, such operation may be continued for at least a half hour without injury to the coupling. The ability of this type of coupling successfully to withstand such severe abuse gives an indication of its ruggedness and of the freedom from trouble that may be expected.

It is suggested that the use of field coils wound directly on the pole would facilitate replacement. The complete coil and pole could be carried as a spare and it would not be necessary to take particular pains in adjusting the pole insulation when repairs were being made in a limited time.

It is noted that the couplings described by the authors employed one-piece circular punchings shrunk on the rim of the spider. Does not this construction require careful turning of the completed stack or the use of very large punches and dies? Our experience indicates that the more usual segmental construction can be used to advantage providing the stack is securely anchored to the spider rim.

A gap of one-fourth inch was selected for the couplings listed as item 2, table I, as a conservative value. Later couplings for ship service have used this value although earlier couplings, particularly those of Swedish manufacture, have used much smaller gaps. It should be noted that the use of a small air gap quite frequently requires that a pilot or centering bearing be used. May we inquire if the 3,000-horsepower coupling listed as item 1, table I, used an air gap of this magnitude?

It should be noted that through the use of special forms of squirrel cage and the proper proportioning of the coupling, variable-speed couplings can be constructed with a full-load slip as low as 3 per cent. This gives an over-all efficiency that compares favorably with the hydraulic coupling.

Reports indicate that some trouble was experienced with certain of the Swedish couplings owing to the field-coil construction employed. It has also been indicated that bushed pins were employed for emergency drive and that under this operation the pins deformed and presented difficulties when their removal was attempted.

The couplings listed under item 2, table I, were equipped with spring plates for emergency drive in order to eliminate this difficulty. No reference is made in this paper to emergency drive provisions and it would be interesting to know what type the authors used.

M. R. Lory, L. A. Kilgore, and R. A. Baudry: In reply to the discussion of C. C. Hutchins, we agree that the general idea is not new and in fact the paper mentions some patents as early as 1891. We are also in agreement that the design problem is difficult, however, the authors by this statement did not intend to imply that there was any part of the electric-coupling performance which could not be calculated with reasonable accuracy.

The reference to a paper in the British Institute of Marine Engineers was overlooked; however, reference 2 is by Nils Erickson, one of the same authors. Not only are the assumptions of this paper different, but they are in error in that the electrical torque is taken to be proportional only to the relative velocity, whereas in appendix *A* the electrical torque is shown to be a function of the slip frequency plus and minus the forced frequency. More important still is the difference in the conclusions; in reference 2 it is stated that "It is quite impossible for any resonance phenomena to occur in a coupling of this type," whereas the authors show in appendix *A* that there is a spring action and that the coupling alone would have a natural frequency.

The significance of the effect described in appendix *A* is questioned. The authors agree that in most Diesel-engine drives under normal conditions the slip coupling will transmit a negligible amount of engine-torque pulsations. However, the propeller torque impulses are of much lower frequency and more likely to occur in or near the natural frequencies of the electromechanical system formed by the propeller, gear, and coupling inertias and the shaft and coupling flexibilities. Also during abnormal conditions uneven firing may result in lower-frequency components of engine torque of considerable magnitude. For these reasons it was thought desirable to study the problem thoroughly and present a method of calculation so that any proposed installation might be checked to avoid any possibility of trouble. Given the inertias and spring and damping coefficients of the coupling, the marine propulsion designer can readily include these effects in his calculations.

In reply to B. C. Seaman's questions, the use of coils wound directly on the pole would make little difference in the ease of replacement. The largest part of the labor involved is in removing and replacing the pole and the extra work involved in putting a new coil on the pole is small. We use coils of edge-wound copper strap whenever possible in spite of their greater cost because of their superiority in mechanical ruggedness.

The core construction employing one-piece circular punching was used to reduce weight. We are now building the largest electric couplings ever made and are using segmental punchings because sheets big enough to make one-piece punchings are not available. The extra depth required to secure the segmental punchings together and to the rim results in increased weight for the same strength.

The air gap used in the 3,000-horsepower coupling, item 1, table I, was 0.143 inch. Large air gaps have operating advantages but result in increased weight, and the gaps used represent compromises between these two considerations. In ship drives the use of a pilot bearing should be avoided since by preventing displacement, it destroys one of the operating functions of the coupling. Also such a bearing may be inaccessible and hard to maintain.

Provision for some form of mechanical drive in emergencies has been incorporated in a few electric couplings. Mr. Seaman mentions one installation made by his company and we have been told that A.S.E.A. furnished this feature on couplings for one customer, but do not furnish it on their standard couplings. We have not furnished it because we do not feel that it is necessary. Unless all of the couplings on the vessel had been practically destroyed, this feature would not be of any use. The increased reliability of multiple-engine drive also extends to the couplings. Any emergency mechanical drive is certain to transmit vibrations which may damage the gear. It should be noted that failure of the excitation source should not be included in the type of emergency in which a mechanical drive might be used as such failure would also shut down the engine auxiliaries which are motor driven on the vessels for which we have supplied couplings. They derive their power from the same source from which the couplings take excitation so that if this source failed, the engines could not be operated at all.

Doctor Liwschitz makes an interesting comparison between the synchronizing torque in the coupling and the additional synchronizing torque of a synchronous motor due to induced currents in the damper winding.

Doctor F. M. Lewis calls attention to the interesting possibility of making one member of the coupling with sufficiently low inertia to move the nodal point up into the engine and obtain effective damping from the coupling. By building the field on the outer member and the cage winding on the inner member it is possible to do this. In fact, the inertia of the inner member of the coupling described in this paper is slightly less than that of the engine.

Starting Performance of Salient-Pole Synchronous Motors

Discussion and author's closure of paper 40-3 by M. M. Liwschitz presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940, and published in AIEE TRANSACTIONS, 1940, pages 913–19.

C. C. Hutchins (Elliott Company, Pittsburgh, Pa.): Every engineer who is engaged in the design of synchronous motors is confronted with the necessity of acquiring a method of calculating the speed-torque and current-torque starting characteristics of a particular motor from its dimensions. Prior to the appearance of the two papers mentioned by the author, there was available only a moderate amount of useful published information in this particular branch of electrical design. Each individual engineer had, however, accumulated certain methods and criteria applying to his particular style of machine. The collection of such information is rather a formidable task as the author has stated.

In reading the present paper, one is necessarily obliged to remember that while the general mode of attack is indicated, the detail involved in carrying it out is left, as is usual, to the skill of the individual reader.

It appears that the procedure recommended in the paper can be considered as a simplifying modification of the more elaborate method described by Linville with certain interesting additions, as for example the breadth factors which are introduced.

Having used a somewhat similar but less condensed procedure during the past several years, there are certain points which naturally have attracted my attention.

The first is in regard to the "equivalent" cage bars of the starting winding. It would seem that provided these bars are chosen of different materials and so located in the pole heads as to have different reactances, that the method employed in determining the nature of the equivalent bar would be the governing factor in the success of the method. It would also appear to be desirable to so determine the equivalent bar that the effect of a rearrangement of the positions of bars of different materials in the pole heads would not be masked in the process. Experience indicates that the relative location of bars of different materials has a great influence on the motor performance. Perhaps the author would be willing to comment more fully upon this particular point.

Noting that a number of simplifyng assumptions are made as must, of course, always be the case and that some of these assumptions must necessarily be quite far reaching the author's comment in the section "Torques and Current Equations" excites interest. Almost any designing engineer would probably agree that a check of torque and average line current over the starting cycle of a synchronous motor within plus or minus five per cent or even plus or minus ten per cent is good, remembering not only the simplifying assumptions but also construction variations, as well as possible discrepancies in testing. It would be interesting to have an expression from the author as to what he considers the probable limit of accuracy of prediction of these characteristics.

Equations 18 and 19 appear to be derived using a form of vector diagram similar to that sometimes employed to determine an equivalent resistance and reactance for the rotor of a double-deck squirrel-cage induction motor.

It would seem that the computation or allocation of the reactance X_m to be used here could become a fairly complicated task.

It is understood that the assumptions listed in the paper are sufficient justification for employing the method indicated. In making a practical computation however, in the past it has been generally true that many of the motor "constants" must be "shaded" judiciously in one direction or the other in a manner varying with the type of machine, degree of saturation, etc., in order to bring results into agreement with test. The present paper indicates that this is the case with most of the constants involved. X_m is probably a particularly good illustration as one can see at a glance that the values of r_{2d} and x_{2d} will be considerably affected by any modifications made in its value.

It is very evident that the author has devoted a large amount of time and effort to the development of the material presented

A. H. Lauder (General Electric Company Schenectady, N. Y.): Mr. Liwschitz mentions that the representation of a multiple-bar amortisseur by a single equivalent winding in each axis of the machine has been known to the industry for some time. The equivalent circuits shown in figures 4 and 5 were presented in almost the same form in a thesis by Davidson,[1] but so far have not appeared in an AIEE publication.

These circuits are an aid to rapid calculation but, when applied to the case of salient poles, a certain amount of experience is necessary in order to predict how much the actual performance of the machine will deviate from the results obtained by the solution of the circuits. The circuit constants can be accurately evaluated for the induction motor because the distribution of amortisseur current is approximately sinusoidal. When the treatment is extended to include salient poles, assumptions must be made which base the circuit constants on a current distribution somewhat different from that existing in the actual amortisseur winding.

With reference to figure 5, attention should be called to the fact that the mutual reactance of the quadrature axis amortisseur with respect to the armature will be slightly less than X_{aq} when the number of bars per pole is even. Likewise in figure 4 the mutual of the amortisseur with respect to the armature will deviate from X_{ad} as the pole-tip bars are moved toward the center of the pole. The mutual reactance of the amortisseur with respect to the field may not be the same as that with respect to the armature. Recognition of this fact is indicated by equation 20. However, equations 18 and 19 do not represent the equivalent resistance and reactance of the rotor circuits of figure 4 except for the case where X_m as defined by equation 20, is equal to zero.

The expression for average torque, equation 4, is approximate as evidenced by the fact that it becomes independent of X_{ad} and X_{aq} when X_1 approaches zero. The final equations in appendix *C* agree in form with appendix 5, reference 2 of this discussion. Equation 9 of this paper and 98 of reference 2 agree in detail, which would seem to confirm this part of the author's analysis.

I agree with the author that if a machine is allowed to attain maximum speed as an induction motor, and excitation is then applied at the most unfavorable angle, more load will be synchronized than will be possible under the conditions defined by equation 10 and the torque-speed curve with the discharge resistor short-circuited. The latter criterion applies specifically to the case where the field is closed prematurely with a load such that the motor can accelerate to the slip defined by equation 10 and operate there until the field is fully built up, at which time it will just be able to synchronize. It has been used in the past to determine the synchronizing ability from the worst angle because it was known to be pessimistic and especially because it could be easily checked by test without connecting the motor to a load. Experience has shown that the accurate prediction of a motor's synchronizing ability from the worst angle by direct calculation is a lengthy process. Empirical formulas have also been found to be less reliable, when applied to machines of radically different torque characteristics, than the previously described criterion for the worst condition increased by an experience factor.

It is believed that the value of the author's paper would be enhanced if in his closure he included more of the reasoning used to justify the derivation of the breadth factors or gave an example of their use in calculating one of the circuit constants.

2. SALIENT-POLE MOTORS OUT OF SYNCHRONISM, A. H. Lauder. ELECTRICAL ENGINEERING (AIEE TRANSACTIONS), June 1936.

S. B. Crary (General Electric Company, Schenectady, N. Y.): Mr. Liwschitz in the section "Influence of the D-C Excitation" has presented an interesting physical explanation of a component of negative damping torque which is proportional to the square of the field magnetomotive force. This component of negative damping has ordinarily been neglected by previous investigators. However, the complete negative-damping phenomena apparently cannot be explained in this relatively simple manner as there are additional effects as shown in the papers by Nickle and Pierce, and Wagner on negative damping. An interesting feature of the component of negative damping pointed out by Liwschitz is that if the resistance is increased sufficiently the damping torque due to this effect becomes positive, indicating a worst value of resistance for given values of reactance.

M. M. Liwschitz: Mr. Hutchins mentions the paper of Linville, Mr. Lauder the paper of Davidson, and I call the attention to the fact that I used the method of treating the unsymmetrical damper winding given in the paper on another occasion in 1921 (*Archiv für Elektrotechnik*, page 96), while the paper of Mr. Linville was published in 1930 and that of Mr. Davidson in 1927.

I agree with Mr. Crary that my paper does not give a complete explanation of the negative damping phenomena in the synchronous machine. My paper treats the starting torques and I mentioned the negative damping only incidentally as far as the speed torque curve due to the excitation shows the possibility of such damping.

Some of the remarks by Mr. Lauder and Mr. Hutchins could be avoided, if my paper would treat not only the method of calculating the starting performance, but also the method of calculating the constants. This was not possible with regard to the space available.

For calculation of the equivalent resistance and reactance of the rotor circuit, figure 4, the equations 18 and 19 must be used. The expression of the torque, equation 4, can be denoted as exact for medium size and larger machines. The influence of the relative location of bars of different materials can be taken into account by combining the chord factor with the resistivity of the winding in consideration. The influence of X_m on r_M and x_M is low. I do not agree with Mr. Hutchins that the constants must be shaded judiciously for different types of machines. As to the limit of accuracy of the calculation, it must be remembered that even for the asynchronous machine ±5 to 10 per cent is a good result. For the synchronous motor, I consider ±5 to 10 per cent at standstill and ±15 per cent at low slip as reasonable results. It must be taken into account that the locking torques at standstill and the asynchronous torques due to the harmonics exist also on the synchronous motor, although they are lower in this motor than on the asynchronous motor.

Rating of Potential Devices and Suggested Material for a Standard

Discussion and authors' closure of paper 40-94 by J. E. Clem and P. O. Langguth, presented at the AIEE summer convention, Swampscott, Mass., June 24–28, 1940, and published in AIEE TRANSACTIONS, 1940 (December section) pages 676–80.

L. F. Kennedy (General Electric Company, Schenectady, N. Y.): To me the most valuable part of the paper presented by Messrs. Clem and Langguth is the appendix. It indicates, that through the experience gained from several years of use, the industry is now ready to standardize performance, and the user can now specify the class of device he needs from published data. While there may be suggested revisions in this material before its final adoption as a standard, the fact that ratings and performance characteristics have been established, at least tentatively, is indicative of the progress that has been made in the design of potential devices capable of meeting all the requirements in their fields of application. It is certainly to be hoped that with these data available, full use will be made of them for specifications, and that the tentative standards will be followed except where there is conclusive evidence that they are not suitable.

Among the important applications of potential devices is for supplying potential to protective relays. Application requirements for this purpose have been presented to the Institute previously, but it seems fitting to review them briefly now in comparison with the proposed standards. Condensing the desired performance data previously presented,[1] we find the following permissible errors:

Type of Relay	Permissible Error in Ratio (Per Cent)	Permissible Error Phase Angle (Deg)
Phase directional	20–30	20–30
Balanced current with voltage restraint	30	Not particularly important
Ground current directional relay	15	15
Carrier pilot relays	20–30	10
Distance relays	5	5–15

While there can be no question but that the suggested class *A* device is the best from all standpoints, it can be seen by comparison with the above tabulation that the class *B* is entirely suitable for most relay requirements.

It has long been my contention that the first requirement that the relay engineer should place on a potential device, is that its errors be defined so that, where possible, the relay settings could be made to compensate for them. Now that this information is fully available, it seems to be the right time to point out that where distance relays are used, more effective coverage of the line can be obtained with the higher-accuracy device, and that particularly on lines of considerable length the greater stabilization of the reach of the first zone of the relay (in terms of miles of line) would certainly justify the use of the class *A* device.

1. APPLICATION OF CAPACITANCE POTENTIAL DEVICES, J. E. Clem. AIEE TRANSACTIONS, volume 58, 1939 (January section).

E. L. Harder (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): The authors have provided the basis for a much needed standardization and it is to be hoped that further work will result in similar proposals in regard to bushing operated devices.

It will perhaps be of value to point out some of the critical application situations in which the performance features being standardized have significance. This should enable those reading the paper to better evaluate the significance of the proposed standards in the light of the applications with which they are concerned.

INITIAL ADJUSTMENT

The fineness of steps of voltage and phase-angle adjustment limit the refinement to which the device can be set at exact ratio and phase angle when connected to a given burden. These standards of adjusting refinement are indicated in the rows corresponding to 100 per cent voltage in the tabulations of voltage and burden variation. In considering the necessary fineness of steps, the method of adjusting the devices and the standard voltage with which they are compared should be considered. In some cases the output voltage can be compared directly with a potential transformer and the accuracy of comparing two meter readings is involved. In other cases it is necessary to use a power transformer temporarily as a potential transformer for adjusting the potential device. It is believed that in view of these factors, the standards of initial adjustment limits are satisfactory. Also with a view to metering and relaying considerations, the bands involved appear proportionate to the class of device.

RATIO AND PHASE-ANGLE DEVIATION WITH VARIATION IN APPLIED VOLTAGE

If the device is used to energize distance measuring relays, it will be required to register voltage quite accurately at a low value of voltage. A typical line protected by distance relaying may have 20 per cent voltage at the relay for fault at the remote end of the line, while for very short lines so protected, the voltage at the relay may be only 5 per cent for fault at the remote end. The percentage overreach or underreach in distance for the relay is directly proportional to the per cent ratio error of the potential device. Phase-angle errors of the small magnitudes encountered are of little significance in impedance relays but are of some significance in reactance-type relays. The class *A* device appears adequate for distance relaying on normal length lines but probably the first-zone elements of distance relays should be set short by 5 per cent more than customary for short lines with the class *A* device. This additional margin should be increased to 12 per cent with the class *B* device.

RATIO AND PHASE-ANGLE DEVIATION WITH VARIATION IN BURDEN

Good performance here simply means that if a device is once adjusted on the system that additional burden may be added or burden may be removed, within limits, without causing excessive errors. It has one additional significance which may not generally be recognized. When three devices supply both residual and three-phase burden, the burden on a particular device is different for ground faults than for phase faults. Therefore in order to obtain uniform ratio regardless of the type of fault, the device should have small regulation with variation in burden.

It should also be recognized that in connecting three devices through star series potential transformers to obtain residual voltage that the result, normally zero, is the vector addition of three large voltages. Consequently small percentage inaccuracies in the individual voltages will result in large percentage inaccuracies in the residual voltage so obtained. This favors the use of class *A* device in such instances, particularly if the relaying requires fairly close discrimination on small values of residual voltage.

There are, of course, many other application problems in which the standardized performance values are significant and those mentioned here are presented principally to stimulate thought along this line so that the committee may have the advantage of comment on the suitability of the values chosen before they are finally standardized.

J. A. Elzi and **J. R. North** (both of the Commonwealth and Southern Corporation, Jackson, Mich.): This paper by Messrs. Clem and Langguth gives a very concise review of the design and general performance characteristics of modern potential devices. Their description of the devices and the factors affecting their rating and performance will be of considerable help to all of those interested in the application and use of potential devices for many purposes. It would have been helpful had a discussion also been included concerning the effect of humidity and other weather conditions on the performance characteristics.

In the fourth paragraph of the section "Basis of Rating," the first sentence should be corrected to read, ". . . below normal voltage rating."

TERMINOLOGY

Confusion is very apt to develop from misunderstood use of the term "potential device", some construing this to mean the over-all equipment, including bushing or capacitor, while others refer only to the secondary network. It is therefore suggested that the section on terminology include preferred wording for the over-all device and the present section entitled "Potential Devices" be termed "Network Devices" or something equivalent thereto.

The terms "main winding" and "auxiliary winding" are used in the table of "Rated Watts Output and Standard Secondary Voltages", and it is felt that these terms should be explained.

Ratio. Since some devices have secondary voltages of 115/66.4, it is suggested that the statement regarding ratio be amplified to include windings and ratios other than the main ratio.

STANDARD RATIO

This paragraph refers to "coupling capacitors" and no doubt it is the intention of the author to include "bushing potential device". This is a very important paragraph and it is felt that some amplification would be worth while. Under the heading of "Rating" it is proposed to give the device two voltage ratings; namely, (1) circuit voltage, and (2) line-to-neutral voltage. It seems, therefore, that the standard ratio should specify which voltage rating is meant.

CLASSIFICATION

A class designation for bushing potential devices should be included even though the authors may not at the present time have sufficient data to specify their rating. Also, the classification is inconsistent in that the three classes are designated as "accuracy classifications", and classes *A* and *B* are set up on this basis, but class *C* is designated as "out-of-phase" type. In other words, there appears to be no choice of accuracy class available in the "out-of-phase" type and it seems that confusion would be avoided if these devices were treated as a type rather than as a class.

RATING

Under this heading it would seem desirable to indicate whether or not the "maximum watts output" is the total combined output of the main and auxiliary winding or if each winding can be loaded to rating individually.

The rating of potential devices should also include:

6. Insulation levels—60 cycle and impulse withstand test voltages

INSULATION LEVEL

The insulation level of the over-all potential devices should be distinguished from the insulation level of the secondary network. The insulation level of the over-all device probably should be the same as that for outdoor instrument transformers of corresponding voltage class. The insulation level of the network itself may then correspond to that of indoor instrument transformers of corresponding voltage rating.

RATED WATTS OUTPUT AND
STANDARD SECONDARY VOLTAGE

Since the watts output and standard secondary voltage given in this table presuppose a certain line-to-neutral primary voltage, it is felt that the primary voltage which will be considered as standard should be given as it is for the bushing potential devices.

MISCELLANEOUS

Additional items which should be included in the proposed standards are:

(*a*). **Effect of transient conditions**
(*b*). **Terminal markings**
(*c*). **Polarity**

J. E. Clem and P. O. Langguth: The discussions by Mr. Kennedy and Mr. Harder will be of great assistance in the application of these devices and form an excellent supplement to the paper. The discussion by Messrs. Elzi and North is very constructive and will be most helpful in the preparation of standards for this equipment. The authors wish to express their appreciation of the excellent and the constructive nature of the discussions of their paper.

Some Problems in the Standardization of Temperature Ratings of Fractional-Horsepower Motors

Discussion and author's closure of paper 40-95 by C. G. Veinott, presented at the AIEE summer convention, Swampscott, Mass., June 24–28, 1940, and published in AIEE TRANSACTIONS, 1940, pages 1055–61.

P. H. McAuley (Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa.): The desire of all concerned with the thermal rating of electrical machinery is to arrive at rational temperature limits and to specify simple and accurate methods of measurement. At the winter convention in 1939, a great deal of information on this subject was presented. Following this, AIEE Standard No. 1 has been revised tentatively to favor the resistance method for determining temperature rise and changing the limits for this method from 55 degrees centigrade to 60 degrees centigrade. In general, our experience confirms the recommendations of these earlier authors whose work resulted in this step, and in particular those of the paper "Measurement of Temperature in General-Purpose Squirrel-Cage Induction Motors," by C. P. Potter, published in AIEE TRANSACTIONS, 1939, pages 468–72.

Surface thermocouples or thermometers often can be applied only to what should be one of the coolest parts of the winding or iron, that is, in the path of the ventilating air. No matter how well located the temperature-indicating device may be, there is always some question of temperature differential between the temperature of the winding at that point and the reading. This intensifies problems of checking results in different laboratories or at different times in the same laboratory. Also, to apply even surface thermocouples to the end winding of a small motor, it is necessary to remove the end bracket. This may or may not be less trouble than isolating the winding from starting and protective devices in a given case, but this partial disassembly introduces mechanical problems.

Our experience has been that surface thermocouples indicate in general, a lower temperature rise than winding resistance and the variations for different locations on the same motor and for different motors are wide. Mr. Veinott has found that the temperature rise by surface thermocouple averages as much or more for the small motor classes. To us, this implies wide spreads which the points tend to show.

We have recently made a few tests where motor temperatures have been measured both by winding resistance and by thermocouples on the stator end turns.

FIVE-HORSEPOWER VENTILATED INDUCTION MOTORS

One motor has been operated at a total temperature of 100 degrees centigrade by winding resistance. Three thermocouples were placed at the top and on each side of the stator winding end turns. The variations in room temperature from day to day somewhat affected the recorded temperatures but the average differences have been determined. Taking the average of all the thermocouple readings, the temperature rise by resistance was 14 degrees higher than by thermocouple. Considering the hottest thermocouple only, the average difference was 11.5 degrees centigrade.

Another motor was tested similarly except that 125 degrees centigrade by resistance was the operating temperature. An average of all the thermocouple readings gave a temperature 23 degrees centigrade lower than the resistance readings. Considering only the hottest thermocouple, the difference was 18.5 degrees centigrade.

ONE-HALF-HORSEPOWER SPLASH-PROOF INDUCTION MOTOR

This motor was used for a number of tests, mostly on cyclic loads to study the application of short time ratings to intermittent duty cycles. The temperature by resistance was used as the criterion of motor performance but thermocouples were located on certain parts of the frame and winding. In all cases, the temperature by resistance was higher than by thermocouple. The difference varied from 3 to 14 degrees depending upon operating temperature for runs made where conditions were constant long enough to assure steady state conditions. These longer runs are summarized in table I.

Table I

Temperature by			
Thermometer Frame (1)	Resistance Stator (2)	Thermocouple Stator End Turns (3)	Difference Cols. 2 and 3
38	46	43	3
46	65	61	4
54	87	78	9
51	90	76	14

On sustained intermittent cycles, thermocouples on the winding and frame lag somewhat behind the temperatures indicated by change in resistance. This is particularly true where the motor is stopped during the no-load period. The effect is similar to that observed in an automobile engine where the thermostat rises for a while after the motor has stopped. When the ventilation and the production of heat ceases, temperatures tend to equalize. If our measurement is made at one of the points of intermittent temperature it may rise, due to this equalizing process. In sustained cyclic tests on this motor, temperatures by thermocouple on the windings of the stator continued to rise for as long as 5 minutes after the motor was shut down. Certain parts of the frame or

Table II. Temperature Rises by Thermocouple and by Resistance for Different Sustained Cyclic Loads With the Motor Stopped During Idle Periods

Running Time Minutes	Maximum Temperature Rise Deg C			Amplitude of Cyclic Temp Variations	
	Thermocouple	Resistance	Difference	Thermocouple	Resistance
5	61	74	13	14	30
5	43	55.5	12.5	11	23
10	55	70	15	23	37
2.5	57.5	70	12.5	6	19
2.5	35	42.5	7.5	4	11
5	57	63.5	6.5	8	13
5	42.5	50	7.5	5	10
15	51.5	65	13.5	12	24
2	54.5	60	5.3	23	29

iron may have a temperature cycle exactly out of phase with the load current cycle.

Surface thermocouple readings do not correctly indicate the amplitude of copper temperature changes on intermittent duty cycles. This is shown in table II which gives the difference between highest and lowest temperatures observed by each method for a number of intermittent loading cycles.

These tests indicate to us the difficulty of measuring temperature rises by thermometers or by externally applied thermocouples with accuracy and consistency. The fact that thermocouples so often indicate temperature lower than resistance methods, shows that the thermocouple gives values in a great many cases considerably removed from hot-spot temperatures. Therefore, for the greatest degree of exactness, thermocouples must be embedded during manufacturing. Otherwise, resistance determinations seem to lead to more uniform results, where other considerations permit their use. As a result, we cannot share the enthusiasm of the author for the general use of external thermocouples for rating purposes, although for the particular application conditions encountered with small motors, the thermocouple method seems necessary and practical. Also, for special temperature studies during motor operation, when the resistance method cannot be used, the thermocouple method is very useful because it gives more accurate results than the thermometer. We agree, of course, with Mr. Veinott to the effect that the results of his tests, as well as those given in some of the earlier papers, indicate a sufficient difference between external thermocouples and thermometers that the past practice of considering the two methods equivalent, can justly be questioned, especially for smaller machines.

P. L. Alger (General Electric Company Schenectady, N. Y.): Mr. Veinott has very well expressed the need of more exact temperature measurements on small motors. I concur with his recommendation that thermocouples be used in place of mercury thermometers for fractional horsepower motor acceptance tests. For a-c motors the resistance method seems best as the standard, but for d-c armatures and as an alternative in other cases thermocouple measurements of temperature are most convenient, and acceptably accurate.

It is a fact, however, that thermocouples and thermometers give identical readings when placed in constant-temperature ovens, or under equivalent steady-state conditions. Therefore, permitting a higher temperature rise by thermocouple than by thermometer must be justified either by a difference in location or on account of reduced time lag under transient conditions.

In putting thermocouples on the exposed ends of a winding, they naturally fit into crevices, and other locations where thermometers do not fit, so that a greater difference between the respective readings may be expected on small motors than on large apparatus. Recognizing the higher thermocouple temperatures so obtainable, the recently revised introduction to AIEE Standards, "AIEE No. 1," includes the following new definition of the embedded detector method of temperature measurement, for which the same temperature rise is permitted as by the resistance method, or 10 degrees centigrade higher than by the thermometer method:

> Embedded Detector: This method consists in the determination of the temperature by thermocouples or resistance-temperature detectors, built into the machine either permanently or for test purposes, in specified locations, inaccessible to mercury or alcohol thermometers.

The way is open, therefore, in any revision of the motor standards to recognize thermocouples as the proper means for temperature measurement. If any higher temperature is allowed by thermocouple than by thermometer, however, the Standards should clearly specify locations that are inaccessible to mercury thermometers.

B. M. Cain (General Electric Company, Lynn, Mass.): Recognition of the greater accuracy of thermocouples compared to thermometers for measuring temperature rise of motor windings is a forward step which needs to be given a place in the program for more precise application of motor drives. Mr. Veinott's suggestion that thermocouple measurements should be standardized as separate and distinct from thermometer measurements should be very carefully considered.

In this consideration it is important to keep in mind that 40 degrees centigrade rise by thermometer has long been a suitable and accepted standard. Users have found that motors built to this standard give satisfactory service. Thermometer measurements have not been challenged even though the well informed user is undoubtedly aware of the relative inaccuracy of thermometers compared with thermocouples.

These two facts—universal trade acceptance of 40 degrees centigrade rise by thermometer, and general recognition by engineers that rise by thermocouple is higher than by thermometer—lend support to making a separate standard for thermocouple measurements.

Mr. Veinott's paper suggests that such a standard be imited to fractional horsepower motors. It is true that the size of the apparatus on which the measurements are being made has a noticeable effect on the difference between temperature indicated by thermometers and by thermocouples. However, the line of demarcation between fractional horsepower and integral horsepower is scarcely well enough defined to warrant a separation of standards particularly for ratings under 5 horsepower.

Mr. Veinott has suggested that temperature rise by thermocouple could equal or replace temperature rise by resistance on fractional horsepower motors. Perhaps we should ask—why limit this statement to fractional horsepower motors? The answer lies in the fact that temperature rise of the end windings in comparison with average machine temperature is not a matter of size alone, but is dependent on type of construction and method of ventilation of the motor.

Mr. Veinott's tests have apparently been limited to a type of construction wherein more heat is lost by radiation than is removed by the ventilating air. If this condition were reversed, it would be found that rise by resistance would exceed the rise by thermocouple. This has been borne out by observation. In totally enclosed and totally enclosed fan-cooled motors, of all sizes, the temperature of the end windings observed by thermocouple may frequently exceed the average temperature observed by resistance measurement. In open motors with ample ventilation the temperature of the end windings will usually be below the average winding temperature.

In view of these facts, the possibility of permitting temperature rise by thermocouple to replace rise by resistance as a general practice for any class of motors seems to require further study.

In establishing standards of temperature rise, the aim is to determine suitable limits from the standpoint of protection and economy. Winding temperatures measured by surface thermocouples represent the temperature of the exposed portion of the winding, the part most in need of protection. A proposal for establishing new standards of temperature rise based on the more exact measurement by thermocouple and giving recognition to the improvements which have been and are continually being made in insulating materials does seem to be very much in order at this time.

R. Rüdenberg (Harvard University, Cambridge, Mass.): I would like to supplement Mr. Veinott's valuable experiments, and

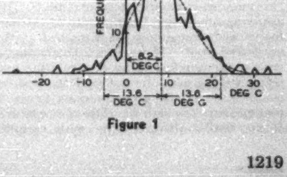

Figure 1

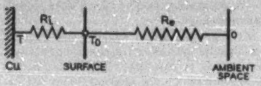

Figure 2

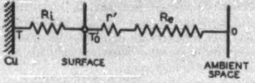

Figure 3

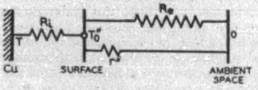

Figure 4

those by others for larger machines, by two results of extensive tests conducted formerly with machines of a European firm.

We had measured the difference between resistance and thermometer methods on hundreds of machines of any type, d-c and a-c, motors, generators, and converters, from 5 kw up to several thousand kva. The overall result is shown by the accompanying figure 1, where the frequency of the measured points is plotted against the difference of the measured temperatures. The average difference of both methods yielded 8.2 degrees centigrade, if the machines were running at rated load, a figure similar to Mr. Veinott's results with small motors under 1-horsepower rating, taken for rated temperatures. The dispersity of our measurements, determined as twice the mean deviation of all points shows a tolerance, however, as much as ±13.6 degrees centigrade. This also is similar to Mr. Veinott's results and indicates that for small as well as large machines a single comparative test may give results very different from the average. So we see that it is not worth while to be too subtle in accepting the general use of the resistance method, which is much better defined in itself than the thermometer method. It is noteworthy that the difference between the two methods was found with hundreds of machines of a second European firm as 8.5 degrees centigrade ± 17.2 degrees centigrade which is very near to the figures mentioned above.

Concerning the measuring of surface temperatures we found that certain precautions are necessary in order to secure correct results. As the accompanying figure 2 shows the surface temperature T_0 of an insulated copper winding is determined by the balance of the heat flow in the internal thermal resistance R_i from the copper with temperature T and in the external resistance R_e to the ambient space with temperature O. By applying measuring instruments at the surface this balance may be disturbed at the measured spot. If we use a thermometer with a surrounding lump of insulating material we increase the external thermal resistance, as in the accompanying figure 3, and measure too high a surface temperature. If we use a thermocouple with metallic leads we decrease the external thermal resistance, as in the accompanying figure 4, since the metal wires form a shunt path to the ambient space, and thus we measure too low a surface temperature. For avoiding such errors, which may have a magnitude of from 5 to 10 degrees centigrade we found it necessary to wind up the leads of the thermocouple near the measured spot in several turns, thus securing a constant temperature and therefore no heat flow within the wires near the junction and simultaneously displacing the shunt heat flow through the wires to a spot away from the junction. A slight heat cover of such spiral thermocouple may compensate by its series resistance the remaining shunt resistance of the leads, thus giving very accurate measurements.

R. E. Hellmund (Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa.): The conclusions reached in the Hellmund-McAuley paper and other points brought out in my discussion of the Montsinger paper plainly show that it is impractical to provide thermal protection for motors for intermittent service by any device connected in the circuit which is not at the same time affected by the temperature of the motor. The only way in which thermal protection could be obtained by a device in the circuit would be to supply special thermal elements for each type of application. This conclusion gives added significance to the inherent overheating protective devices described in the second part of Mr. Veinott's paper. Mr. Veinott gives results obtained with such a device for various sustained loads as well as for short-circuit conditions. It would be of interest to know more about the results obtainable with various intermittent-duty load cycles.

In the conclusions of the Veinott paper, it is pointed out that if the resistance method of measuring temperature is used instead of the thermometer method for fractional horsepower motors, a rise of 50 degrees centigrade should be adopted for a-c motors and 60 to 65 degrees for d-c motors. On the surface, this of course appears to be rather inconsistent, but it should be realized that these figures represent conditions which have existed for some time and which have given satisfactory practical results; they are a natural consequence of the use of the thermometer method of measuring temperature, which is not representative of actual conditions in these small motors. Fortunately, the existing practice makes allowance for some factors which make a difference in the temperature rise between a-c and d-c motors desirable.

It is well known that the voltage conditions on a-c systems over the country vary to a great extent, so that the a-c motors are used over a wide range of voltages. The data given in the third part of Mr. Veinott's paper in figures 9 and 10 plainly indicate that a 10-degree margin is not any too great to take care of these varying voltage conditions for a-c motors. In the few d-c systems, the voltage conditions are in general more uniform and therefore the same margin of safety is not necessary for d-c motors.

The difference in temperature rises is also justified by the fact that with these small motors, which are used to a great extent on various appliances, mechanical interchangeability of a-c and d-c motors is of considerable importance. Since d-c motors inherently call for somewhat larger dimensions than a-c motors built for the same temperature rise, any attempt to design d-c motors for a temperature rise of 50 degrees by resistance would mean that a greater mounting space would have to be allowed on all appliances for motors; in other words, the very small number of d-c motors used would handicap the design of all these appliances. It is obviously more economical from an all-round point of view to avoid such handicap by allowing a higher temperature rise in d-c motors even if this should result in a somewhat shorter life in the few cases in which they are used.

C. G. Veinott: Mr. Alger agrees that thermocouples are better than mercury thermometers for fractional horsepower motor acceptance tests, but indicates a preference for the resistance method as the standard. As the resistance method is generally less convenient and sometimes impossible to employ in application tests, an alternate standard is desirable to replace the present thermometer method, which is recognized as inaccurate but which is, nevertheless, accepted. Unfortunately, the thermocouple method is now recognized in AIEE Standards—with the same limits as for thermometers. But different limits are given for the resistance method. The evidence given in this paper shows that, for the cases studied, the thermocouple method approximates the resistance method instead of the thermometer method, with which it differs.

Mr. Alger points out that in the new standards, the same temperature limits are given for embedded detectors as for the resistance method. But the definition quoted by Mr. Alger could hardly be interpreted as including a surface thermocouple installed in a completed machine, particularly when the present definition of "thermometer or thermocouple" is allowed to remain. The recommendations of this paper could be carried out by omitting all reference to thermocouples in the "thermometer method," and in the limits for it; and by amending the description of "embedded detector" to include specifically a thermocouple installed on the end windings of a fractional horsepower a-c motor. Such a revision would be more in accord with factual data than the present reading of the standards.

Replying to Mr. McAuley's discussion—it is not always necessary to remove a bracket to install thermocouples in open motors, particularly when the conduit box, with its large opening, is cast integral with the bracket. Moreover, in the case of a small motor, it is often easier to remove and replace a bracket than it is to isolate, for a certainty, the connections of the main winding. Small motors today often have quite involved wiring because of control devices built into them. For example, take a dual-voltage, capacitor-start, thermally protected gasoline-pump motor with a centrifugal switch, built-in voltage changer and line switch. Such a motor has a dual-section main winding and uses 15 separate leads in its wiring. For a user to find and bring out the correct leads for taking resistance measurements would certainly involve dismantling the motor and the subsequent difficult task of locating the proper leads.

Installation of thermocouples is a much easier task in such a case, and the hazards of inaccuracy are minimized.

Mr. McAuley's data on a 5-horsepower motor needs no comment as the recommendations of this paper were limited to fractional horsepower motors. His data on the $^1/_3$-horsepower motor do, however, fall within the scope of this paper. While he has a number of temperature runs, they are all taken on the same motor. The 56 points given in figure 6 of the paper were taken on approximately 50 different motors with not more than two runs on a single motor. Of these 56 points, 20 (36 per cent) of them show no more rise by thermocouple than by resistance, but the median of the points shows definitely that the tendency is for thermocouples to give higher readings than resistance measurements. Note that figure 6 shows scattered points comparable to Mr. McAuley's data. I cannot help feeling that the average results of the tests on 50 motors are more reliable than the tests upon a single motor.

I was interested in Mr. McAuley's observation that the thermocouple temperature of the windings increased for as much as five minutes after the motor was shut down. In practically all the temperature runs reported in the paper, there was no perceptible rise in temperature after shutdown.

Mr. Cain's remarks line up quite well with my own thoughts on this subject. NEMA defines a fractional-horsepower motor as "a motor built on a frame smaller than that having a continuous rating of 1 horsepower, open type, at 1700–1800 rpm." This definition provides a fairly sharp line of demarcation between fractional and integral horsepower motors. However, as Mr. Cain points out, the use of thermocouples need not be confined to fractional horsepower motors. It is, of course, correct that the difference between thermometer and resistance readings will vary with different types of mechanical construction as he points out and it would be useful if similar data could be given on other types of construction.

I am happy to know that Mr. Cain concurs with my opinion that a revision of the standards is in order.

Dr. Rüdenberg's remarks are interesting. His data, and mine as given in figures 1 and 2, show a figure slightly less than, but reasonably close to the allowance of 20 per cent given in the standards as the difference between the thermometer and resistance methods. His precautions regarding the use of thermocouples are timely and suggest that if the AIEE standards are revised as proposed, some information as to how and where the thermocouples should be located would be in order.

Mr. Hellmund has inquired as to the performance of an inherent overheating protective device such as I have described on intermittent loads. The temperature data I have given in the paper obtains on long sustained overloads of the least value which will cause the device to trip. If heavier overloads are imposed, the device will trip at lower winding temperatures than given, but if the load is allowed to cycle at a higher value by means of the thermal device, the winding temperatures may more nearly approach the temperatures that are reached on long sustained overloads. The reason is fairly simple: if a load is imposed on the motor which is the least load which will cause the thermostat to trip, the winding reaches its ultimate temperature rise and the disk reaches its ultimate rise above the bracket; if a heavier load is imposed, the ultimate rise of the disk is substantially above its tripping temperature and, as the rate of temperature rise of the thermostat is faster than that of the motor, the disk will heat faster than the winding, because of the latter's relatively greater thermal capacity, and trip before the winding temperature has risen relatively as much.

I am grateful that Mr. Hellmund agrees that a higher temperature-rise limit for d-c motors than for a-c motors can be justifiably established. Needless to say, I am very much in accord with his remarks on the subject.

A Study of Short-Time Ratings and Their Application to Intermittent Duty Cycles

Discussion and authors' closure of paper 40-93 by R. E. Hellmund and P. H. McAuley, presented at the AIEE summer convention, Swampscott, Mass., June 24–28, 1940, and published in AIEE TRANSACTIONS, 1940, pages 1050–5.

P. L. Alger (General Electric Company, Schenectady, N. Y.): It is very desirable to use a simple and flexible method of rating electrical apparatus, that will tell the user its output limitations in as few words or symbols as possible. All that the user really needs to know about the capacity of his apparatus is that it has adequate power for his maximum peak loads, and that it will have satisfactory life under his actual load conditions. Only two numbers should be needed to define these two output limits, corresponding to the momentary and the continuous ratings.

Under the present motor rating system, no less than six numbers are used in describing the capacity of an induction motor, representing the rated horsepower, the breakdown torque, the starting current, the temperature rise, the duration of the temperature rise test, and the service factor. Can we not reduce these six numbers to two for all ordinary purposes?

Suppose that we define the "effective" horsepower rating of a motor as the maximum momentary output, divided by an agreed factor of safety. The maximum output may be limited by the breakdown torque, by commutation, or by mechanical strength of some part. In the case of an induction motor, the American Standards require that the breakdown torque shall not be less than 175 per cent of the rated torque. I propose that we turn this rule around and define the "effective" horsepower rating of an induction motor as the horsepower output substantially equal to one-half that corresponding to the breakdown torque, but not greater than 57 per cent of this value. Since the starting current of an induction motor is roughly proportional to its breakdown torque, the effective horsepower so defined fixes both starting current and breakdown torque, and enables one number to replace three required by the present rating system.

Suppose, also, that we define the "service factor" rating of a motor as the horsepower it can deliver continuously at rated voltage and frequency, without exceeding the temperature rise permitted by the American Standards for the class of insulation used. Instead of giving any motor a $^1/_2$ hour or other short time rating, all motors would be given continuous heat runs. This "service factor" rating is conveniently defined as the product of the "effective" horsepower rating by a service factor.

This proposal is in accord with the present system of rating general purpose motors, which meet 40 degrees centigrade rise by thermometer at their rating and are good for 115 per cent load continuously. The only difference is that under the proposed plan general purpose motors would be given temperature tests at 115 per cent of this nameplate rating, and at this load they would be required to meet 50 degrees centigrade rise, instead of meeting 40 degrees centigrade rise at 100 per cent load. Under the present system, a motor for intermittent duty may be rated 10 horsepower, 50 degrees centigrade rise, in one hour, and is required to have 275 per cent breakdown torque. Under the proposed plan, such a motor would be rated 15 horsepower "effective," 0.6 service factor. It would have substantially the same starting current and breakdown torque as a general purpose 15-horsepower motor, but would only have heat dissipating capacity sufficient for a continuous load of 9 horsepower. This service factor rating is equal to the rms equivalent load that can be carried over any short time duty cycle, and so the proposed system fits in neatly with the universally used rms method of calculating the apparatus size required for intermittent loads.

By thus giving all motors a service factor, which may be more or less than unity, we can again use a single number to replace the three numbers required under the present system of rating.

To sum up, I propose an a-c motor rating system substantially the same as that proposed by L. E. Hildebrand ("Duty Cycles and Motor Rating," AIEE TRANSACTIONS, volume 58, 1939, pages 478–83), including the following specific elements:

1. All motors will be given an "effective horsepower" rating.
2. The breakdown torques and starting currents of all motors will be directly related to the "effective horsepower" by ratios similar to those now customary for general purpose motors.
3. All motors will have a "service factor" which will indicate the fraction of the "effective horsepower" at which the motor may be operated continuously without exceeding the standard temperature rise for the class of insulation used.

This system accords with the proposed methods of rating welding generators and transformers discussed in other papers at the standards conference. It has the advantage of giving approximately single valued relationships between the starting current, the breakdown torque, and the horsepower rating of any motor, whether for intermittent or continuous use. It would simplify the choice of wiring and protective devices which largely depend on the service factor and the starting current values. It gives a much truer representation of the effectiveness of a motor for duty-cycle service than the short time rating method. By making all motors of a given insulation and enclosure type meet the same temperature rise, it eliminates the temperature question from discussion, and so simplifies the understanding and use of motors by the general public. And, finally, it does not disturb present continuous rated motor designs, but merely extends the rating methods used for them to cover duty cycle motors also.

Of course, this proposed method does not fit every case, such as motors for highly intermittent duty, which would exceed permissible temperatures if operated at no load. Also, extended experience with the plan must be obtained before it can be generally adopted. My immediate proposal, therefore, is that this plan be considered along with other systems of short time and intermittent rating by the AIEE Standards Co-ordinating Committee No. 4 and other interested groups. Out of this study there should be evolved a statement of general principles for the guidance and co-ordination of specific standards for different types of apparatus analogous to the revised AIEE Standards No. 1 just issued.

T. C. Johnson (General Electric Company, Schenectady, N. Y.): Two important points that should be brought out in this discussion are that:

1. The rms horsepower method of determining motor size is inherently conservative for short cycle times, and

2. A service factor, defined as suggested by P. L. Alger can be readily determined for each type of application.

General use of the rms method and the service-factor rating should simplify and standardize motor applications.

Standard general-purpose 40-degree motors, having the usual torque margin and temperature-rise versus load curve may be applied to intermittent loads as shown in figure 1 of this discussion. If the motor is on continuously 1.15 times rated load can be carried, while if it is on only 10 per cent of the time and the cycle is long enough for the ultimate temperature rise to be reached the motor can be loaded to 1.4 times the rated value because of the ability of the insulation to stand higher temperatures for short times and still give the same useful life. For shorter cycle times during which the temperature does not vary so much a higher loading may be allowed; e.g., 1.35 times rated load for 30 per cent of cycle time.

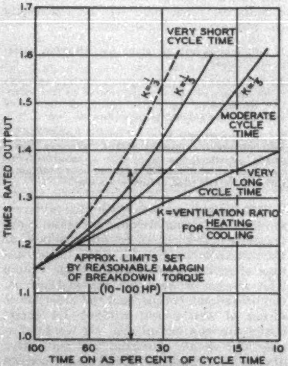

Figure 1. Allowable output for standard general-purpose motors for same insulation life—on-off cycle

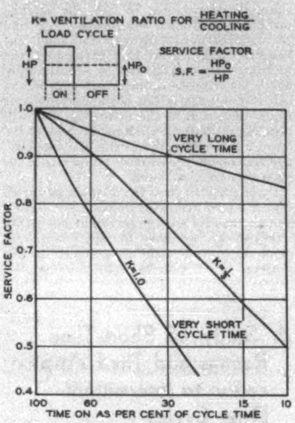

Figure 2. Service factor for same insulation life—on-off cycle

Such allowable-output versus per-cent-time-on curves give a relatively simple and definite basis for motor application provided the heating and cooling thermal time constants of the motor are known. Mr. Hellmund has pointed out the complexity that occurs when these must be considered. However, it is fortunate that most motor applications are for cycle times so short that the motor temperature does not vary much.

For most motor applications the temperature does not vary during the cycle and the motor can be loaded to a limit determined only by the necessary torque margin and the allowable continuous insulation temperature. It is only important to know the relative amounts of heat that can be dissipated during running and standing times; i.e., the ventilation ratio, K. Thus, if during standing the motor can dissipate $^1/_3$ the heat for the same time running, the insulation temperature limit would allow almost 1.55 times rated load to be carried for 30 per cent of the time ($K = ^1/_3$, figure 1). For the usual motor applications this ratio K is taken as $^1/_3$, while for transformers, of course, it is equal to unity.

The rms horsepower method of determining the allowable motor loading has been found to agree closely with the curves of figure 1. (Standard general purpose motors on very short cycles.) Therefore, if the ventilation ratio is known for a particular type of motor the rms horsepower method may be used to apply the motor accurately to an intermittent load by using the weighting factor K for the standing time.

Intermittent motors, because of their higher torque margins have a smaller temperature rise for a given change in load, and, therefore, their curves of allowable output versus time-on lie above those for the general purpose motors. The rms horsepower method is thus conservative for intermittent rated motors on short time cycles.

It is evident that the rms horsepower method offers a reasonable basis for establishing service factors for intermittent rated motors as shown in the accompanying figure 2. It is possible to reduce the duty cycle of any usual industrial application to an equivalent rectangular cycle with the equipment running a definite fraction of the cycle time. Then the appropriate service factor is determined by the ventilation ratio K. Thus motor service factors would be given by the middle curve, while the lower curve would give those for transformers which cool equally well whether loaded or not. This is conservative for intermittent rated motors, as was shown above, but if the cycle time is very long compared to the thermal time constant of the motor, then a larger service factor must be used, as shown by the upper curve, thus setting a definite limit to the possible range of applications.

As an example, if the load cycle is 15 per cent time at rated load, and 85 per cent shut down, and the motor is of usual thermal characteristics, it should be designed and rated for a service factor of 0.6.

L. A. Finzi (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): It may be remembered that many years ago the American delegates of the International Electrotechnical Commission at Bellagio (1927) and at Prague (1934) wanted to avoid any narrow standardization for motors for intermittent duty cycles, as actually used in a few European countries. They suggested that for such intermittent services a reference to the continuous or still better to the short-time ratings of the motor might be of more general use. This met its main opposition in the argument that such reference "neither will bring a reduction in the technical work required for fixing the ratings nor will make the choice of the motor an easier one." A German delegate was given the task of investigating whether a simple rule could be found for determining the length of a short-time rating thermally equivalent to a certain given intermittent cycle. There is no evidence that any progress has been made up to the present date.

The methods suggested by Hellmund and McAuley make it actually possible to check the thermic applicability of a motor to given intermittent duty cycles, in terms of its "short-time" ratings and without need for further analysis of the various losses, their distribution, etc., in every single case. The reference to "short-time" ratings is also a very practical procedure from the application point of view, since a motor for intermittent duty, in view of the required starting and breakdown torque, often will be chosen from designs rated for short-time service.

Hellmund and McAuley point out indeed that the thermic behavior of a motor in sustained intermittent service is quite different from that in typically transient "short-time" service. The considerations leading to the curves shown in figure 6 and to formula 3 of the paper are based on actual

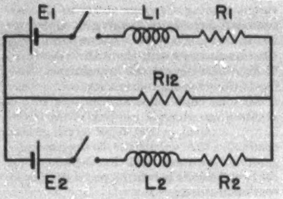

Figure 3

experimental heating and cooling curves, as obtained in proximity of the 60-degree rise of temperature for some typical sustained cycles after reaching a quasi-steady state. This is the best practical way to cope with all difficulties arising from the difference of the time constants of the windings, iron, etc. The results are by all means more reliable than those which may be reached by piecing successively together portions of heating and cooling curves obtained from a continuous service test. Such a proceeding does not take into account that the average iron temperatures (and herewith the actual cooling of the windings) in both heating and cooling periods of a sustained intermittent service may be greatly different from those determining the shape of the curves in a test at continuous load.

For a more general attack of the problem, the reciprocal influence of the actual temperatures of the various parts in the transient state would have to be taken into a closer account. The technical literature although rich in studies about the thermic behavior of a machine, shows few contributions on this point. Examining the question, it can be suggested that, with some practical simplifications, the determination of the rises of temperature of iron and copper can be reduced to the determination of the currents in an electric circuit as shown in the accompanying figure 3. As the circuit is not very complicated, the integration of the differential equations is not difficult. The constants E, R, and L, correspond to physical constants of the motor and may be determined with usual heating and cooling tests in continuous service at two different loads. Inductance represents thermal capacity and resistance represents heat dissipation to the ambient, respectively for copper and iron. The mutual resistance then represents heat transfer from copper to iron or vice versa. Finally, electromotive forces represent copper and iron losses.

Cyril G. Veinott (Westinghouse Electric and Manufacturing Company, Lima, Ohio): The paper presented by Hellmund and McAuley outlines a method of testing to determine just what intermittent duty cycles a short-time rated motor would be able to handle without exceeding the rated temperature. Mr. Alger's discussion was very interesting; it seems to me that he outlined a short-hand system or simplified method for presenting results which can, or should be, obtained by the method outlined by Hellmund and McAuley. The latters' principles seem to be more basic, however.

Open, general-purpose induction motors carrying a continuous rating of 40 degrees centigrade rise by thermometer may also often be used for intermittent load in excess of their rated horsepower. It would appear that the Hellmund-McAuley method could be applied equally well to open, general-purpose motors and I should like to inquire if the authors have given any thought to this subject.

R. E. Hellmund and P. H. McAuley: Mr. Veinott has brought up the question of the applicability of the methods in our paper to general-purpose motors. The basic methods given can be applied to any apparatus or conductor. If the typical ratio R is determined for three or more well selected loads in excess of the continuous current, corresponding to the maximum safe temperature rise, a curve covering the entire range of loads can be plotted. In figure 4 of this discussion, load currents corresponding to the 5-, 15-, and 30-minute ratings have been used, but, obviously, any other properly spaced current values are suitable.

Mr. Alger has suggested a simple method of rating. Simplification, while desirable, should not be carried to the point where it interferes with satisfactory results combined with reasonable economy. Furthermore, simplification which can be applied to a specific field, may unduly complicate the broader situation. Nearly every type of electrical device has to meet requirements other than temperature limitations, and in some cases it may seem immaterial whether such other requirements or the temperature limitations are used as the primary basis for ratings. However, since temperature limitations apply to practically all electrical apparatus and conductors, it would seem most unfortunate if the one tie common to nearly all standards were ignored through the use of a multitude of other factors as the primary basis for rating apparatus and conductors.

Some other aspects of Mr. Alger's and also Mr. Johnson's discussion are covered in the discussion by Hellmund of the Montsinger paper "Effect of Load Factor on Operation of Power Transformers by Temperature." (AIEE Transactions, 1940, pages 632–6.) It should furthermore be pointed out here that our paper gives a basic method for deriving results from curves obtained from simple tests. In contrast to this, most of the discussions deal with certain methods of applying motors which can be used only if certain factors are known. These factors must be determined either by a basic method such as given in the paper, by more extensive testing or from previous experience. If reliable factors have been previously determined for all requirements, our method is not required except possibly as a check. As Mr. Veinott has pointed out, our method can be applied directly but it is also suitable for deriving factors needed for Mr. Johnson's method.

With due appreciation of the difference between the methods in the discussions and in the paper, it will be seen that there is rather substantial agreement on many of the points made. It is generally agreed that for short load cycles and constant cooling conditions, the rms method is satisfactory. We also agree that the suggested use of a service factor, expressing the continuous current for the maximum safe temperature in per cent of the rated current, is convenient for standardization purposes.

With long-time load cycles and constant ventilation, loads must be reduced as compared with the previous case, and proper values can be derived directly by the method in the paper. However, since the necessary reduction is not very great for the usual long-time applications, it should not be difficult to establish service factors in accordance with Mr. Johnson's suggestion and which will permit safe and economical applications of motors. However, the same service factors cannot be applied to the wiring and protective devices because of their very much shorter time constant. Thus, the choice of wiring and protective devices is not so simple as claimed in Mr. Alger's discussion. This will be discussed more in detail during the standards conference.

Unfortunately, conditions become more complicated when cooling conditions of the device change as they do in motors standing still during the idle periods. Widely different service factors are encountered for different sizes, speeds, and types of motors. Moreover, appreciable differences occur with the same motor operated with different load cycles. Nevertheless, reasonably correct results can be obtained for a definite type and make of motor on which considerable practical data are available and given in such curves as shown by Mr. Johnson. The data in figure 5 of this discussion are of interest in this connection. The results in the first two columns are obtained on the same motor frame with a weak field and with a stronger field. As expected, the motor with the stronger field and heavier wiring has a somewhat higher current rating. Its rate of temperature rise is less than that of the other motor on account of the lower copper losses, but the rate of temperature drop is also lower because with a stronger field the core is hotter and the heat from the winding does not transfer to the core during idle periods as readily as in the other motor. As a result, the factor R is not much different and the permissible "on-time" of the motors for the rated currents is about the same. The third column gives figures for the motor with the strong field operated enclosed. The rate of rise is now appreciably increased on account of the re-

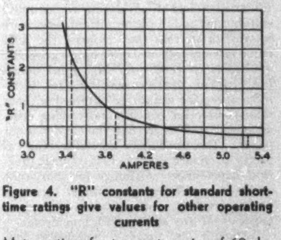

Figure 4. "R" constants for standard short-time ratings give values for other operating currents

Motor ratings for temperature rise of 60 degrees centigrade:

5 minutes	5.25 amperes
15 minutes	3.90 amperes
30 minutes	3.45 amperes
60 minutes	3.25 amperes

	30 MIN. RATING CURRENT IN AMPS.	RATE OF TEMPERATURE CHANGE NEAR 60° RISE DEGREES PER MINUTE		$R=\frac{d}{r}$	$100\frac{R}{R+1}$ OR MAX. % OF RUNNING PERIOD
		RISE	DROP		
WOUND FOR WEAK FIELD OPEN	20.2	1.9	2.5	1.32	57
WOUND FOR STRONG FIELD OPEN	23.5	1.15	1.6	1.38	58
WOUND FOR STRONG FIELD CLOSED	21	2.7	.95	.35	26

Figure 5. Data for 7.5-horsepower 30-minute motor frame size

duced ventilation, while the rate of drop is decreased for the same reason. As a consequence, the ratio between the two is appreciably altered and the permissible "on-time" with the rated load is considerably reduced as compared with the open condition. Translating this into the rms method with a service factor, it is found that the two open motors give a service factor of about 0.76 for short cycles. For longer cyles with 10 per cent "on-time" the service factor may be as low as 0.31. With the enclosed motor, the service factor for short cycles is 0.5. Numerous other examples could be cited to illustrate the variations encountered in practice. A test on the larger motor of the paper indicates that the cooling rate with the motor running is 1.5 to 2 times as great as with the motor standing still. These values correspond to the reciprocal of the factor K in Mr. Johnson's discussion. The generally assumed value of $K={}^1/_3$, although safe in this particular case, would not result in economic application.

Therefore, it seems that the direct method given in the paper is by all means preferable to a method requiring a different service factor for practically each type of apparatus and application. On the other hand, it is well to realize that the rms method already is firmly established for problems of this kind and that it may meet with greater favor than the direct method if it is found possible to derive a reasonable system of service factors to cover the great variety of applications. Whether or not this is possible, can be determined only after a great many types and ratings of motors have been analyzed.

From the discussions by Mr. Finzi and Mr. Veinott, it is evident that they have fully recognized the relation of the method given in our paper to some of the more or less empirical methods used for everyday applications of apparatus. Mr. Finzi's remarks regarding attempts by the International Electrotechnical Commission to establish suitable methods for intermittent service are interesting in that they indicate the difficulty encountered in establishing a generally applicable method. As Mr. Finzi points out, correct performance data for intermittent service cannot be obtained without duly considering heating and cooling characteristics such as given in the curves of our paper. The temporary heat-absorbing capacity of all electric devices is of great practical importance. Although for short-time cycles it is sufficient to consider this in a qualitative way, a quantitative analysis is required for any service with long cycles.

Although the extreme simplicity suggested by Mr. Alger may not be realizable, steps in this direction are certainly desirable. The authors believe, for instance, that there is no need for as many different short-time ratings as are now contained in the various standards. Instead of 5-, 15-, and 30-minute and continuous ratings, a 15-minute and a continuous rating would be quite sufficient for many of the smaller motors.

Effect of Load Factor on Operation of Power Transformers by Temperature

Discussion and author's closure of paper 40-96 by V. M. Montsinger, presented at the AIEE summer convention, Swampscott, Mass., June 24-28, 1940, and published in AIEE TRANSACTIONS, 1940 (November section) pages 632-6.

L. W. Clark (The Detroit Edison Company, Detroit, Mich.): Mr. Montsinger proposes a rule of allowing 3 per cent increased load for each 10 per cent that the daily load factor falls below 100 per cent. We believe that this rule is conservative if load factor is used as a basis but, in our opinion, load factor alone is not a suitable measure upon which to base permissible loading. As pointed out by Mr. Montsinger, the permissible load may actually vary over a wide range, depending upon the shape of the load curves, and yet the load factor of these curves may have the same numerical value.

Another factor which Mr. Montsinger could not consider in setting up a general standard is the actual thermal ability of the individual transformer. He predicates his loading values on the ASA "standard" 55-degree-centigrade rise transformer. Consideration of the individual transformer indicates that there is usually some added margin of load capacity available, and that that margin is great enough to make it worth while considering each individual transformer on its merits. To illustrate this point, we include figure 1 which shows the variation in load-carrying ability of 126 substation transformers, ranging in size from 100 kva to 10,000 kva. It compares these 126 transformers with the ASA "standard" 55-degree-centigrade rise transformer, having 45-degree-centigrade oil rise and a ratio of full-load copper loss to iron loss of 2:1. It shows that about 50 per cent of the transformers studied permit 5 per cent greater continuous loads than the 55-degree-centigrade transformers, and that 5 per cent of the transformers permit 13 per cent greater continuous loads.

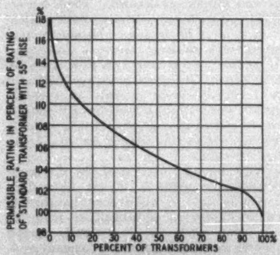

Figure 1. Showing variation in load-carrying ability of 126 substation transformers ranging in size from 100 to 10,000 kva

The new ASA guide for transformer loading (referred to in the paper) permits continuous loads corresponding with 95-degree-centigrade hot-spot temperatures and emergency short-time overloads corresponding with 105-degree-centigrade hot-spot temperatures for 24-hour periods. In our opinion there should be a much greater spread between these two conditions. If a transformer will give satisfactory life when operated continuously at 95-degree-centigrade hot-spot temperature, it certainly should not be damaged by two or three 24-hour emergency operations during its life with hot-spot temperatures considerably in excess of 105 degrees centigrade. Also, if transformers are normally loaded to give hot-spot temperatures of 95 degrees centigrade, they will almost certainly encounter emergency peak loads which will result in hot-spot temperatures in excess of 105 degrees centigrade.

We have been studying methods of determining the load-carrying ability of transformers based on the actual shape of the load curves without reference to load factor as such, and taking into account the thermal characteristics of the individual transformers. We believe we have arrived at a fairly accurate method which has the virtue of requiring very simple calculations. Briefly, the method converts the daily load curve into an equivalent steady load which would cause the same insulation aging. This is accomplished by the use of empirical conversion factors which were determined from a study of all the types and shapes of load curves actually encountered. The accuracy of the method has been checked by the

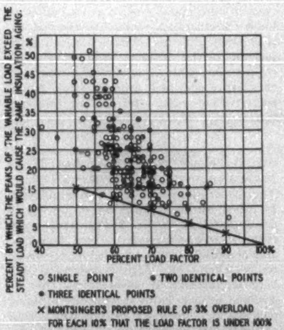

Figure 2. Showing, for different load factors, the range of peak load values for various shapes of 240 load curves with equal aging effect on the transformer insulation

rigorous method, as outlined in previous papers by Mr. Montsinger, and has been found to be accurate to within plus or minus 5 per cent for most of the encountered load curves having load factors of 50 per cent or greater. Occasional odd-shaped load curves, not usually encountered, show this short-cut method to be in error by as much as plus or minus 10 per cent.

Using this short-cut method, we have analyzed some 240 daily load curves to indicate the relationship between the peak load of the curve and the steady load which would produce the same aging effect as the actual load curve. The results are shown in figure 2 of this discussion plotted against the load factor of the curve, and it shows a wide range of peak load values for curves of the same load factor, any one of which gives equal aging effects. In this same figure, the effect of the proposed allowance of 3-per-cent increase in peak load for each 10-per-cent increase in load factor is indicated. It is obvious that full advantage of temperature loading would not always be realized if this rule were followed. For instance, for the load curves having approximately 60-per-cent load factor, the peak loads ranged from 111 per cent to 143 per cent of the steady load which would cause the same amount of transformer aging. If Mr. Montsinger's 3-per-cent rule were adhered to, no peak could exceed 112 per cent of the equivalent steady load.

R. E. Hellmund (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): The greater part of all electrical apparatus is subjected to intermittent or varying loads. Whenever the safe load is limited by temperature considerations, the determination of the temperature due to different load conditions and the evaluation of its influence upon the life of insulation is of utmost importance. The paper by Mr. Montsinger and other papers presented at this session deal with this problem. However, since the papers presented seemingly attack the problem in different ways, it may be well to point out the interrelation of the various methods, including the time-honored rms method.

In figure 3 of this discussion, case I shows the load fluctuating from no load to maximum load through relatively short intervals for a rotating machine running at constant speed and thus having uniform cooling conditions. The temperature will vary slightly from the permissible value, as shown by curve *A*, if the rms current is about the same as the continuous current giving the prescribed temperature rise. While curve *A* temporarily exceeds 60 degrees to a small extent, this is of no practical consequence and, therefore, straightforward methods of figuring the rms current will give satisfactory results.

If we now assume for case II that the motor is standing still instead of running during the no-load periods, the average cooling effect is of course materially reduced. An attempt to use the same rms current as in case I would result in very much higher temperatures as indicated in curve *B*, and a material reduction in the rms current is necessary to bring the heating to permissible values as in curve *C*. Applications of this latter kind have at times been treated by figuring the rms current using one-third of the not-running period instead of what it actually is. This, of course, is a very rough approximation and does not uniformly apply to the many different conditions met in practice. Enclosed motors, for instance, will be entirely different from open motors in this respect and the size of the motor will have considerable influence. Application engineers have developed empirical methods of making suitable allowances.

In case III it is assumed that the motor is running continuously but with the time for each cycle considerably longer than in case I. If the same rms current as in case I is used, the temperature will fluctuate appreciably as shown by curve *D*. In other words, it will be appreciably in excess of 60 degrees for long periods and therefore deterioration of the insulation will be hastened. In order to have the same deterioration as in case I, the rms current has to be reduced sufficiently to obtain a heating curve similar to *E*. A slight excess of temperature as indicated by *b* is permissible.

In case IV the motor is assumed to be standing still during idle periods. Because of reduced ventilation, a temperature rise as shown in curve *F* is likely to occur with the rms current still the same as for *E* and a greater reduction is necessary to obtain the permissible temperature conditions indicated by curve *G*.

Cases V and VI correspond to III and IV except that the load period is assumed much shorter. Here a maximum temperature somewhat higher than in previous curves is permissible because the time of the high temperature is reduced. In case VI, the ventilation is even less than in case IV because of the longer periods of standing still, and therefore the rms current of case VI must be still less than in case IV. The variations in rms current for the different cases are appreciable and with many motors the permissible rms current for applications like case VI can be only about one-half that of case I.

Case VII reproduces figure 7 of the Montsinger paper and represents a 24-hour load period. Usually with transformers the ventilation does not change, but there are some instances where blowers are operated during the heavier load periods and shut down during the light loads. The dotted curve *N* in case VIII indicates what would happen if the same load were used as in case VII. Obviously the load must be reduced to give permissible temperature conditions as shown in curve *O*.

Summarizing, it can be stated that for case I, which occurs frequently, the straightforward rms method is satisfactory regardless of the type of apparatus involved. For motors with intermittent loads, covered in cases II to VI inclusive, the method given in the Hellmund-McAuley (*Transactions pages 1050–5*) paper is basically a correct one. Case VII can be handled by the methods given in the Montsinger paper. The first difference between the two methods is that the time-temperature curves in the Hellmund-McAuley paper are determined by test because the greatly varying ventilating conditions make a theoretical determination impractical. In contrast to this, Montsinger has shown that for a wide range of transformer designs, the time constant and ventilating conditions do not materially change and therefore determination of time-temperature curves by calculation becomes practical in his case. The second difference between the two methods is that in the Hellmund-McAuley paper no attempt is made to quantitatively determine the permissible excess temperature indicated by the small *b* areas. Advantage of this permissible short-time excess temperature is taken to serve as a margin of safety, with one of the simplified and approximate methods discussed in the paper. In the Montsinger paper, a definite attempt is made to determine quantitatively the areas *a* and *b* to obtain the same insulation deterioration as with the rated continuous load. It is of course, quite possible to apply the Montsinger method to other cases, but such refinement does not seem justified until additional attempts have been made to apply motors closer to their permissible limit than is currently done. The transformer engineers, encouraged by simpler conditions to be met in their case and through efforts extending over a period of years, have made considerable progress in the economical application of transformers.

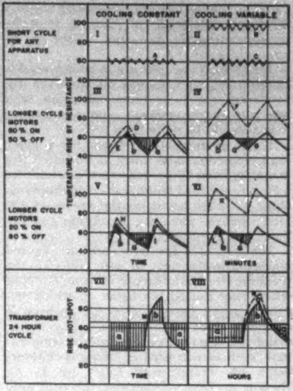

Figure 3

Any method suitable for all types of apparatus would be too complicated for practical use. The best procedure, therefore, is to consider certain classes of apparatus and applications individually and to make in each case the approximations and simplifications justified by the conditions involved. This will naturally result in a number of different methods of attack, as presented in various papers. Increased use of automatic protection as described in the Veinott paper (*Transactions pages 1055–61*) for motors and as used extensively with transformers will assist materially in economical applications of apparatus.

L. H. Hill (Allis-Chalmers Manufacturing Company, Milwaukee, Wis.): The method of attack and analysis used by Mr. Montsinger is effective in obtaining a solution. However, if his results are to be used as an extension of the ASA rules for short-time overloads, they should be based on the same assumptions, that is, a hot spot at full load of 25 degrees centigrade above a 40-degree-centigrade oil instead of a 20-degree-centigrade hot spot above 45-degree-centigrade oil.

Likewise, if the rules are to be universal in application, they should be based on the minimum time constant shown by tests and not on the average, and the ratio of losses should be more than 2:1.

If the permissible overload for a given load factor varies as much as indicated (for example, from 16 per cent to 40 per cent for a 50 per cent load factor), the rule should include a factor based on the nature of the load cycle if users are to obtain the full benefit of the principle.

Temperatures for overloads are figured mathematically but do not consider the possibility of the existence of some hot spot which may exceed the figure on which calculations are based. Hence, I believe it desirable there should be a safety factor which increases with the estimated temperature, such as was used in "Effects of Overloads on Transformer Life" by L. C. Nichols in 1934. Otherwise the constants determined mathematically should be reduced by an amount sufficient to give this protection.

Attention is called to the constant *C* in the section on calculation of hottest-spot temperature, where the evaluation should be divided by 60 to put it on an hour basis. Also, the ASA rule for 1.4 times full load gives 25 minutes for recurrent conditions and approximately 100 minutes for emergency conditions instead of the values as printed.

It should be pointed out that while these proposed rules give permissible overloads due to load factors which do not take out more life than when operating at full load continuously and 40-degree-centigrade ambient, in the long run this might not give satisfactory life for the transformer. Previous papers relative to the life of transformers have given figures varying from about $1^1/_2$ to 7 years for operation at full load continuously and with 40-degree-centigrade ambient. The new tentative ASA standards recognize that transformers operating at full load continuously and with 40-degree-centigrade ambient might not have satisfactory life by recommending that for continuous full-load operation the average ambient should not exceed 30 degrees centigrade.

The tentative ASA standards now include permissible overloads well beyond those ever permitted by previous standards and likewise increased loads permitted when ambients below 30 degrees centigrade are allowed. Now if the remaining factor which affects the life of transformers, namely load factor, is used to permit overloading it is conceivable that with all of these factors combined, a transformer life may result which will be far shorter than is obtained under present conditions of operation; and hence a word of warning is perhaps in order: That while all of these various rules for permissible overloads are useful and valuable for specific purposes, they must be used intelligently if the life of the transformer is to be maintained at its present comparatively high value.

M. F. Beavers (General Electric Company, Pittsfield, Mass.): The term "load factor", as normally used in the industry, does not attempt to define the shape of the load cycle but simply ". . . is the ratio of the average load over a designated period to the peak load occurring in that period." For example, two extreme conditions for a 50 per cent load factor are: (*a*), a load cycle having 100 per cent peak load for an infinitesimal period and 50 per cent of peak load for the remainder of a 24-hour period; (*b*), a load cycle consisting of 100 per cent peak load for 12 hours and no-load for the remaining 12 hours.

Load factor for cycle *b* may also be expressed as the percentage of the total time which the peak load would have to be held to produce the total actual number of kilowatt-hours for the period of the load cycle under consideration.

It has been generally recognized that insulation deterioration is a function of both temperature and time. Since temperature is a function of losses, the relative kilowatt-hour loss for a given load factor should provide a rough measure of the effect of a load cycle on the transformer insulation life.

Inasmuch as the load factor does not define load cycle shape, let us consider the relative kilowatt-hour loss resulting from two extremes in load cycles having a given load factor. Assuming the total actual kilowatt-hour I^2R loss at 100 per cent peak load for 24 hours (100 per cent load factor) as 1.0, the relative total kilowatt-hour loss for a load cycle such as cycle *A* (which has 50 per cent peak load for the 24-hour period) is 0.5^2 or 0.25, while the relative kilowatt-hour loss for cycle *B* (which has 100 per cent peak load for 12 hours and no-load for 12 hours) is $1.0 \times 12/24 = 0.5$. In other words, when the cycle has a shape similar to cycle *A*, the relative loss is equal to the load factor squared, but when it is of the shape of cycle *b*, it is equal to the load factor.

Thus, it may be seen that the transformer aging will vary considerably depending upon the type of load cycle and the load factor. For the example just given (50 per cent load factor), the relative loss varies by the ratio of 2 to 1 (that is, $0.5/0.5^2$) while the loss for the two extremes of load cycles with say 25 per cent load factor will vary by the ratio of about four to one (that is, $0.25 \div 0.25^2$). Therefore, it is evident that, unless the shape of the load cycle is definitely specified, "load factor" is not a relative index to the transformer overload capacity.

Mr. Montsinger takes account of the limitations of loading by load factor, and therefore tables II and III of his paper are based on the type of load cycle giving the highest aging factor, namely—a cycle in which the peak load exists for the percentage of time equal to the load factor, and no load existing for the remainder of the period.

This method of transformer loading is interesting in that it represents a new approach to the problem. However, because of the assumed "fixed" load cycle shape, it does not have the flexibility (and purposely so) of the ASA loading curves which give recommendations for various initial load conditions in addition to no load. By means of the equivalent (or rms) load method described in reference 12 of the paper, the actual fluctuating loads of a daily load cycle may be converted into an equivalent rectangular load. Then upon reference to curves based upon the ASA recommendations, the required transformer size can be determined relatively quickly and with reasonable accuracy. Thus, each load cycle may be considered on its own merits rather than on a "fixed" basis.

I am glad to know that Mr. Montsinger is contemplating the preparation of a paper for large transformers similar to the one for distribution-type transformers described in reference 12 of his paper.

V. M. Montsinger: It is true, as Mr. Clark says, that the 3-per cent rule does not allow taking full advantage of loading by temperature for many of the shapes of load curves encountered in service. As pointed out in the paper, the 3-per cent rule for general use was purposely based on the most severe conditions. When some particular bank of transformers gets individual attention, the method used by Mr. Clark should be satisfactory.

It should be possible to set up rules for permitting safe overloads ranging from 3 per cent to approximately 6 per cent for each 10 per cent that the load factor is below 100 per cent. This is a matter that should be taken up and considered by the AIEE transformer subcommittee.

In reference to Mr. Clark's figure 2—I am not quite certain what the permissible overloads are based on, unless it is those to bring the rise up to 55 degrees rise in cases where the rise is under 55 degrees during the factory test. This of course is something that cannot be covered either in standards or in general loading recommendations.

As to permitting higher temperature limits for emergency operations, the transformer subcommittee has this question under consideration, and higher limits may be recommended, especially for a limited number of emergency operations of, say, one per year.

Mr. Hill suggests that the overload heating be based on 40-degree oil rise and 25-degree hot-spot rise over oil, and the minimum time constant.

If the 3-per cent rule was not very conservative as pointed out in my paper and by Mr. Clark, I would agree with the suggestion. Also, if and when the maximum loading is obtained by taking into account the nature of the load cycle as suggested by Mr. Hill and as was done by Mr. Clark, I would again agree with the suggestion of using 40 degrees oil rise and 25 degrees hot-spot. But, when as shown in the paper and as given in Mr. Clark's figure 1, the 3-per cent rule gives only about one-third of the maximum permissible overload (under certain load-cycle conditions), I feel that using an oil rise and hot-spot rise that would result in less overloads than given by the 3-per cent rule, is hardly justified.

Mr. Hill rightly points out that taking full advantage of all factors like low ambients, low load factors, ASA short-time overloads, "rating up" to give a 55-degree rise, etc., might result in a transformer life shorter than has been obtained in the past under usual service conditions. This is a very good reason why it is advisable when setting up general rules to use the 3-per cent rule for low-load-factor conditions, instead of squeezing the last drop out by taking full advantage of the load cycle as suggested by Messrs. Clark and Hill.

If full advantage is taken of the load-cycle curve by ordering a smaller-kilovolt-ampere transformer when the nature of the load curve is known in advance, the following factors should be taken into consideration:

1. Poorer regulation
2. Better voltage-control equipment
3. Capacitors may be necessary
4. The extra capacity for emergency overloads will be reduced

Proper consideration of the above points may show that it is not advisable to go too far in basing the overloads on thermal limits alone.

Reference Values for Temperature, Pressure, and Humidity

Discussion and authors' closure of paper 40-92 by P. L. Bellaschi and P. H. McAuley, presented at the AIEE summer convention, Swampscott, Mass., June 24–28, 1940, and published in AIEE TRANSACTIONS, 1940 (December section) pages 669–75.

H. W. Tenney (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): Messrs. Bellaschi and McAuley have rendered a very valuable service in tabulating the reference values for temperature, pressure, and humidity generally used in the various branches of electrical engineering. With these data presented so concisely, direct comparisons of the reference values used by national and international bodies become possible. The very important problem of co-ordination, particularly of such fundamentals as reference values, is receiving more and more attention from our engineering societies and standardizing bodies.

In the early days of standardization, the reference to temperatures at which tests were to be made was very indefinite—usually nothing more than "at room temperature." Later, the practice was modified and the specification read—"at room temperature or approximately 20 degrees centigrade." For the practical reasons given in this paper, the trend in this country for some time has been toward the use of 25 degrees centigrade, as is indicated in the table of reference temperatures for ASTM and AIEE specifications.

From an international point of view the whole question of reference temperatures is complicated by the different climatic and living conditions in different countries. In England, for example, the usual temperature at which testing is done is generally somewhat lower than in this country because of natural climatic and living conditions. Under these conditions a reference value of 20 degrees centigrade is perfectly suitable and logical.

If flashover values are established on a given piece of equipment at 20 and 25 degrees centigrade, the value at 25 degrees centigrade is 1.7 per cent lower. On the other hand, if flashovers are established at vapor pressures of 0.45 inch (International Electrotechnical Commission standard) and 0.6085 inch (present American standard) of mercury, the flashover value at the higher vapor pressure is 5 per cent greater. Consequently, flashover values on a given piece of equipment at the higher reference temperature and humidity will be approximately 3 per cent more than the flashover at the lower reference values. Translated into the problem of designing equipment to meet a definite insulation level at either set of reference values, the equipment meeting this level at the lower reference values will be 3 per cent stronger. In international trade this gives a slight advantage to a manufacturer who rates his equipment at the lower reference figures (IEC values) and naturally those having a slight advantage in characteristics will exploit this fact.

The difference in ratings at different reference values enters into the problem of co-ordination of insulation and should be recognized. It is quite possible that the change would be so small that it would not be serious, but at least it must be given consideration.

P. H. McAuley: Mr. Tenney has pointed out the different reference temperatures in Europe and America have a more or less logical basis when climatic conditions are considered. It is more difficult to justify the American reference standard for humidity, except for those cases where electrical creepage and moisture absorption are important. In any case, it is apparent that we have, at present, the uneconomical luxury of different reference values for similar measurements. At least we should avoid any further tendencies in this direction and, if this paper contributes only in this respect, it has served a useful purpose.

Low-Voltage D-C Measurements on Electrical Insulating Oils

Discussion and authors' closure of paper 40-81 by J. L. Oncley and W. C. Hollibaugh, presented at the AIEE summer convention, Swampscott, Mass., June 24–28, 1940, and published in AIEE TRANSACTIONS, 1940 (November section) pages 625–8.

Hubert H. Race (General Electric Company, Schenectady, N. Y.): The flat portion called region *B* (figure 1) of the conductance-time curve for insulating liquids has always puzzled me. The authors state that "region *C* represents the time during which the ions are swept out of the space between the electrodes and space charges built up in the spaces near the electrodes". It seems to me that this statement must also apply to region *B* because certainly the current carriers are ions. Therefore, if we assume that on the average the charge per ion is constant, we must have conditions such that in region *B* the number of ions remains constant while in region *C* the number of ions is gradually decreased. From his work on nonaqueous solutions, Doctor R. M. Fuoss of our laboratory suggests the explanation that in the region *B* there is an equilibrium between associated and dissociated ions so that new ions are formed by dissociation as fast as they are swept out by the field. When the supply of undissociated ions is exhausted, however, further current flow decreases the ion concentration and the current decreases as in region *C*. The mathematical form of this time dependence is given by Doctor Fuoss as follows:

Let

Λ_0 = limiting equivalent conductance
k = dissociation constant
F = chemical equivalent (96,500 coulombs)
t = time in seconds
i = current per kilovolt per centimeter in a unit cube
C_0 = initial concentration of A^+B^- in mols per liter

The dissociation equilibrium is expressed by the relations:

$$[A^+][B^-]/[A^+B^-]=k \tag{1}$$

$$A^+ + B^- \rightleftharpoons A^+B^- \tag{2}$$

Assuming

$$C(t)=C_0-it/F \tag{3}$$

the current-time function can be shown to be

$$i(t)=\frac{\Lambda_0 k}{2}\left[\sqrt{\left(1+\frac{\Lambda_0 t}{F}\right)^2+\frac{4C_0}{k}}-\left(1+\frac{\Lambda_0 t}{F}\right)\right] \tag{4}$$

which is of the form shown by sections *B* and *C* in figure 1 of the paper by Oncley and Hollibaugh.

Eric A. Walker (Tufts College, Medford, Mass.): In this paper the authors present some data on the electrical characteristics of oil which are surprising in their simplicity. These results are attained because of complete and careful control of the test specimens and they serve to emphasize the fact that if consistent and worth-while results are to be obtained on electrical insulating oils the control of the specimen is of paramount importance.

The authors state that certain deviations are caused by fluctuations in temperature. Perhaps in future work a curve of the variation of the a-c conductance as a function of temperature will be obtained. There are some unpublished data in use by a number of companies which contend that the ratio of the power factor at any arbitrary temperature to the power factor at 20 degrees centigrade is a constant which is not affected by the degree of oxidation. Confirmation of these data by other investigators is desirable and apparently Messrs. Oncley and Hollibaugh are well equipped for such work.

No statement is made of the amount of moisture present in the oils tested. It is presumed that, as the samples were in closed containers into which pure dry oxygen was admitted, the moisture present was only that caused by oxidation. However, if the samples were open to the atmosphere, moisture might be present in solution, and if the temperature were suddenly lowered, in minute droplets. Under such conditions the test results would be much more complicated. This is another effect which should be investigated.

J. B. Whitehead (The Johns Hopkins University, Baltimore, Md.): The conductivity of insulating oils is ionic in character. There are a number of possible sources of the ions present. The commonest source is the presence of electrolytic impurities. These may be largely removed by filtration, redistillation, and similar methods. However, even after ultimate purification a conductivity still remains. Possible explanations of this residual conductivity are, inherent dissociation of the liquid molecule, dissociation of organic acids due to oxidation, radioactive influence either local or extraneous, such as cosmic radiation. The conductivity of a good insulating liquid is so low in value that only a very small volume of ionization is necessary to account for it. Values of conductivity of the simplest and purest chemical liquids are of the order of 10^{-18} mhos. Values for the oil studied by Messrs. Oncley and Hollibaugh are in the neighborhood of 10^{-13} mhos, that is 100,000 times greater, a value somewhat higher than the best commercial oils, but still not unduly high from the standpoint of general insulating properties.

The conductivity of an oil is a function of the conditions of measurement, particularly those of potential gradient and time. Referring to figure 1 of the paper, region *A* is a very unusual one and has been found in only a few cases. The distinguishing characteristics of most insulating oils are an initial horizontal region *B*, indicating constant conductivity, and the region *C* indicating a continually decreasing conductivity. The region *D* is due to an equilibrium condition of ions accumulating in the liquid as a result of the action of the ionizing agency, and the processes of recombination and diffusion to the walls of the containing vessel. These ions are relatively large consisting probably of a central charged particle surrounded by a cloud of neutral molecules. Under applied potential they move towards the electrodes and the initial conductivity remains approximately constant over an appreciable interval of time, say several tenths of a second, as determined by the number of ions present and their mobility. Thereafter, as shown by region *C*, of figure 1, the conductivity decreases due partly to the discharge of ions at the electrodes, and partly to the accumulation of space charges near the electrodes, the space charges setting up a counter, or polarizing influence on the applied field. The final value of conductivity in region *D* of figure 1 is a measure of the rate at which new ions are liberated in the liquid due to the external ionizing agency. If, after reduction to the condition *D*, the oil is allowed to stand on either open or short circuit, it returns to condition *A* or *B* after a few hours.

The conductivity indicated by region *B* of figure 1 is directly proportional to the applied continuous voltage. This was clearly shown in my paper, "The Conductivity of Insulating Oils" (AIEE TRANSACTIONS, volume 50, number 2, 1931, page 692) for potential gradients up to 30 volts per mil. Moreover, we have shown in several places [Whitehead and Shevki, ELECTRICAL ENGINEERING (AIEE TRANSACTIONS), volume 54, June 1935, page 603], that for the same range of stress, the time duration of the constant value of region *B* decreases with increasing voltage and vice versa. The range of stress in which these relations are found to hold has recently been increased to 60 volts per mil. Messrs. Oncley and Hollibaugh have made observations in a very low range of stress which afford interesting confirmation of our earlier experiments.

As regards behavior under alternating stress, dielectric loss is completely accounted for as a conduction phenomenon, in that measured a-c values are in close agreement with those computed from the conductivity of region *B*. This means that during the alternating cycle there is no loss of ions by discharge to the electrodes, and that the ions oscillate back and forth within the liquid, causing a frictional or resistance loss. This suggests that the amplitude of oscillation of the ions is in general so short that few reach the electrode during the alternating half cycle. From this point of view, it is evident that we should expect an influence of the a-c frequency on the agreement between d-c and a-c measurements here under discussion, and also of the values of a-c and d-c potential gradient at which the measurements are made. Moreover, it happens that cases have been found even at the relatively low potential gradients mentioned above, in which the conductivity of region *B* increases with increasing continuous voltage. In this case measurement at low-voltage direct current would not give agreement with a-c loss measurements at higher values of stress. For these reasons and also because of the possible occurrence of region *A*, figure 1, in comparative measurements of this character, I have always felt that it is safer to make both continuous and alternating measurements at the same values of potential gradient. The authors do not state the values of voltage at which their alternating measurements were made.

Other interesting evidence that the dielectric loss in oils is a conduction phenomenon is found in the experiments of Whitehead and Shevki in which it is shown that over a prolonged extension of regions *C* and *D*, momentary measurements of alternating loss are always accounted for by the contemporaneous values of d-c conductivity. The same relation holds for measurements on the recovery curves of the oil both on open circuit and on short circuit.

Andrew Gemant (nonmember; Detroit Edison Company, 2000 Second Ave., Detroit, Mich.): This subject seems to have attracted quite an interest recently; in fact, I also have just finished some computation on this matter. The basic assumption in these computations was that the first relatively fast drop of the conductivity is due to the removal of ions in a state of total dissociation while the subsequent slow decrease is caused by the removal of ions belonging to partially dissociated electrolytes. Equations were deduced for the first case and applied to curves published by J. B. Whitehead. The ionic mobilities computed were of the order of 10^{-7} centimeter per second per volt per centimeter, involving radii of the expected order 10^{-7} and 10^{-8} centimeter. Mr. Oncley mentioned mobilities down to 10^{-9} centimeter per second, and consequently very large radii. These results are probably obtained from the latter part of the conductivity curves, where a continuous regeneration of ions makes the mobilities appear much too low. This difficulty is, however, avoided if the simple equations, not taking account of a dissociation, are applied to the first part of the curve only.

V. M. Montsinger (General Electric Company, Pittsfield, Mass.): I am very much interested in the curve shown in figure 1 as it has practically the same shape of the curve of dielectric strength versus time of both solid insulation and oil.

In 1935 I published an article on "Breakdown Curve for Solid Insulation" (AIEE TRANSACTIONS, volume 54, page 1300) in which it was shown that the dielectric strength drops quite rapidly down to 3 microseconds, and then the strength remained approximately constant for approximately 100,000 microseconds. It then dropped rapidly corresponding to the *C* region shown in figure 1. I designated these regions as *A*, *B*, and *C*.

During the discussion of the paper, Mr. Bellaschi presented a similar-shaped curve for the breakdown of oil, although his region *A* lasted somewhat longer than region *A* for solid insulation. Also, the time during region *B* (for constant strength) lasted for only approximately 10^3 microseconds as against 10^5 microseconds for solid insulation.

The principal point I wish to bring out is that the similarity of the shapes of all these curves indicates that there is some relationship between the conductance and dielectric strength of insulations. I do not believe that it is merely a coincidence.

I note the authors state that region *C* represents the time during which the ions are swept out of the space between the electrodes and space charges built up in the space near the electrodes. The rapid decrease in dielectric strength of oil during region *C* might be due to some extent to the same phenomena, although it no doubt is also due to the lining up of impurities in the oil.

The rapid decrease in dielectric strength during region *A* may be due entirely to the suggested cause for the rapid change in the conductance during region *A*, namely, the orientation of large polarized particles.

Herman Halperin (Commonwealth Edison Company, Chicago, Ill.): It may be well to point out that since the preparation of this paper in October 1938 considerable progress has been made in this research project at the Massachusetts Institute of Technology. The oil-testing cell illustrated in figure 2 has been replaced by a much-improved cell for routine tests. With the old measuring cell, it was necessary to transfer the oil sample from the container where oxidation was taking place to the measuring cell. This involved some handling and possibilities of contamination. Furthermore, thorough cleaning was necessary after each measurement.

With the new system, measurements of power factor and other electrical characteristics of the oil are made directly in the sealed container in which the oxidation takes place. This not only takes care of the objections just mentioned but also permits the making of more frequent measurements. The new scheme is also used for measurements on small paper capacitors immersed in the oil in the oxidation apparatus.

In the paper and in discussions given by others at this meeting concerning d-c measurements, it must be noted that the remarks apply to moderate or low stresses, that is, from a few volts per millimeter up to about 1,500 volts per millimeter.

As the authors point out in their discussion of figure 1, the d-c conductivity of oil is a rather complicated phenomenon, being the sum of several electrical processes. Still other characteristics appear when the stresses are increased to very high values. Some special studies with direct current are being made in Chicago at such high stresses. The work is being done by Doctor H. J. Plumley of the Commonwealth Edison Company in a part-time special research at the University of Chicago under the sponsorship of the Utilities Research Commission. This work is carried on at stresses up to the order of 100,000 volts per millimeter. In general, Doctor Plumley has found that insulating liquids perform differently at higher stresses than they do at the lower stresses. He expects to give some details on the results of his investigation and his ideas of theories to account for the characteristics of liquid dielectrics in the near future.

J. L. Oncley and W. C. Hollibaugh: We would like to make a few remarks concerning the discussion of our paper. The gradients used in obtaining the results reported in table II were 2 volts per mil for the a-c measurements and 0.5 volt per mil for the d-c measurements. Results recorded in figures 4 and 5 were obtained with gradients of 0.5, 5, and 12.5 volt per mil. The oils used in these measurements contained practically no moisture. We have attempted to make measurements on oils containing droplets of water, but found that it is a very difficult matter to obtain reproducible results under these conditions. The a-c conductance of several oils has been studied as a function of the temperature, and will be reported by Balsbaugh and others in the near future.

The calculations mentioned by Doctor Gemant appear to be of the same type as those we have made, and were obtained from the initial portion of the conductivity curve. Thus the mobilities obtained from our measurements are considerably smaller than those obtained from Whitehead's curves.

The improvements in cell design and oxidation technique referred to by Mr. Halperin have been reported in part by Balsbaugh and Howell (*Rev. Sci. Inst.*, 1939, page 194) and by Balsbaugh, Howell, and Assaf (paper presented at the Symposium on Electrical Insulation, American Chemical Society, April 1940).

The behavior in regions *B* and *C* can be explained by the assumption of either total or partial dissociation. Calculations of mobilities as made by us, and as referred to by Doctor Gemant in his discussion, assumed total dissociation. Doctor Race gives equations for the case of partial dissociation. Without further experiments on simple systems it would appear very difficult to differentiate between these explanations. Either predicts that region *B* is not absolutely constant, but only a very small decrease in conductance will occur during this small time interval.

The main point of the work reported by us is just that mentioned again by Professor Whitehead; namely, that "the time of duration of the constant value of region *B* decreases with increasing voltage and vice versa", and our work was prompted by the observations he refers to in his discussion. Thus by making the applied voltage sufficiently low, we can prolong region *B* to any desired extent, and hence we can obtain conductivities which truly represent the state of the oil before the test was begun. In case results for high gradients are required, it is obvious that the technique of Whitehead and his collaborators must be used. However, an amplifier-oscillograph arrangement is somewhat complex for routine testing of oils, while the low-voltage bridge method, which we describe, can be applied with but little more labor than can the standard (but arbitrary) one-minute test for conductance.

A Method for Detecting the Ionization Point on Electrical Apparatus

Discussion and author's closure of paper 40-84 by G. E. Quinn, presented at the AIEE summer convention, Swampscott, Mass., June 24–28, 1940, and published in AIEE TRANSACTIONS, 1940 (December section) pages 680–2.

Wm. A. Del Mar (Habirshaw Division, Phelps Dodge Copper Products Corporation, Yonkers, N. Y.): Mr. Quinn's paper holds more than usual interest for us, since we have employed the cathode-ray oscilloscope for a number of years in electric cable research and quality control.

Our experimental techniques have developed similarly, and we have noted substantially the same limiting factors. Like the author, we found the air-core reactor a more critical means of ascertaining the initial ionization point. But, we noted a difference in the character of the superimposed high-frequency oscillations, which was more pronounced with a resistance shunt. By this difference, we have been able to classify the type of ionization and its position of origin. Thus, with the resistor, if the high-frequency harmonics appear on the peak of one-half wave the corona is internal, if on the other, it is external, and if both half waves show high-frequency harmonics, there are both internal and external corona. It is easy to find which half wave corresponds with a particular kind of corona by substituting a sample of known corona characteristics. The high-frequency harmonics sometimes appear as distinct surges which may have an amplitude several times that of the fundamental wave, and sometimes as mere fuzziness of the fundamental wave. The former were found when ionization occurred at a metallic surface such as conductor or shield and the latter when no metal or other high-emissivity electrode was present.

The resistance oscilloscope test therefore possesses certain advantages over that used by the author in enabling an analysis of the location and type of ionization to be performed. We, therefore, suggest that the equipment be provided with both reactor and resistor shunts.

Let me now say a few words on the use of the cathode-ray oscilloscope in quality control. The data on ionization point of rubber-insulated cables obtained by Professor Paine (AIEE TRANSACTIONS, 1940, pages 709–14) showed how close this point may be to the working voltage. It, therefore, seemed desirable to check all high-voltage rubber cables of an unusual character for ionization voltage. Samples are sent to the research laboratory for this purpose as the test apparatus has not graduated to the stage of practical plant use and the interpretation of results requires the judgment of an expert in its use.

J. B. Whitehead (The Johns Hopkins University, Baltimore, Md.): It is my impression that the first published oscillographic records of high-frequency oscillations on the crest of voltage waves applied to dielectrics and insulation were those of Professor Edward Bennett (AIEE TRANSACTIONS, volume 32, 1913, page 1787). Professor Bennett used the electromagnetic oscillograph. Since that time these oscillations have been widely studied, particularly by Professor Paine of the University of Illinois, and latterly, since the general availability of the cathode-ray oscilloscope, by many other research workers. We have been using the oscilloscope as a convenient and rapid instrument for the qualitative detection of gaseous discharges in insulation for several years. The convenient self-contained setup described by Mr. Quinn will doubtless lead to an even wider use of this method for the detection in practice and the study in research, of these important discharges.

The discharges referred to by Mr. Quinn are mostly those in the air, external to the insulation of high-voltage equipment, as for example, in current transformers and lightning arresters. Another well-known danger spot is the slot of an a-c generator. The discharges attack the material of the insulation both thermally and chemically, leading to well-recognized processes of destruction.

It should be possible, on the basis of well-known dielectric principles and the properties of air and dielectric materials, to so design many types of electric equipment that they will be free from discharges of this character. The minimum potential breakdown gradient for air is in the neighborhood of 30 kv per centimeter for plane surfaces and with well-known corrections for any value of radius of curvature, temperature, pressure, etc. These, with the values of dielectric constant of the insulation and the dimensions of the equipment, should make it possible to compute the stress at the danger spots and thus to modify design which, with suitable factors of safety, will ensure the avoidance of external gaseous ionization.

Such discharges also occur in the interior of insulation walls, when air or gas pockets are present. A conspicuous example is found in the high-voltage underground cable with so-called solid-type insulation. The operation of the cable results in temperature cycles causing expansion and contraction of

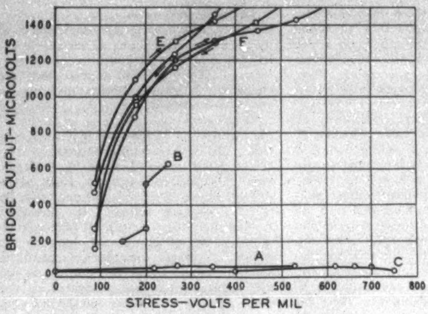

Figure 1

the insulation, with consequent voids or gas pockets which become ionized under the applied stress, causing the type of oscillation on the crest of the voltage wave indicated in Mr. Quinn's figure 3.

In figure 1 of this discussion, I show the results of a study of these discharges using a quantitative method as applied to impregnated-paper insulation as found in high-voltage cables. The method is that of Arman and Starr modified and extended somewhat to meet the conditions obtaining in these studies. The principal feature of the method is the balancing of a Schering bridge containing the sample under study, for a minimum reading for the high-frequency discharges set up in an auxiliary discharge gap across the high-voltage circuit, and at a voltage below that at which the specimen under study discharges. The auxiliary gap is then removed, the voltage raised on the specimen, and the bridge becomes unbalanced when the specimen discharges. The method, therefore, gives not only the detection of the first occurrence of discharge, but also permits a quantitative study of the volume of discharge for higher values of voltage, or for their growth with time. In figure 1 curve *A* shows the behavior of a specimen on an initial gradual increase of stress up to 700 volts per mil and shows that there is no internal discharge up to that point. Curve *B* shows the behavior after discharge had started at 700 volts per mil maintained for ten minutes. Curve *C* was taken after a 36-hour rest period, indicating a recovery of the insulation. Curve *E* indicates the discharge after application of 700 volts per mil for one hour, followed by 750 volts per mil for 55 minutes. Curve *F* was taken immediately following curve *E*.

H. A. Brown and **E. B. Paine** (University of Illinois, Urbana): This paper is of great interest to the authors of the following comments, and they strongly feel the importance and desirability of perfecting means of directly detecting the presence of ionization within, and surface corona discharge on electrical apparatus. They also believe that it is often very important at times to have means of quantitatively measuring comparative intensities of such disturbances. It is shown in Engineering Experiment Station Bulletin No. 260 of the University of Illinois that cases occur in solid-type paper-insulated high-voltage cables wherein internal ionization discharge will occur before the power factor shows an increase, as the voltage is raised. In testing rubber-insulated cables lying on a flat metal test plate, the power factor is only slightly affected when the cable is covered with the usual braid, the latter resulting in high power factor at voltages much below the corona point. This is shown in a paper by the authors of this discussion, "Corona Discharge on Rubber Insulated Cables" presented before the 1939 Northeastern District meeting of the AIEE (paper No. 39-108, AIEE TRANSACTIONS, 1940, pages 709–14).

The apparatus used in the previously mentioned Bulletin No. 260, and in the later paper just referred to, differs from that shown in figure 1 of Mr. Quinn's paper in several respects, particularly in that a bridge circuit or a coupled filter system is used to balance out or suppress almost completely the 60-cycle charging current components and harmonics thereof. In the cases of some paper-insulated cables the 60-cycle charging current is more than a thousand times as great as the mean ionization discharge current intensity. Many times the latter was detected only with the aid of a 90-decibel-gain amplifier system and highly sensitive head receiver, and increased very gradually at first from the starting point as voltage is raised. In the case of standard 500-foot lengths of such cables it is indeed difficult to detect inception of ionization when the charging current is measured in amperes, and the long high-capacitance circuit weakens the ionization discharge effect. For these a partially resonant type of discharge detection bridge circuit, described in the above mentioned bulletin, partially solves this problem. This circuit includes capacitance and variable inductance, and it is believed that the loading capacitor shown in Mr. Quinn's figure 1 may give a similar result.

The effectiveness of the blocking capacitor in Mr. Quinn's diagram would be limited, it seems. Its impedance would be of the order of 10 megohms, at 60 cycles, and the oscilloscope amplifier input impedance is probably 2 megohms. At the random heterogenous discharge frequencies of around 5,000 cycles the impedance would be roughly 0.1 megohm for the blocking condenser, and 0.5 megohm for the amplifier input. This may suppress the charging current in a ratio of say 25 to 1; but if the charging current is 1,000 or more times as great as the ionization current the comparative amplitude of the former is still quite high. A bridge or effective coupled-filter system, previously referred to, is strongly recommended, especially in testing apparatus wherein the capacitance charging current is considerable. In testing rubber cables such a filter was used, and the inductance between the test sample and ground was 150–200 millihenries instead of 4 henries plus 4 millihenries. This gives better suppression of the 60-cycle charging current, because of the comparatively high ionization disturbance frequencies.

In using an air-cored inductance, care must be used to eliminate the effect of stray *magnetic* fields, such as may be encountered near cables, busses, or even transformers. It has been found quite necessary to use astatically wound coils for the inductance between test piece and ground. It is granted that a filter system produces distortion of the ionization discharge current pattern, and oscillograms show that regularly damped oscillations are set up in the filter, but much experimental evidence has shown that this does not affect the sensitivity of detection. An aperiodic resistance-capacitance filter will not greatly distort the pattern, and is sufficient if the test piece comprises one arm of a balanced shielded resistance-capacitance bridge.

The cathode-ray oscilloscope with a two-stage input voltage amplifier is a valuable and convenient addition to the test equipment.

Since the ionization discharges are of a random nature, stationary patterns on the oscilloscope screen would be difficult to obtain. The writers wonder if one of the new persistent-screen cathode-ray tubes and a high-speed lens, shutter, and film was used to obtain the photograph shown in figure 3 of Mr. Quinn's paper.

C. W. Germeck and **C. Mannal** (General Electric Company, Pittsfield, Mass.): Mr. Quinn has called attention to a very interesting phase of dielectric behavior and has developed a simple and ingenious method for the study of the high-frequency oscillations accompanying ionization discharges. Under extremely adverse conditions the ability to localize the discharge on the crest of the applied voltage wave may be of considerable advantage in determining which of the peaks observed are spurious and which depend on the apparatus under test.

It is interesting to note that Mr. Quinn's apparatus embodies all major components essential to a standard radio-noise-testing equipment as recommended by the Joint Coordination Committee of the Edison Electric Institute, National Electrical Manufacturers' Association, and Radio Manufacturers' Association. If an r-f series impedance were inserted in the line between the loading condenser and the testing transformer and the coil combination in series with the device under test replaced by a 600-ohm non-inductive resistor, the uncompensated circuit as recommended in EEI Publication G9 would be obtained. It would, of course, be necessary to replace the CRO and associating blocking capacitor by a radio-frequency voltmeter having the desired characteristics. Since standard meters are now commercially available in the same price range as the CRO, it can be appreciated that the circuit is readily convertible to the standard radio influence-voltage circuit, which permits of quantitative evaluation of the radio noise influence voltage.

In a sense any device which indicates the magnitude of high-frequency voltage may be used for the investigation of ionization in high-voltage apparatus. Mr. Quinn obtains the deflection of a spot on a cathode-ray screen. The standard method recommended in the EEI Publication G9 utilizes the deflection of a pointer on a calibrated scale. Both are indications of the high-frequency voltage existing as a consequence of ionization discharges.

Mr. Quinn has performed a distinct service in reviewing in his introduction the chemical and thermal effects accompanying ionization. It is too infrequently emphasized that the term "corona" covers a plurality of effects—thermal, electrical, chemical, aural, and visual—of which certain are important from the standpoint of radio-interference potentialities and others from the standpoint of insulation failure.

If it is permitted to restrict Mr. Quinn's remarks to the apparatus with which we are familiar in Pittsfield, our conclusions would be that there are two modifying factors worthy of consideration. They are the *quantity* of ionization at operating potential and the *location* of the ionization. Although the voltage at which ionization can first be detected is of importance, particularly in design, it is the latter two factors which are more closely related to the life expectancy of the insulation and probability of radio-interference complaint.

It should be emphasized that the effects of ionization which bear on the life expectancy of insulation are thermal and chemical and that even these are not related in a simple way to the deterioration of the insulation. Exactly how the high-frequency voltage appearing across the terminals of the apparatus in question is related to these primary effects and hence to the life expectancy of the insulation is obviously a very complex matter.

It would, therefore, be desirable to establish a correlation between a quantitative measurement of the high-frequency voltage and the other aspects of corona. Basic to any such generalization is the accumulation of a considerable body of data concerning the high-frequency voltage at operating potential and the condition of given types of insulation as determined by physical examination.

E. R. Thomas (Consolidated Edison Company of New York, Inc.): I am somewhat surprised to hear comments that the method presented by Mr. Quinn of using a cathode-ray oscilloscope for determining the value of voltage at which ionization takes place on a piece of electrical equipment should be questioned as a method for determining this value. The further comments suggested that the radio noise meter developed by the Joint Co-ordination Committee on Radio Interference of the EEI, NEMA, and RMA should be the preferred instrument to measure the value at which ionization takes place. While it may properly be discussed whether or not a piece of electrical equipment is satisfactory for operation on a voltage above which ionization can be detected, it does not seem logical to me to make use of an instrument which measures the radio noise from a given piece of electrical equipment and say that this necessarily is, or even is related to, the value of ionization potential. The radio noise meter consists of a selective radio-frequency amplifier with an indicating voltmeter arranged to measure the audio-frequency component of the radio emission after detection. This integral of the audio-frequency component of a damped radio-frequency wave may vary over extremely wide limits for a given peak value of radio frequency existing in the wave train. While ionization sets up radio-frequency emissions, the frequency of these emissions is determined to a large extent by circuit constants which may be made up of the apparatus alone or of connecting circuits in conjunction with the apparatus. Measurements made therefore on such a piece of equipment by means of a radio noise meter will generally give different values for different values of frequency in the radio spectrum. Radio frequencies are also generated by means other than ionization; variable surface leakage and varying contact resistances are equally important factors in causing radio interference such as would be measured by a radio noise meter.

To conclude, it appears to me that Mr. Quinn has proposed a simple and workable method for measuring the value of ionization potentials. If it is desired also to specify certain limits of radio noise generation by electrical equipment operated at normal voltage then the radio noise meter is a perfectly satisfactory instrument to measure that noise at specified values of radio frequency.

A. T. Sinks (General Electric Company, West Lynn, Mass.): Mr. Quinn's paper suggests a method for detecting corona in electrical apparatus which is different from the method conventionally employed. In so doing, the question is naturally raised as to which method is the better, especially from the standpoint of detecting destructive corona, since the latter is what the author seems to be primarily concerned about. In considering this question of the relative value of the two methods, one cannot help but wonder about the absolute value of either method and, therefore, quite naturally seeks data to determine these values. In order to get such information the instrument-transformer department of the General Electric Company obtained nine 15-kv current transformers which had been in service at 13.8 kv on the lines of a nearby utility company for from 15 to 20 years, and made radio-noise tests. Some of these transformers were similar to the one the author calls defective because it showed low starting voltage. All the transformers tested showed radio noise at operating voltage, ranging from a few hundred microvolts to over 9,600. However, only one of these transformers showed any signs of damage to the varnished cambric insulation, either when tested electrically or when inspected mechanically. Moreover, the only evidence of damage on this one current transformer was a small hole in each of the two outer layers of cambric, the total insulation being 18 layers of cambric. This transformer and one other which, judging from rust on the iron core, had been operating in a wet or damp location, showed some deterioration of the cotton tape over the black varnished cambric where the rust had built up, but the cambric under the tape was affected on only one of the current transformers. The transformer which had the highest radio noise, showed no evidence of any damage whatsoever. Moreover, these were not special transformers; thousands of others like them have operated for years without any indication of trouble.

It is recognized, however, that corona can be destructive and that insulation failures have at times been attributed to it. Therefore, the question is: "What is destructive corona?" On the basis of experience and tests, it seems doubtful whether "radio-noise influence voltage" or "corona starting voltage" tells us much about it, and furthermore, upon analysis there seems to be no very good reason why they should. It seems only reasonable to suppose that damage due to corona at any point would be associated with the intensity of the corona at that point, whereas the radio noise is probably the result of corona or ionization at many points, so that the intensity of corona in critical regions of the insulation cannot be determined by either of the methods of measurement mentioned.

While no good engineering reason can be adduced for having corona or radio noise in electrical apparatus it is sometimes expensive to eliminate it entirely and in the light of experience it is a question to what extent this expense is justified.

Therefore, if for economical reasons a certain amount of radio noise must be tolerated, a means of measuring the magnitude of the radio influence voltage rather than the line voltage at which this radio noise starts is desirable.

Moreover, a high corona starting voltage does not insure a low radio-noise influence voltage at operating voltage unless the latter is below the starting voltage, and even then there must be a considerable factor of safety because measurements of radio-noise and corona starting voltage are sometimes impossible to check from time to time.

It would be quite helpful if some means of telling when corona is seriously harmful could be developed, but until such means are available it would seem that experience is the best guide.

P. L. Bellaschi (Westinghouse Electric & Manufacturing Company, Sharon, Pa.): The results that Mr. Quinn has found comparing the radio-noise and the oscilloscope methods for detecting the ionization point on electrical apparatus are of interest.

Experience with the method recommended by the Joint Co-ordination Committee on Radio Reception of the EEI, NEMA, and RMA has been satisfactory. For instance, several years ago a laboratory was built at Sharon. Circumstances required that this laboratory be located adjacent to the high-voltage laboratory, and that its power supply be taken from the adjacent shop building where sources of interference from welders and similar equipment are inevitable. Yet it was possible, through ordinary design procedure and the application of available equipment and recognized methods, to put the laboratory into effective routine operation in the regular course of a short time. The laboratory has been in satisfactory operation since, and in it a wide range of tests and investigations have been made. More recently the same coupling method, consisting however of portable equipment, has been used in connection with measurements on large high-voltage apparatus. These tests of necessity had to be made in the shop building where all sorts of other electrical equipment are in operation. Again the results have been found satisfactory. Experiences such as these are fairly typical no doubt, and they are repeated elsewhere where similar installations are in daily service.

In his contribution, Mr. Quinn raises another important question. This pertains to the so-called "ionization point", to its significance and evaluation in the field of engineering. The writer is well aware of the controversial character of this question and merely wants to restate the principle that engineering is an art in which scientific methods and economics are inevitably interlocked. Apparatus design usually is the result of the happy combination and balance between these two and often conflicting factors. From the operating standpoint, it has been stated frequently that the criterion of satisfactory apparatus is that it should render a good account of itself in terms of good service and economical service. From the practical engineering end, the so-called "ionization point" then takes on a somewhat different significance and requires broader interpretation than would otherwise be the case were it considered from the purely physical approach.

S. W. Zimmerman (General Electric Company, Pittsfield, Mass.): Mr. Quinn's paper is an excellent example of the versatility of the cathode-ray oscilloscope in the hands of the electrical engineer. In the lightning arrester laboratory at Pittsfield, experiments have been made with equipment similar to that described by Mr. Quinn. A simplified circuit was used for determining the value of applied voltage at which high-frequency oscillations occur in the test piece. The oscilloscope measured the voltage drop across a resistance shunt. The errors introduced into measurements due to the use of a high-resistance shunt are insignificant when the 60-cycle current is small. However, the use of a resistance shunt is subject to limitation as indicated in the paper. If the 60-cycle current passed by the test piece is relatively large, the small superimposed high-frequency components of the current may cause only a small deflection which will be difficult to detect on the oscilloscope screen.

The start of ionization can also be determined from the volt-ampere characteristic of the test piece obtained by an oscilloscope. This method was reported by Peek ("The Law of Corona and the Dielectric Strength of Air—IV", F. W. Peek, AIEE TRANSACTIONS, 1927, pages 1009–1024) as well as by Lloyd and Starr, in connection with corona studies.

It has been the writer's experience that a fair correlation may be obtained between determinations of the starting point of ionization made with the oscilloscope and with the standard method recommended by the Joint Co-ordination Committee. The standard method was found to be more sensitive and is recommended since with it a good correlation can be expected from tests by different investigators which is an essential requirement. In addition, the standard method permits quantitative measurements of the disturbance generated which is not obtained from the oscilloscope equipment.

G. E. Quinn: Mr. Del Mar's experience with the cathode-ray oscilloscope method of test and particularly his use of a resistance shunt for classifying the type of ionization are of great interest. In general test work the initial point of ionization is the most important consideration and therefore a reactive shunt was used to get maximum amplification. However, in manufacturing, it is essential to know the nature and source of the ionization and Mr. Del Mar's suggestion should prove of great value. With the addition of this important feature, it should be more readily possible to raise the minimum voltage at which ionization occurs in electrical equipment.

Dr. Whitehead has described a very useful method of obtaining quantitative results and when such information is necessary it appears definitely superior to the radio-noise-meter method. As pointed out by Dr. Whitehead, it should certainly be possible to design many types of electrical equipment so that they will be free from ionization discharges at operating voltage. The test data which Dr. Whitehead submitted should prove of value to anyone interested in this subject.

Professors Brown and Paine also have referred to an excellent method of making quantitative measurements. In answer to their questions:

1. The work referred to in this paper was all done on equipment of low capacitance and the constants used were found adequate. However, recent cable tests have shown that under high-capacitance conditions it is desirable to reduce the impedance of the air-core reactor and resort to additional amplifiers in the input circuit to the oscilloscope.

2. Figure 3 was obtained using a persistent screen and a high-speed camera, timed for one sweep of the oscilloscope. However, figure 4 was taken with a much longer exposure. It will be noted that the patterns are stationary enough to produce a fairly sharp figure.

C. W. Germeck and C. Mannal indicate that the method recommended by the joint committee of EEI, NEMA, and RMA for radio-noise testing, which also includes a circuit for the measurement of radio-noise influence voltage is now "standard" for the type of testing discussed in this paper. This assumption has been adequately disposed of by E. R. Thomas in his foregoing comments. As Mr. Thomas points out, the radio-noise meter does not measure true ionization peak, is limited in frequency range, and responds to other disturbances as well as to ionization. This extension of its field is very definitely open to question.

Mr. Sinks is correct in his assumption that the primary consideration in this paper is the possible deteriorating effect of ionization rather than the radio noise which accompanies it. The results of his inspection and tests on nine current transformers serve only to emphasize the futility of depending on radio-noise measurements. As was to be expected, he found no relation between radio-noise influence voltage and deterioration. As Mr. Sinks agrees, corona can be destructive and insulation failures have been attributed to it. Since radio noise tests are no measure of this deteriorating effect, the solution lies either in raising the minimum voltage at which ionization occurs or in developing a method of determining its probable deteriorating effect.

Mr. Sinks has found it impossible at times to reproduce the voltages at which ionization occurred. This trouble is sometimes encountered in unsatisfactory equipment, but when the voltage at which ionization occurs is satisfactorily high, retest usually gives essentially the same results.

Mr. Bellaschi stresses the economic considerations that must enter into design, and we are in agreement on that point. Experience has shown, however, that when deficiencies are called to the attention of manufacturers in a competitive industry, changes in design and improvements in the quality of manufacture usually are effected at much lower cost than first anticipated.

S. W. Zimmerman reports fair agreement between the oscilloscope and the radio-noise-meter methods of checking the minimum voltage at which ionization occurs in electrical equipment. This substantiates the findings in the paper except that in one case there was a very decided difference. As indicated, this may be ascribed to the narrow band of response of the radio-noise meter. The oscilloscope method does not have this restriction and therefore is to be preferred. Mr. Zimmerman has apparently not had Mr. Del Mar's success with the resistance shunt, but it is to be hoped that he will continue the study further.

It was the purpose of this paper to promote discussion of methods of checking ionization in electrical equipment and the excellent response received is very gratifying.

Rapid-Recording A-C Bridge

Discussion and authors' closure of paper 40-82 by W. Mikelson and H. W. Bousman, presented at the AIEE summer convention, Swampscott, Mass., June 24–28, 1940, and published in AIEE TRANSACTIONS, 1940 (November section) pages 628–31.

George Keinath (consulting engineer, Larchmont, N. Y.): I am very pleased to see that the General Electric Company is recommending the same procedure for testing high-voltage equipment as I did when I presented a paper on the same subject at the winter convention of the AIEE in January 1939. My experiments in this line started seven years ago, after some very bad experience with voltage transformers, which showed that the passing of the ordinary one-minute test is in no way an assurance of good performance in the field. First I used a photographic recorder for the active component of the capacity current, a vibrating mechanical rectifier, and a d-c galvanometer. The diagrams gave the active component first in function of the increasing voltage, during the proper test in function of time. A number of such diagrams have been published,[1] but the recorder was too delicate for routine testing and so I decided to build an ink recorder.

The "Numograph," as originated by Geyger[3] uses two watt-hour meters, one tuned for the active, the other for the reactive component of the amplified current in the diagonal of the bridge, together with a zero indicator and motor.

So far as I know, at least 20 of these recorders are used all over Europe, by laboratories as well as by manufacturers, for development and for routine testing.[1–5] Recording power factor and capacity has proved to be of extreme value, and, as I pointed out when I presented my paper, I was able to reduce the weight of instrument transformers to a small fraction of the former weight, without any sacrifice in safety.

Apparently, as far as performance is concerned, there is no difference between the General Electric recorder and the "Numograph." It seems to me that the latter is simpler because zero indicator, phase selector, and motor are united in one element.

I found it very important to have a record of power factor not only at constant voltage, but also during the increase of voltage, beginning with 10 or 20 per cent of full test voltage. To obtain this, there were two ways: one was to increase the test voltage proportionally with the time and also to move the paper proportionally with the time with an ordinary clockwork; the other was to move the paper proportionally with the test voltage. These diagrams revealed with absolute clearness the position of the ionization point, and their shape was highly informative. The same recorder was used for temperature tests on transformer oil, increasing the temperature proportional to the time or moving the paper proportional to temperature. Such tests, running without attendance, gave far more information on the qualities of transformer oils than any test at constant temperature, be it low or high temperature.[6]

The main objection to my proposition for such a method of testing high-voltage equipment and insulation material in general was the high price of the outfit. Therefore I should like to hear from Mr. Mikelson what will be the approximate price of his recorder, of course, minus Schering bridge and minus standard capacitor, because these two items are also necessary for any hand-operated bridge.

Furthermore, I should like to get the fol-fowing information:

A time of one second is given for balancing the bridge. Is this the time for the pen to travel across the whole width of the paper or the average time for smaller deflections? I should not think that it is necessary to have such a short time, after we have always spent about half a minute to get just one reading with the manually operated bridge.

Has the phase shift of the amplifier to be exactly zero or 90 degrees or only approximately?

Is the output of the amplifier changing the indication or only affecting the speed of the recorder?

W. Mikelson and **H. W. Bousman**: Concerning Doctor Keinath's questions, the balancing time of one second is the time required to rebalance through the whole chart width, for example, when switching from one specimen to another. This seems to be quick enough for the applications of the bridge made thus far. We can conceive that a record of specimen behavior every half cycle might be useful in understanding the phenomena accompanying breakdown. This would be in the oscillograph range rather than the bridge range. The point we wish to make is that it is unsafe to say that an instrument responds more quickly than is necessary. As soon as a better instrument is available, more is learned, pointing the way to the need for a still better instrument.

The amplifier phase shift must of course approximate an integral multiple of 90 degrees. The approximation need not be very close; 15 or 20 degrees difference seems to make little difference in bridge behavior.

The bridge balance point is not affected by amplifier condition. It is only necessary that the amplifier sensitivity be sufficient to furnish a signal to the motors when the bridge is out of balance by any amount in excess of the allowed error.

The Dielectric Strength and Life of Impregnated-Paper Insulation—II—Influence of the Thickness of the Paper

Discussion and author's closure of paper 40-104 by J. B. Whitehead, presented at the AIEE summer convention, Swampscott, Mass., June 24–28, 1940 and published in AIEE TRANSACTIONS, 1940 (December section) pages 660–3.

H. H. Race (General Electric Company, Schenectady, N. Y.): I believe I am speaking for the subcommittee of the AIEE committee on research, which has followed Dr. Whitehead's work very closely, when I say that we are particularly pleased by the care with which this work has been performed and by the demonstrated reproducibility of the results. The number of similar specimens tested has been sufficiently large and the deviations in the life results have been sufficiently small to leave no doubt in our minds as to the validity of the trends which Dr. Whitehead has plotted in his figure 1.

I think the readers of this paper will be interested in the objectives which were agreed upon at the beginning of the work, as indicated by the minutes of the first meeting of the supervisory committee. "The factors which result in deterioration and eventual failure of oil-impregnated paper insulation under high voltage stress may be grouped roughly in two classes: first, those factors which, in the absence of gaseous ionization, cause gradual chemical changes resulting in increasing dielectric loss and eventual thermo-electric failure, and second, those factors which directly cause gas liberation, gaseous ionization, carbonization and electrical failure." It was agreed to conduct these experiments so as "*to minimize chemical deterioration not resulting from electrical stress and to accentuate and study the factors affecting ionization or other physical effects of high voltage stress.*"

An understanding of the above objectives is important in evaluating the results. Since the tests last only three days or less and since the testing temperature is only 40 degrees centigrade, it seems safe to assume that chemical deterioration, in the sense in which the term is used in AIEE paper 39-113 ("Tests on Oil-Impregnated Paper—IV—Mechanism of Breakdown," by H. H. Race, AIEE TRANSACTIONS, 1940, pages 721–9), is negligible in Dr. Whitehead's researches. Furthermore, it seems that the stated objectives of these researches have been met in that the evidence indicates that the cause of failure is progressive ionization, and the effects of changing paper thickness have been determined and tentative explanations offered for the results obtained.

In attempting to evaluate these results in terms of practical operation of oil-impregnated paper insulated cable, we should remember, however, that these tests were made at very high gradients and that the order of excellence of such specimens might be entirely different if they were tested for years instead of days at gradients comparable to service conditions. This is true of all short-time high voltage tests. To my mind the major advantages of such tests are: first, the information gained concerning the mechanism of failure so that the results of changes in construction can be scientifically predicted; and second, the knowledge that the best specimens on such tests have the highest factor of safety on transient overvoltages.

J. F. Calvert (Northwestern Institute of Technology, Evanston, Ill.): The matter which I should like to hear discussed by the author is not directly in line with this paper but perhaps is sufficiently closely associated to raise at this time.

In 13-kv armature insulation which has been stressed to failure, if the bond is largely washed out by a solvent, usually it is found that a small hole is burned out perpendicular to the mica and tape for some distance without deviating as much as from $^{1}/_{8}$ inch to $^{1}/_{16}$ inch to go around a flake of mica. Then near the end of this straight shot the path may show a rather extensive area of burning sideways along a layer or two of tape for as much as from $^{1}/_{2}$ inch to 3 or 4 inches before it again travels perpendicular to the layers as at the section where the path was first traced. Generally speaking it seems that the more compact samples of such insulation and those having the higher breakdown are the more likely to show a pronounced side shift (path burned out parallel to the layers of tape).

These tests were made at 60 cycles at room temperature and failure occurred within about one minute on a steadily rising alternating voltage. Some of the tests were made under oil to prevent flashover, and some were not. The latter seemed to have no important effect. The oil had too little time to penetrate the insulation on the rectangular bar sample. Some of the tests were made with asphaltic bonds, and some with various other types of bonding material. The physical appearances of the failures were substantially the same. In all cases hand-wound half-overlapped mica tape was used with the same bond employed in the tape as was brushed on to fill between the layers of tape. The mica tape was composed of two outer layers of Jap paper nominally 0.001 inch thick, and two to three layers of mica between giving an over-all thickness of about 0.007 inch for the finished tape when finally in the coil. The bar samples were vacuum treated and impregnated in an asphalt gum tank. The vacuum treatment removed most of the solvent, but the gum impregnation seemed to furnish more of a hydraulic pressing action than an actual impregnation of the tape with gum.

These observations were made some years ago at the Westinghouse company in collaboration with Messrs. Krogh and McCullough.

One might safely assume that as the voltage was raised, that rather intense internal corona was produced at various locations within the coil, and probably that it occurred in many cases in flat sheets of corona in the sides of the coil between the paper layers. It is interesting to note, however, that no partial failures were found in the outward direction (i.e., perpendicular to the mica layers). I would greatly appreciate hearing the author's theory concerning the probable mechanism of such dielectric failures as I have described above. It would be interesting to know whether he feels that the actual puncture starts from the electrodes, from the ionized air pockets, or from both and something of the way in which this failure occurs.

J. B. Whitehead: As is well known, there are a number of elements or factors which enter into the question of the stability and the life of the insulation of high voltage underground cables. The great problem in the improvement of cable insulation and in cable design has for many years been the proper evaluation of the relative importance of these various elements. The problem is as yet unsolved, but steady progress is being made. For a number of years we have been studying one after another of the limiting elements referred to, taking one at a time and eliminating as far as possible all the others. Thus, for example, we have reported upon the drying process, the relative values of different oils in accelerated life programs, the dielectric loss in impregnated paper as related to the losses in its constituents, and others.

Dr. Race has described the aims in view in the research in which we are now engaged. In somewhat simpler terms, the work might be described as a study of the conditions under which high stress leads to the liberation of gas and failure in impregnated paper insulation. Very clear cut evidence has already been obtained as to the influence of a variation of the density and of the thickness of the paper and further evidence is now being produced as to the influence of the oil viscosity. A great deal of evidence has been collected as to the conditions under which initial failure occurs, and its growth to final breakdown. This will be presented in a later paper.

Dr. Race has emphasized the high stresses in our work as compared with the operating stresses in cables, and that caution should be used in making direct deductions for cable design. I concur in this view. I wish to point out, however, that the only question here is whether there is any difference in the mechanism of initial gas liberation at high stress and at low stress other than a difference in the time rate for liberation and that of progressive failure following initial gas liberation. This is an old question. Thoroughgoing investigations of the time element in cable failure have always broken down by reason of the long time involved and the wide spread of experimental values amongst a number of specimens. In view of the uniformity with which we are now able to construct our specimens, of the narrow spread of experimental results, and of the methods which we have developed for detecting the beginnings of failures and partial failures, I am confident that an investigation of the time element in cable failures is not nearly so difficult as formerly, and am hopeful that we may find opportunity in our further programs for studying this important question.

As to Mr. J. F. Calvert's question, I have received the impression that the failures in armature bars which he describes, originate in local point discharges from the surface of the slot. Such point discharges have very definite drilling power and would account for the short straight holes he describes. However, as the depth of the hole increases, the conductivity of the spark constitutes a point of ground potential advancing into the wall of the insulation. As it advances, a horizontal or lateral component of the stress is developed and in increasing magnitude. Finally, this lateral component is able to cause a discharge through a gas layer or over a mica or other surface or even over the contact surface between two different materials. This discharge parallel to the layers is also conducting and will eventually pick out another weak spot in a direction normal to the conductor surface. I judge that internal corona-forming gas layers are often present in such insulation. Such layers would facilitate the mechanism as suggested above. The rate of increase of voltage described by Mr. Calvert is rather rapid. A slower rate of increase, say over a period of days to breakdown, might possibly develop partial failures such as we have had no difficulty in obtaining in cable insulation.

The Type CB Impregnated-Paper Cable

Discussion and author's closure of paper 40-121, by S. J. Rosch, presented at the AIEE summer convention, Swampscott, Mass., June 24–28, 1940, and published in AIEE TRANSACTIONS, 1940, pages 1041–9.

R. W. Atkinson (General Cable Corporation, Perth Amboy, N. J.): Rosch shows the results of load-cycle aging tests on two cables, in one of which the conductor is shielded by carbon-black tapes, the other cable being similar except without this shield. His data are in line with those obtained by other laboratories in indicating that the addition of shielding tapes improves cable performance. However, while others give credit for the improvement to the *electrical shielding* effect of the tapes, Rosch apparently attributes the improvement to the *adsorptive* effect of the carbon black in the tapes. As will be shown later, Rosch's own data do not bear out his conclusion.

That the electrical shielding effect is actually of major importance has been effectively demonstrated by weight of evidence obtained in different laboratories. The tests in our laboratory have included load-cycle aging tests, each several weeks in duration, on some 48 cables, half with shielded conductors in comparison with a like number without shielding. Some of the shielded conductors were shielded with carbon-black paper and some with aluminum foil, and we found no difference in the effect of the two kinds of shield.

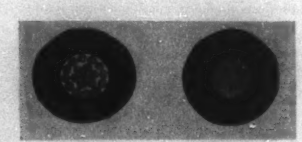

Figure 1. Styrene wafer showing cross section of cable with conventional and compack round strand bringing out the difference in oil space of conductor surface. (Partly due to difference in wire sizes)

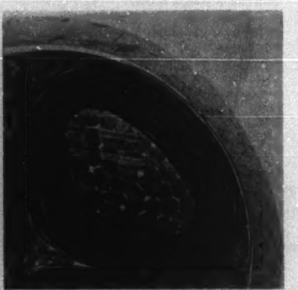

Figure 2. Styrene wafer of three-conductor 350,000-circular-mil compack sector with 250 mils paper, 9/64 inch lead. After accelerated aging test

In a paper presented informally by the speaker at an Edison Electric Institute meeting in February, and published in the April 1940 issue of *Electric Light and Power*, the "change in structure" that produced the gain of about 12 per cent in voltage strength there indicated was the use of shielding tape over the conductor. Further details of this investigation were printed in the July issue of *Electric Light and Power*.

In brief, important gain is found by the use of shielding tapes over the conductor. This gain is found whether the tape is paper made electrically conducting by the incorporation in it of finely divided carbon or by a covering of thin aluminum foil. From this, it will be clear why we do not agree with the author's crediting of this gain to some special property of the carbon incorporated in his CB paper.

Rosch's data of test 6 reported in his tables III and IV show the results of some interesting comparisons. Table I of this discussion will be found enlightening. While this shows that electrical shielding, whether over the conductor or over the insulation, produces great improvement, it fails to show that a carbon-black shield is superior to a metal shield.

Does the carbon black have an important function in adsorbing conducting ions from the oil? Rosch's data seem to show such a tendency, but are hardly sufficient to warrant such a conclusion. Doubtless he now has considerable supplemental data. Tests carried on in our own laboratory establish that *ordinary insulating paper* placed in oil may reduce the rate of power-factor increase when the oil is heated in the presence of oxygen, presumably by adsorption of ions responsible for the electrical conduction. The same action also occurs with carbon black, varying in extent with the type of carbon black. However, in order to demonstrate this characteristic, even in a minor degree, it has been necessary to carry on these tests on a test tube scale under closely controlled laboratory conditions. In cables which have been made with metal shielding and with shielding of carbon-black paper, the over-all improvement due to the shielding has been so great that any difference between the two methods of shielding has been too small to be differentiated from the total gain if, indeed, there is any difference.

Aside from the general results of the load-cycle aging tests showing the over-all benefits obtained, the gain may be illustrated in various ways. Figures 1 and 2 of this discussion, showing the spaces around the conductors which are shielded from the electrical stress, illustrate well the advantages which might reasonably be expected from the shielding.

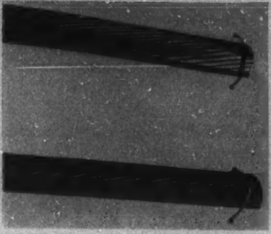

Figure 3. Appearance of shielded and unshielded conductors after load cycle aging test. Note wax on unshielded and none on shielded construction

Figure 3 shows a shielded and an unshielded conductor from which the compound has been drained in an oven following dissection after test. The thickened compound and wax in the interstices of the unshielded strand and in the valleys between the edges of the innermost tape is very obvious on direct examination, contrasting with the complete absence of wax in the strand which was shielded.

Figure 4 shows tree design on an unshielded conductor following the load cycle aging test. This contrasts with the fact that on the cables with the shielded conductor, no deterioration of this sort has been found.

Figure 5 shows measurement of power factor at very high stresses, such as is obtained in relatively short-time breakdown tests and shows a large reduction in the power factors at high stresses resulting from the conductor shielding.

This paper and our comments may be summarized as follows. The author has performed a limited amount of testing indicating some beneficial effect of carbon black on power factor of oil exposed to highly oxidizing conditions. His test 6 on cable is supposed to show the superiority of the carbon black over another form of shielding, but clearly this experiment supports no such conclusion. From the above and from tests in which comparison is made between cable where the conductor is shielded with carbon-black paper and other cables without conductor shielding, he attempts to draw the conclusion that all or substantially all of the gain shown by the cable with the shielded conductor, comes from the *adsorptive properties* of the carbon black rather than from the *electrical shielding*. Such a conclusion is wholly unjustified from the data. Moreover, our laboratories have shown by extensive tests that suitable conductor shielding accomplishes important benefits and that such benefits are obtained by the use of metal faced tapes as effectively as with tapes made electrically conducting

Table I. Comparisons Taken From Tables III and IV by Rosch

Comparison Between Lengths Nos.	Nature of Comparison	Effect of Change of Structure on Breakdown Strength
1 and 2	Addition of CB tapes at conductor	*Gain* of 94 volts/mil
2 and 6	Addition of copper shielding tape	*Gain* of 121 volts/mil
2 and 4	Addition of CB tapes near the sheath	*Gain* of 185 volts/mil
6 and 7	Addition of CB tapes near the sheath	*Loss* of 4 volts/mil

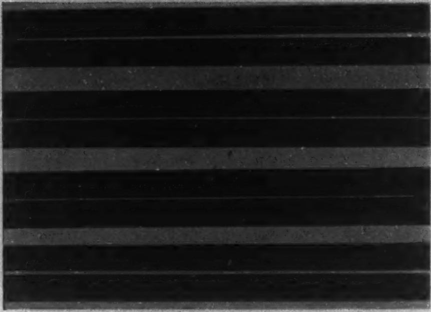

Figure 4. Typical tree designs found on inner tapes of samples with unshielded conductors

with carbon black. Though such shielding has long been known in the art and though it is covered by patents so old as to have expired, it has remained for recent tests by our laboratories and others to give actual demonstration of the really practical, as well as theoretical gain from this shielding.

Wm. A. Del Mar (Habirshaw Division, Phelps Dodge Copper Products Corporation, Yonkers, N. Y.): Mr. Rosch deserves great credit for espousing the cause of conductor shielded cable in America. Such cable has offered a fertile field for inventors, both here and abroad, since 1914 when Beaver patented a cable with metallized paper shielding on a stranded conductor. The general idea developed out of (1) a statement made by Jona in 1904, that the dielectric stress at the surface of an insulated stranded conductor is much greater than that at the surface of an equivalent solid conductor and (2) the belief that the life or breakdown voltage of a cable is, in some way, increased by lowering the calculated stress at the conductor surface.

I shall not discuss the Jona theory about the stress at the surface of a stranded conductor being increased due to its geometric configuration as it is immaterial to my argument.

However, I do take issue with those who try to explain the advantages of conductor-shielded cable on the basis of a reduction of geometrically calculated field intensity.

According to the maximum stress theory, stress may be calculated from the geometrical form and applied voltage. The life of insulation under voltage will depend upon keeping the stress, at the point of calculated maximum stress, below a critical or high value.

If this theory be correct, cables of equal maximum stress should show equal lives on voltage-time test. D. M. Robinson ("Dielectric Phenomena in High Voltage Cables," page 164) however, cites the case of two cables of widely different conductor sizes designed, however, for equal geometrical maximum stresses. On voltage-time test, the cable with the small conductor required a much greater voltage to break it down. M. Klein, in his "Kabeltechnik", 1929, page 68, gives similar data and indeed such data may be obtained from the records of any laboratory which has made many breakdown tests on cables.

According to the same theory cables with small conductors should be more heavily insulated than those with large conductors. Yet AEIC insulation thicknesses are the same for all conductor sizes regardless of stress and some engineers believe that thinner walls may be used safely for small than for large conductors, both negations of the ordinary maximum stress theory.

Another experimental fact which may be interpreted as conflicting with that theory is the greater dielectric strength of oil between small spherical electrodes than between large ones.

According to the same theory, the maximum stress in a 700,000-circular-mil cable will be something like 20 per cent less than that in a 500,000-circular-mil cable and if we accept Jona's and Atkinson's view that shielding a stranded conductor reduces the maximum stress by 20 per cent, a shielded 500,000-circular-mil stranded conductor should be only the equal of an unshielded 700,000- or 1,000,000-circular-mil conductor. Tests, however, show it to be better.

The fact that shielding is not equivalent to making the conductor smooth, is afforded by the favorable test data obtained on shielded conductors as contrasted with results obtained by a direct experimental comparison of equivalent stranded and smooth conductors as given by Fernie in BEAMA, September 1921. This comparison showed no difference between them. Similar comparisons have been made by others, with the same result.

If it be urged that the maximum stress theory is supported by the fact that cable failures almost invariably initiate near the apex of a strand where the stress is greatest, I would reply that this occurs, not because of greater geometrically calculated stress, but because the oil gap is thinner there than between strands and therefore subjected to a locally greater stress.

The value of strand shielding must, in my opinion, be explained otherwise than by the maximum stress theory, a theory which requires complete restudy in the light of P. L. Hoover's AIEE paper of 1926. It is not that deterioration is not a function of maximum stress but that maximum stresses as calculated by geometric formulas, alone, are not correct.

Now comes Rosch with a new theory—the theory of adsorption. He explains the advantage of conductor shielding by a chemical, rather than an electrical, theory. He seems to rely, very largely, on the data in his figure 6, giving rises of power factor of cables made with carbon blacks of different adsorptive indices. If the data shown in this figure mean anything it seems to me that they show that adsorption is not the essential factor, as low power-factor rises are obtained with carbons of both high and low indices while comparatively high power-factor rises are shown for intermediate values. However, I doubt whether these data have any significance, as the differences in power-factor rise, for cables with the various carbons, lie within the normal variations to be expected between samples of identical construction.

More positive information was obtained in our laboratory by placing CB paper from one of Mr. Rosch's CB cables in a bombardment cell with Sun XX oil and subjecting the oil to bombardment, making a similar run on the oil without CB paper. The cell used for this test is described in the following.

Power-factor tests of the oil before and after a 450-minute bombardment run in the cell showed no difference due to the presence of the CB paper. The CB paper, however, reduced gassing about 20 per cent showing that only the gaseous products of deterioration and not the more harmful liquid products were adsorbed. A point of saturation of gas adsorption is reached after which the protective value of the carbon black, as an adsorbent, ceases.

Such long-time improvement in power-factor stability as may occur due to the use of CB paper must therefore be due to reduced ionization resulting from less gas formation, rather than to adsorption of those products of oil decomposition which tend to raise the so-called "solid" power factor.

This brings us to a third theory of the conductor-shielded cable propounded in 1929 by engineers of the Siemens-Schuckert Company and given in British patent No. 349,-289 dated May 28, 1931. This patent describes a high-tension cable with impregnated paper insulation and lead sheath in which a few layers of paper containing "soot" are placed directly upon the conductor or directly under the sheath, or at both points. Emphasis is placed on the fact that these layers have comparatively low insulation resistance and that due to this, "The field intensity in these is so far reduced that ionization can no longer occur."

In other words, the soot (i.e. carbon black) in the paper, is used to lower the intensity of discharges near the conductor surfaces. Discharges from metal are always more violent than discharges from high resistance nonmetallic surfaces or coated metallic surfaces such as paper-backed metal foil, in which the paper adheres firmly to the metal.

This may be demonstrated very clearly in the laboratory by oscilloscope observations of the wave form of charging current of a vacuum discharge cell. Such a cell, designed by E. J. Merrell, is shown in the accompanying figure 6. It consists of a metal electrode in a vacuous flask and a water electrode outside the flask. Alternating voltage applied between electrodes causes a discharge from the metal electrode through a sample of oil in the bottom of the flask. The oil rises in power factor and gives off gas, a reaction characteristic of a cable with ionized voids. The gas evolution is measured by a mercury manometer and the power factor rise by measurements with a Davidson type cell. When discharges take place from the metal electrode, the transients are well defined whereas if the metallic electrode is replaced by a nonmetallic or a coated metallic electrode, they appear as a mere fuzz on the wave.

Mr. Rosch's figure 10 showing condition of cable after high-voltage time test supports the energy theory rather than the adsorption theory as it is hard to see why adsorption should prevent the formation of corings (i.e. burned spots) such as appear on the tape of stranded cable. On the other hand, this is the obvious result to be expected on the basis of the energy theory.

When comparing Beaver's aluminum-coated paper with CB paper according to the energy theory, bombardment tests showed that whereas CB paper improves gassing but has no effect on power factor stability, aluminum has a marked effect on improving power factor stability at the expense of a slight increase in gassing.

Which of the two materials will prove better in service, only time will tell, as the relative importance of gassing and "solid" power-factor rise may not be the same under service conditions as in accelerated tests. I believe that some form of conductor-shielded cable will be adopted very generally, but the fact that neither the "soot" cable nor the metallized paper cable found favor in Germany or England where they were well known because of the patents of Siemens-Schuckert, Beaver and others, should give us pause before we commit ourselves to them wholeheartedly, particularly as means to reduce insulation walls.

An example of the difficulties that may arise is that the makers of carbon-black paper say that they must use rosin size, sodium abietate, to hold the carbon black in suspension. This material, unfortunately, is highly corrosive of copper as noted by Stephens and Gehrenbeck in AIEE TRANSACTIONS, June 1940, page 359. Ordinary cable paper is free of this material but such CB paper as I have seen, judging by the color it imparts to a flame, contains considerable sodium, and judging by the Liebermann-Storch test, it contains considerable abietic acid. Whether these are in combination, I do not know. Perhaps Mr. Rosch can tell us whether such difficulty has been overcome.

Until such matters have been discussed and settled satisfactorily, I prefer to attain power factor stability by the combined use of the most stable impregnant and by the scientific use of the elastic properties of paper, by which means *both* reduced gassing and "solid" power-factor stability are attainable. Conductor shielding, however, is a promising field that should be carefully studied, and its greatest value may be found in combination with these other improvements.

Our laboratories have been studying the subject from the point of view of the energy theory outlined in the foregoing and there are indications that the best conductor shielding may be neither CB paper nor metallized paper.

For some years it has been a favorite indoor sport of the cable purchasers to make radial power-factor curves and to give their approval to cables having low boundary power factor. Now comes Mr. Rosch with a cable in which the boundary papers are deliberately given a power factor of about100 per cent. In my discussion of Wyatt and Spring, AIEE TRANSACTIONS, 1936, volume 55, page 204, I asked: "Is it not possible that a high power factor of the inner tapes may be a good thing?"

Now we have the answer and doubtless to the surprise of many, it is affirmative, with the proviso that the high power factor must not be due to cumulatively deteriorating material. If you start with 100 per cent power factor, as in CB paper, you cannot have any rise, cumulatively or otherwise, but you accomplish a suppression of the energy of discharge due to this property of the paper. This idea was back of my question in 1936.

G. B. Shanklin (General Electric Company, Schenectady, N. Y.): The effect of corrugations at the surface of stranded conductors and the advisability of smoothing the surface by some form of shielding has been a perennial source of theoretical discussion and trial ever since high-voltage cable came into use. Mathematicians have shown that for the average conductor size with relatively small strands, as used in power cable work, the increased stress at the apex of the strand is a very few per cent as compared with an equivalent smooth surfaced conductor. Practical trials have also shown that this small theoretical advantage of a smooth surface cannot be realized unless this surface is pervious and allows an outward flow of compound for maintaining impregnation in the adjacent paper tapes.

The semiconducting carbon treated paper tape described by Mr. Rosch is pervious and does smooth off the conductor surface but Mr. Rosch is not quite as modest as the mathematicians in the benefits claimed. In addition to improvement of ionization characteristics by reduction of electrical stress gradient at the conductor surface, Mr. Rosch also claims that the carbon-paper wrappings act as an absorptive screen and prevent the spread of metallic soaps into the main body of insulation.

Ionization and metallic soap formation both result in increased dielectric loss, but they are different effects from distinctly different causes. In reporting his test results Mr. Rosch makes no distinction between them. In my case at least this has led to confusion in trying to translate and evaluate his test results in terms of actual life under service conditions.

The causes and results of ionization in solid-type cable under normal service conditions are too well known to require comment here. Metallic soap action is much rarer and less well known. The following comments may be of some interest.

Metallic soap formation is an oil oxidation

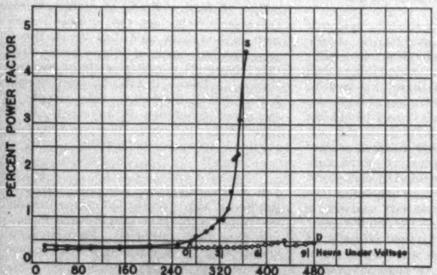

Figure 5. Curves showing change in power factor with voltage during short-time breakdown tests

Curve "*S*" shows results for a group of samples with unshielded conductors while curve "*D*" shows results for a group of samples with shielded conductors and with a change in paper and saturant from "*S*". Conductor shielding has been found to be the predominant factor in the large reduction in ionization

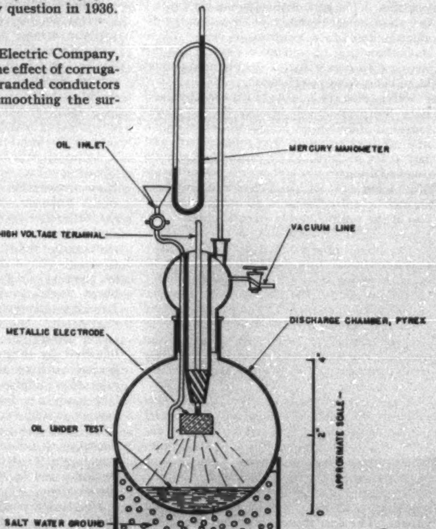

Figure 6

action. It can only occur in the presence of oxygen, which must first pass into a combined and corrosive form in the oil. Striations on the inner paper tapes, such as shown in figure 1 of Mr. Rosch's paper, are an accurate and sensitive measure of the degree and severity of metallic soap action in cable. The dark markings are a form of oil sludge and represent an end result of the oxidation cycle. This sludge is formed by precipitation of metallic soaps from colloidal solution in the cable oil or compound. While in colloidal solution the metallic soaps can penetrate more or less into the main body of insulation, depending upon the degree and severity of the action. This results in a corresponding increase in dielectric loss, which in severe and exceptional cases can be very pronounced. In ordinary cases it does little more than form a moderate upbend in the radial power-factor curve in near proximity to the copper conductor and sheath. When all oxidation impurities are consumed a maximum condition is reached and precipitation may even reduce losses thereafter.

We have carried on a study of metallic soap action in cable for some years past. The chemistry involved is very complicated but the cause and prevention are well understood and we have been able to reproduce this action and the resulting striations at will and to any degree desired in the laboratory by controlling the amount and kind of oxygen impurities introduced into the cable. We have also been able to eliminate this action by following the fundamental expedient of keeping all oxygen and oxidation impurities out of the cable.

A study of the test data in Mr. Rosch's paper leads to the conclusion that his miniature samples, tests 2 to 5 inclusive, are not representative of modern high-quality cable, but instead contained an appreciable and variable amounts of oxygen or oxidation impurities. The striations alone in his figure 1 are convincing evidence of this, but the dielectric loss data confirm it also. These data show that no ionization existed and the increase in power factor during aging must have been due to oxidation.

Refer to Rosch's table II for example, and note the pronounced increase in the power factor at 100 degrees centigrade after only 5 and 10 days aging at that temperature and 100 volts per mil. The unshielded sample reached a maximum 100-degree power factor of 23.8 per cent within 5 days and remained stable thereafter because all oxygen impurities in the sample had been consumed. The carbon-paper shielded sample reached a 100-degree power factor of 8.7 per cent in 5 days and a further increase to 10.5 per cent in 10 days, showing that all oxygen had not yet been consumed. Plainly, the carbon-paper shielding did not prevent the penetration of oxidation action into the insulation. From the standpoint of practical operation the difference in stability and quality of these two samples is not very marked. Both are unacceptable.

Rosch's test 1 gives a direct comparison of the comparative absorptive abilities of regular cable paper and carbon-treated paper. His table I shows there is little practical difference between them. The amount of oxidation impurities absorbed from the oil by regular insulating paper is only a little less than that absorbed by carbon-treated paper. The first three wrappings of regular cable paper next to the conductor shield the rest of the insulation about as well as the same amount of carbon paper would. This points to the conclusion that the right time and place to purify oil with activated materials, such as carbon or Fuller's earth, is before it is used in the cable and not afterward.

If a service failure has ever occurred in solid-type cable due to metallic soap action, I have never heard about it, nor have I ever seen evidence of striation markings on inner paper tapes under normal operating conditions. The properties of solid-type cable are not favorable to this kind of action, except under accelerated and exaggerated conditions in the laboratory. Even under accelerated conditions the action is not pronounced in modern cable of good stability unless an excess of oxidation impurities are present. I would still rather depend upon the well founded principle of removing all traces of impurities from the cable initially and making sure that none enter during installation and service.

Ionization still remains our real problem with solid-type cable. If strand shielding proves of practical benefit it will be because of improvement of ionization stability. Any stable type of conducting or semi-conducting shielding that removes stress from the compound lodged in the strand crevices will accomplish this purpose.

Rosch's test 8 is of particular interest in this respect. Here, he used two 45-foot lengths of regular cable of good quality. Contrary to the miniature samples, the test data show that ionization was the primary cause of instability. One of these three-conductor cable lengths had conductor strand shielding and one did not. Mr. Rosch does not state whether the sector conductor was compacted. The smoother surface of compacted conductors would have some bearing on comparative results.

These lengths were subjected to load cycle life test at 100 volts per mil. The length without strand shielding began to show signs of instability at the end of 52 days and finally failed in 202 days. The length with strand shielding reached instability in 210 days but had not reached final failure at the last report in 400 days. Its behavior after instability started was much the same as that of the first length.

As far as this one test is concerned some advantage for strand shielding is shown. Normal variations in individual test lengths could, however, cover a wider range than the difference between these two lengths. Additional tests of this kind are needed for averaging. Before this is done I would like to suggest that the conditions of this test are too favorable to strand shielding as compared with actual operating conditions. Ionization in service is caused by compound migration. During such migration the larger strand spaces drain first and this is followed by drainage of the smaller butt spaces between paper tapes. Finally, if migration still continues, even smaller capillary spaces are drained through the wall of insulation and "dry spots" develop. Cable must be on a slope for this kind of complete drainage to occur. When it does, ionization is scattered throughout the insulation thickness and not concentrated at the strand spaces alone.

Mr. Rosch used a test length of 45 feet and this was laid out level on the floor. The only drainage that occurred was circumferential and was due to a slight stretching of the lead sheath. It was distributed uniformly along the length and there was no longitudinal drainage at all. This kind of compound movement is hardly enough to drain the strand spaces in the upper half of the cable cross section. Incipient ionization is accordingly concentrated at the conductor surface and strand shielding will reduce this.

Load-cycle tests with longer lengths arranged to allow a reasonable amount of longitudinal migration would be more representative of service conditions and give a more accurate comparison of the benefits of strand shielding. It may be that repeated tests of this kind will prove that strand shielding is sufficiently worth while to warrant the cross-sectional space taken up. At the present time it is an interesting speculation, as it always has been in the past.

L. G. Smith (Consolidated Gas, Electric Light and Power Company, Baltimore, Md.): The development in cable design described by the author is very interesting. Investigations of this type contribute to progress. However, as the author has stated this is a progress report, there are several questions that might suggest possible future studies.

In the type CB cable, does a sufficient amount of the total oil in the cable contact the carbon-black paper to obtain the desired stabilizing effect? Might not the beneficial results be due to shielding? If the standard samples used in the tests reported in table II and figures 3 and 4 were not shielded, these tests might indicate the effectiveness of shielding rather than the effect of carbon black upon the oil. Test 4, in which smooth cylindrical conductors were used, may not be as effective as a conducting paper applied over the conductor in shielding.

In table I, which represents only the stabilizing effect of carbon black upon the oil, only a 25 per cent reduction in power factor and 11 per cent improvement in resistivity are shown. On the other hand, in table II the effect of the CB model indicates a 2- or 3-to-1 improvement. This may indicate that it is the shielding obtained rather than the effects of carbon black. In table IV, the fact that sample 7 with more carbon-black tape than sample 6 had an equivalent one-hour life no better than that of sample 6 indicates the same conclusion. Likewise, in table IV since sample 3 was but little better than sample 1 the same conclusion is indicated. It is believed that the results in figure 8 may be attributed to conductor shielding.

J. B. Whitehead (Johns Hopkins University, Baltimore, Md.): In the CB cable two well-known protective principles for cable insulation have been combined. First the well-known principle of shielding with its reduction of local stresses and its protection against void formation, and second, the use of finely divided activated carbon for the purification of the oil. The two principles are combined by the simple expedient of incorporating the finely divided carbon black in the structure of the paper during manufacture of the latter. This gives the paper a measurable electrical conductivity so that two or three layers next to conductor or to sheath serve as shielding layers. Furthermore, the incorporation of the carbon black in the structure of the paper prevents its migration into the oil and the possible formation of bridging paths leading to local failures.

The author presents an impressive series of experimental data indicating superiority of the CB cable over those of ordinary type in the solid cable class. The author's thesis is that the advantages shown by the CB cable are largely due to the purifying and absorptive properties of the carbon-black paper. There is some evidence of this in the results of the separate experiments on oil and on impregnated paper, as given in table I. The evidence is not so clear in the results of figure 12 on the aging characteristics of both "standard" shielded cable and the CB cable. Here, it is true, we have a superior performance for the CB cable, but there is no direct evidence that this is due to the properties of the carbon black. The cyclic aging tests are commonly supposed to bring about internal gaseous ionization and to measure the stability of a cable against its effect. Therefore, in the results of figure 12 it would appear that the proper conclusion is that the CB tape constitutes a better shield than does the "standard shield". This conclusion is supported by inspection of the values of table I in which improvements in both oil and impregnated paper by the presence of carbon black, while evident, are not particularly great.

Somewhat similar methods of applying carbon black for shielding purposes have been used both abroad and in this country in connection with rubber cables. The carbon black is incorporated in thin inside and outside layers of the rubber structure before vulcanization. In this country a prominent manufacturer incorporates the carbon black in an asbestos braid covering outside the main wall of rubber insulation. Obviously in these cases the chief advantage gained is protection of the rubber against attack by gaseous ionization both adjacent to the conductor and on the outer wall, that is, the function of the carbon black is solely that of a shielding layer.

W. B. Wiegand and **J. W. Snyder** (respectively Columbian Carbon Company, and Binney & Smith Company, New York, N. Y.): We have for some years been studying the colloidal properties of carbon black. Consequently we were very much interested in the data shown by Mr. Rosch since obviously his findings are the result of adsorption phenomena associated with colloids. It was felt that this institute would be interested in comparing Mr. Rosch's results with some observations which we have made in the course of our studies.

Carbon-black particles are very small. The latest electron microscope pictures, as shown in figure 7 of this discussion, which have just been released to the American Chemical Society indicate a particle size of less than 30 millimicrons. This degree of fineness means that one pound of carbon black has a surface area of some fifteen acres.

It is well known that surface is a controlling factor of adsorption, in fact adsorption data are used to measure total surface. In the case of carbon black another factor has a bearing; namely, a carbon oxygen complex on the surface of the particles. It is found that a normal carbon black with about 2.5 per cent of oxygen selectively adsorbs alkali as shown in figure 8. If however this oxygen be removed it is found as in figure 9 that the alkali adsorption decreases while the acid adsorption increases.

Table II

Grade	pH	DPG Adsorption Index	Per Cent Volatile Matter
High-grade, long-ink carbon (Peerless)	2.6	58.4	12.0
High-color carbons:			
Easy-wetting, high-color (Neo Mk. II)	2.8	97.2	14.0
Highest color (Royal Spectra)	3.1	96.0	12.8
Medium-color (Superba)	3.2	77.7	9.4
High-color (Super Spectra)	4.1	42.5	7.2
Rubber-grade carbons:			
Fine-particle, slow-curing (Mark II)	3.6	16.0	6.1
Standard-curing (Grade A)	4.1	10.1	5.1
Fast-curing	4.6	8.4	4.5
DeGussa CK-3	5.7	5.3	3.4
Nonimpingement carbons:			
P-33	8.2	1.8	0.4
Acetylene	8.2	4.1	0.6
Fumonex (or Gastex)	9.3	2.5	0.7
Deactivated rubber carbons:			
HS-421 (1.5 hr. to 1,500 deg F., 0.5 hr. at 1,500 deg F.)	9.0	5.1	1.1
HS-355 (2.5 hr. to 2,000 deg F., no further heating)	10.0	4.6	0.4
HS-335 (2.5 hr. to 2,000 deg F., 3 hr. at 2,000 deg F.)	10.6	4.8	0.2

Table III. Changes in Relative Electrical Resistance of Liquids Caused by Colloidal Carbon

Dispersion Medium	Relative Resistance (in Ohms) of Dispersion Medium	Medium + Carbon Black A	Medium + Carbon Black B
Water (distilled)	4,700	1,700	3,500
Ethyl alcohol (15%)	21,000	28,000	50,000
Methyl alcohol	670	800	21,000
Acetone	4,700	12,000	24,000
Butyl acetate	1,690,000	1,716,000	3,380,000
"Cellosolve"	21,000	80,000	130,000
"Cellosolve" acetate	1,000,000	260,000	3,500,000
Nitrobenzene	35,000	200,000	240,000
Pyridine	28,000	19,000	14,000
Ethyl alcohol (abs.)	10,000	15,000	15,300
Lacquer thinner	254,000	856,000	1,210,000
Phenyl cyanide	29,000	143,000	100,000
Aniline	300,000	340,000	320,000
"Hexalin"	210,000	250,000	250,000

The accompanying table II points out the availability of a wide range of carbon blacks varying in composition as shown by the volatile matter content, ability to adsorb diphenylguanidine, and pH. It will be seen that carbon blacks are available containing from 0.2 to 14.0 per cent of volatile matter. Incidentally, this volatile matter is really a measure of oxygen content. If the volatile matter driven off the carbon black be analyzed it would be found to be essentially oxides of carbon. Roughly 50 per cent of the volatile matter will be oxygen. The adsorption index varies from 1.8 to 97.2 while the pH covers the range of 2.6 to 10.6. All of these factors are considered in the everyday control of carbon-black production.

Carbon black strongly adsorbs moisture. The degree of moisture pick-up depends on the adsorptive properties of the particular grade of carbon. The highly adsorptive paint blacks pick up appreciable quantities of water as in figure 10. Moisture pick-up is somewhat of a problem to the carbon-black manufacturers who in many instances have to use special packages to eliminate moisture pick-up. That this moisture is very strongly held is evidenced by the fact that drying at 105 degrees centigrade does not remove all of the water. A toluol distillation moisture test will show about 1 per cent more moisture than the ordinary drying test.

Many organic liquids contain enough moisture and electrolytic impurities to lower the electrical resistance of those liquids. By filtering through carbon black the water is adsorbed and consequently the resistance of the liquid increases as shown in table III.

Not only do carbon blacks adsorb moisture, but they also take out electrolytes from solution. This phenomenon presents a prob-

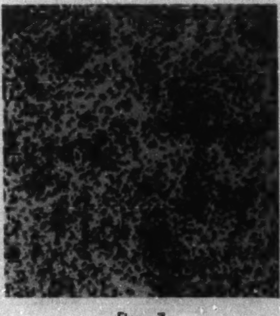

Figure 7

lem in the paint industry where carbon black adsorbs metallic drier and retards drying. In the case of naphtha solutions of cobalt naphthenate it is seen in figure 11 that depending on the particular adsorptive properties of the carbon black various amounts of metallic drier will be removed and made ineffective.

Whether it be water adsorption or electrolyte adsorption carbon blacks have been found as in table IV to improve transformer oils. The addition of 3 per cent carbon black to transformer oil followed by a filtering operation to remove the carbon black has been shown to effect definite improvement in the electrical breakdown of the oil. Improvements range from 40 per cent to 59 per cent.

Table IV. Effect of Colloidal Carbon on Insulating Oils

Carbon	Control Breakdown Volts	Breakdown After Treatment Volts	Per Cent Improvement
A.....3%	20,796	32,475	+56
B.....3%	20,796	29,075	+40
C.....3%	20,796	33,000	+59
D.....3%	20,796	31,575	+52
E.....3%	20,796	30,350	+46

Svedberg has shown that in the case of gold sols, the dispersion of gold shows a higher electrical resistance than the dispersion medium. In other words, the introduction of a conductor has resulted in lowered conductivity. A similar phenomenon is recognized in figure 12 when carbon black is added to a rubber insulating compound. The introduction of a conductor, carbon black, up to 10 per cent by weight on the rubber results in higher resistivity and higher electrical breakdown.

It is hoped that this short review of some of the adsorptive properties of carbon black will throw further light on the results reported by Mr. Rosch.

Thomas F. Peterson (American Steel & Wire Company, Worcester, Mass.): I find it difficult to reconcile certain impressions gained from a study of the paper presented by Mr. Rosch with others gathered from the specification of the Rosch Patent No. 2,102,129, referred to in his bibliography.

Considerable data has been presented to show marked improvements in cable samples and models when carbon-black paper is employed next to conventional electrodes (conductors and sheath). In the absence of more conclusive tests, I would attribute these improvements to three functions of the carbon:

1. Shielding—either full or semiconducting shielding.
2. Provision of fairly inert electrodes at which there is less tendency for soap formation, etc.
3. Adsorptive properties.

Moreover, I would weight the importance of the first two much more than the third.

Unfortunately, the test results presented do not allow of any specific discriminations between the three effects. If, for example, the conductivity of the carbon tapes had been given, and had been varied over a fairly wide range, while other characteristics remained constant, we might have had something indicative of the importance of the shielding function of the carbon. On the other hand, if, with constant conductivity, the adsorptive properties had been varied, the importance of this characteristic would have been brought into full relief.

The results shown in table II and in figures 1, 2, 3, and 10 can best be explained by shielding action of the tape. Results such as those shown in figure 8 can easily be explained by shielding action, the inertness of the electrode in the case of the carbon tape, and the fact that carbon tape replaces the paper tape that usually shows the maximum change in power factor during aging period. Moreover, figure 6 shows a remarkable improvement in aging characteristics for all models, regardless of the type of carbon employed in the CB tape. Certainly, there is very little to justify the argument that the improvement increases with adsorption index, since cables using carbon with adsorption indices less than 20 show up better than those having values of 24, 57 and slightly poorer than those having values of 75 and 95.

The patent referred to above is quite specific in attributing the improvement in the cable to the adsorption of gases, etc., by carbon. The statement is made that certain "blacks" are to be definitely avoided, since they actually injure the cables. Perhaps Mr. Rosch can reconcile these points with the data shown in figure 6, and can indicate the relative importance of shielding effect, inertness of electrodes, and adsorption.

J. C. Balsbaugh (Massachusetts Institute of Technology, Cambridge, Mass.): The results as presented show a very definite improvement in the performance characteristics of impregnated-paper cable insulation when carbon-black paper tapes are used in proximity to the electrodes. It is therefore of interest to attempt to evaluate the reasons for the improvements found.

It would seem logical to attribute these to two effects: (1) the adsorptive effect of the carbon black on removing oxygenated or loss components from the insulation, and (2) the shielding effect. The first one of these would account for the decreases in power factor observed; and the last one, the improvement in breakdown strength. On the basis of past experience it would not be expected that the removal of loss components from the oil would substantially improve the breakdown strength. With respect to the shielding effects of the carbon-black tapes, it might be presumed that the improvement is not only due to smoothing out such irregularities as might exist in the metallic conductor but also in substituting for the metallic conduc-

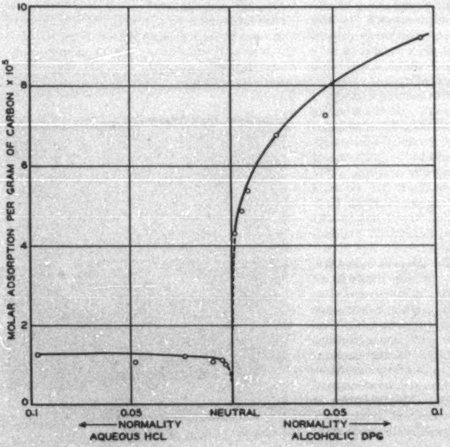

Figure 8 (left). Selective adsorption isotherms—acid (HCL) versus alkali (DPG)—standard rubber carbon

tor an electrode consisting of a "semi-conductor."

In his figure 7 Mr. Rosch shows the improvement in power factor of unaged cable samples when using carbon-black tapes as given in his table III. Since the carbon-black tapes following impregnation adsorb loss components throughout the insulation wall, principally by diffusion, it is somewhat surprising that this effect would be evident immediately following impregnation. It would be expected that impregnation of the "normal insulation" in a carbon-black paper cable would be at least partly due to oil passing through the carbon-black tapes. Thus in this case the oil would receive the equivalent of an additional refining treatment. This latter effect might account for most of the improved power factor shown immediately following impregnation. This effect might be checked by impregnating a type CB cable and another cable without carbon-black tapes with an oil that had previously received a filtering and contacting with carbon-black tapes and then making power-factor measurements immediately following impregnation of these two samples.

Andrew Gemant (The Detroit Edison Company, Detroit, Mich.): Up to now it has been thought that the carbon-black paper had essentially the role of shielding the conductor, but from the present paper it appears that adsorption processes also have a certain role. I am, however, not quite convinced of the importance of adsorption in this case. The test described in the report, using smooth conductors instead of stranded ones, is not quite decisive in that paper does not adhere very well even to smooth metal, while it adheres well to the carbon-black paper; thus the carbon-black paper probably eliminates ionization even in this case. A possible test to decide the main issue would be the following: Remove the CB paper from a cable after a prolonged test and compare its adsorptive index with an unused CB paper by using some organic acid or dye. If the carbon really has adsorbed as much material, as assumed, then it should be in a fairly saturated state, and its further adsorptive power for similar products must be considerably diminished.

Herman Halperin (Commonwealth Edison Company, Chicago, Ill.): As stated in this paper, the Commonwealth Edison Company has been actively interested in the Type CB cable. In our aging tests, the Type CB cable with reduced insulation thickness performed better than belted-type cable with standard insulation thickness, as indicated by low and practically constant power factors and ionization factors and by the absence of visible deterioration of the insulation after the test.

The need and, consequently, the magnitude of the cleansing action of carbon tapes will vary with variations in manufacturing processes, in materials, and in kinds of cable. Perhaps, carbon tapes will also become of interest for oil-filled cable.

For solid-type cable the main insulation problem is to suppress ionization. Carbon-black tapes seem to be beneficial in this respect mainly by reducing stress concentration at the stranded conductors, as indicated by a comparison of figures 5 and 6 of the paper.

Apparently, carbon-black paper is beneficial in absorbing some of the products of deterioration, but it probably will not absorb all of the hydrogen which would be liberated due to severe ionization. In figure 12 the increase in power factor after about 345 cycles of the aging test was followed by an increase in minimum pressure which might have been due to such liberation of hydrogen. This increased pressure persisted for the remainder of the test.

We are wondering whether in some cases the carbon-black tapes could be the only shielding over the insulation in three-conductor cable. Usually, however, metallic shielding will be desired also to reduce the probability of having failures involving more than one phase of the three-phase circuit.

As brought out in R. W. Atkinson's article "Load Cycle Aging Tests," in the April 1940 issue of *Electric Light and Power*, the General Cable Corporation also has

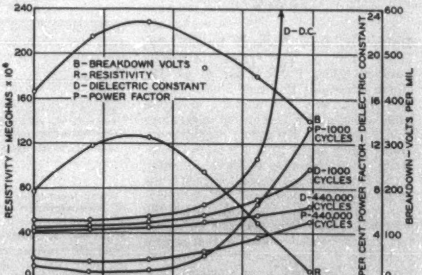

Figure 12. Effect of colloidal carbon in 40 per cent rubber insulating compound

been making some experiments and improvements in cable. According to Mr. Atkinson, these improvements include not only the use of conductor shielding but also changes in paper and in compound. We have also made some accelerated aging tests on such three-conductor, shielded cable with reduced insulation thicknesses. Again we have found that the insulation was perfectly stable throughout the tests, in contrast with some varying degrees of deterioration found in tests on belted-type cable.

With these demonstrations by the manufacturers and by our test data, it definitely appears that the total required insulation thicknesses for shielded-type, three-conductor cable can be safely reduced from the recommended thicknesses in the AEIC Cable Specifications. The Commonwealth Edison Company has placed orders on an experimental basis with each of these two manufacturers for 500,000-circular-mil, three-conductor, shielded cable for 12-kv operation, with 18 or 20 per cent less total insulation than the standard thickness of 172 mils. Economically, the shielded cable with reduced insulation thicknesses are competitive with the standard belted cable. Technically, it is better from the standpoint of dielectric stability, and it appears to have a small advantage in the way of less temperature rise for a given loading. Furthermore, for a given diameter limitation as set by existing ducts, a larger conductor size may be used as a result of these recent developments.

I understand that some of the other manufacturers have begun trials to determine how much the insulation thickness of their three-conductor, shielded cable could be reduced without impairing the stability of the insulation. In some cases they, too, are considering special constructions. We have already made arrangements with some of those manufacturers to obtain samples for tests like those described for the two manufacturers mentioned above.

Those of us who have followed cable matters closely in recent years have come across a large number of special types of cables other than the solid-type cable. Also, it has developed in the minds of some people in this country that solid-type cable has distinct limitations and hazards and that its use should be limited to 33 kv, or 27 kv, or even less. Some thought that all of the appreciable improvements in solid-type cable had been made—that there was nothing further to do. These recent developments have definitely improved the quality and useful range for solid-type cable.

Hubert H. Race (General Electric Co., Schenectady, N. Y.): There are several questions which I should like to ask Mr. Rosch concerning this very interesting paper. First, were the author's miniature cable samples kept completely oxygen-free during the runs at 100 and 85 degrees centigrade, which lasted 10 and 20 days respectively? The reason for asking this question is that I think the specimens described in the author's table II must have contained oxygen or oxidized oil. The evidence for this statement comes from our tests on miniature cables[1,2] sealed in glass so that oxygen is eliminated. Specimens 202, 212, and 243 were 0.065 inch thick using standard cable paper and standard cable oil. They were given daily heat cycles with a maximum temperature of 60 degrees centigrade. The post-mortem power-factor measurements were made at 60 degrees centigrade. The voltage gradient on these specimens was much higher than that used by Mr. Rosch, being roughly 350 volts per mil for the first 150 days and 450 volts per mil thereafter. The major difference between these specimens was that the oil used in No. 202 was preoxidized 96 hours at 115 degrees centigrade in an open air oven, and in No. 243 the paper was shrunk into the strand spaces on the inner electrode,[3] thus reducing the maximum potential gradient in the oil spaces at the electrode surface and preventing ionization at the test voltage.

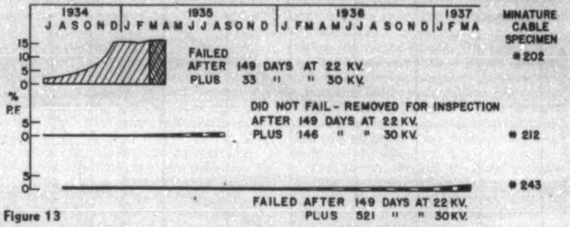

Figure 13

The accompanying figure 13 and table V show the life histories and post-mortem radial-power-factor measurements on these three specimens. From such data we have concluded that if oxidation and ionization are both eliminated, chemical deterioration is very slight even after nearly two years operation at very high gradient.

This last statement leads to my second question; namely, were the miniature cables for which data is given in Mr. Rosch's table II immersed in oil during the high voltage tests or were they allowed to drain so as to accentuate ionization effects? In research work we often impose experimental conditions which are quite different from practice in order to accelerate specific effects. This is perfectly legitimate as long as the conditions are stated so that the causes of the effects will be easily recognized. In the absence of either oxidation or ionization in voids it is difficult for me to account for the high power factors quoted in Mr. Rosch's table II.

My third question is concerned with the permanence of the benefit derived from using the limited amount of carbon black which can be included in a few tapes in a cable in long-time service. If long-time deterioration in such cable results from a slow but continuous leakage of oxygen or oxidized oil from the joints, will not the absorbing property of the carbon black soon become completely saturated so that further purifying action is negligible and the effect of the presence of the carbon black is simply to provide an initial period of as yet unknown duration, in which oxidation products will not cause an increase in the power factor of the cable? Furthermore, would it not be better to keep the oxidation products out in the first place by careful manufacturing, installation, and operating procedure?

this improved type of cable as determined from accelerated laboratory tests may necessarily obtain in actual operation, the Consolidated Edison Company of New York, Inc., has decided to install some of this cable and obtain experience in the field with it.

In figure 12 of the paper, the data indicates that standard shielded cable continued to show loading pressure changes from below atmospheric pressure to pressures above atmospheric on each load cycle up to the end of the tests, while the type CB cable changed from this type of characteristic to one essentially of changes in pressure above atmospheric pressure even on the cooling cycle after the cable had been under test for a considerable period of time. Is this a typical characteristic on type CB cable and if so what is the author's explanation of the phenomenon?

J. F. Calvert (Northwestern Technological Institute, Evanston, Ill.): I would like to ask the author if he would make just two or three further comments concerning his very comprehensive investigation:

First, would he show by a numerical calculation the length of time that the carbon black can be expected to be effective as an anti-oxidant; and would he also state what the "normal" operating conditions are assumed to be for this calculation with regard to initial oxygen present and that oxygen which may get into the cable during service?

Second, is there data available to show the relative amounts of oxidation occurring at the electrodes and toward the middle of the insulation for the temperature, frequency, and voltage gradients employed in the tests which he reports here. In this connection, would there be any application for the methods described in the paper "A Method for Detecting the Ionization Point on Electrical Apparatus" which Mr. G. E. Quinn presented at the 1940 AIEE summer convention in Swampscott, Mass.?

E. A. Hauser (Massachusetts Institute of Technology, Cambridge, Mass.): The improvements in overcoming insulation instability as just reported by Mr. Rosch are bound to create considerable interest among electrical engineers. For them the actual data obtained in comparative tests will be most significant. From the point of view of the colloid chemist or physicist it is the principle of Mr. Rosch's work which is of primary importance. His contribution is to the best of my knowledge, the first one which applied typical colloidal phenomena to high-voltage insulation, thereby opening an entirely new field for theoretical and applied colloid chemistry alike.

Mr. Rosch attributes the beneficial effect of the carbon black to a purifying effect and the retarding influence on the formation of deteriorating bodies. Both effects must unquestionably be the result of adsorption. It is a well-known fact that so-called adsorbent carbons are used in the clarification of oils, sugar solutions, etc. The latter effect is presumably due to adsorption of oxygen present or formed in the oil, thus preventing excessive depolymerization.

From a colloid chemical point of view an answer to the following questions would be of extreme interest. They should prove of equal value to the electrical engineer interested in furthering this remarkable development.

1. Ascertain on which of the two effects the influence of the carbon actually depends.

2. Ascertain if the phenomenon is specific to adsorbent carbon or if other known adsorbents, like silica—or alumina gel, activated clays, etc., could be substituted.

3. Mr. Rosch speaks only of activated carbon or carbon black of the adsorbent type, without giving more details as to source and properties. From test 5 of the manuscript I infer that Mr. Rosch refers to "channel blacks" only. (Obtained by incomplete combustion of natural gas.) This assumption is further substantiated by a review of the literature cited by Mr. Rosch. If experience with other truly activated carbons, as for example, "Norit" have not yet been carried out, this ought to be done, because the channel blacks are far less active than activated carbon made from vegetable charcoal.

E. F. Nuezel (Cincinnati Gas & Electric Company, Cincinnati, Ohio): As outlined in this paper based on commercial orders and laboratory tests, the comparative tests indicated that the use of carbon black has a decided inhibiting effect on cable dielectric deterioration. It is interesting to note in these tests the comparison between the insulation stability of carbon black versus standard belted when the carbon-black is applied solely on the conductor and no carbon-black paper is present on the outer conductor layer to provide shielding effect. While the report does not give sufficient data to determine the effect of the inner carbon-black tape alone as against both the inner and the outer applications or carbon black, it appears evident from tables III and IV that the application of the inner tape alone effects a considerable improvement in the dielectric. It is believed that if appreciable practical results were obtained it would be a very worth-while move to utilize the carbon black on belted cable as there are still many places where it is advantageous to use this type of cable.

The use of carbon black should no doubt result in the use of thinner walls of insulation as based upon tests made by the Commonwealth Edison Company on 13,000-volt cable insulated with 130 mils of total paper instead of the standard 172 mils. This reduction in wall thickness will result in smaller cable diameters which in turn will result in lower sheath duties because of the reduction in oil volume and also reduced hoop stresses in the lead sheath. This is important because the general experience indicates that progress in lead sheath extrusion has not kept pace with the improvement in the dielectric.

It would also appear that the purifying effects of carbon black as used for solid-type cable could be applied with equally good results to oil-filled cable. There is little doubt that the use of carbon-black paper will increase the useful sphere of solid-type impregnated-paper insulated cable. Its performance in commercial installations over a period of time will dictate the upper voltage limit.

F. W. Nimmer (Ohio Edison Company, Akron, Ohio): The development of the type CB impregnated cable is especially unique because of its simplicity. We have all known for a number of years that the insertion of two plates in an insulated medium will uniformly distribute the potential gradient between the two plates. We had been of the opinion that we had accomplished this result in the type H cable, however, it seems evident from the test data presented by Mr. Rosch that substantial improvements can be obtained with the addition of several layers of carbon-black paper. The very marked improvement in power factor and in the cyclic aging characteristics, plus the improved operation of the various layers of paper tape, as indicated in figure 4, seem to point to the definite conclusion that this new type of cable should be substantially superior to previous types developed.

Many times an improvement results in complications in installation, preparation of joints, etc. Fortunately, this development of CB cable does not incur these handicaps, and therefore provides additional usefulness and keeps to a minimum the disadvantages.

E. W. Greenfield (Anaconda Wire and Cable Company, Hastings-on-Hudson, N. Y.).: This discussion deals only with the adsorption or purification phase in the mechanism of carbon-black protection to impregnated-paper cable. Elimination of strand and other stress concentrations by means of the shielding action of the carbon black has been amply demonstrated in the formal paper. It may be of interest, however, to note that the action of strand-stress concentrations on impregnated paper has been most carefully studied with relation to field configuration. Also the range of carbon-black paper electrical resistance required to effectively eliminate such concentrations has been determined and probably will be published at some future time.

A. Behavior of Carbon Black as an Adsorptive Agent

1. *Definition of Adsorption.* In simplest terms an adsorptive medium is one which operates to preferentially concentrate and retain upon its integrated structure specific gases or liquids with which it contacts. This essentially means a type of loose fixation (from the chemical standpoint only) of one substance on the surface of another. Highly adsorptive substances are those which possess these fixation properties to the greatest degree as a result of their large free surface energies and the polar nature of the surfaces.

2. *Identification of Carbon Black as a True Colloid.* Carbon black, properly termed colloidal carbon, is the most highly adsorbing form of carbon. Produced by the careful impingment of a natural-gas flame against a cool surface, the colloidal carbon is nonoily, possesses jet blackness, and is characterized by extremely small particle size.

X-ray diffraction patterns indicate that the five-atom molecular building unit of carbon is completely intact in colloidal carbon, but the axes of the units are scattered heterogeneously so that there are no regular planes of densely packed atoms as, for example, exists in graphite. This anisotropic form of structure is indicative of the ultimate in dispersion with regard to the colloidal state.

Particle size of colloidal carbon is found to vary over wide limits in the range from less than 25 millimicrons to over 200. Con-

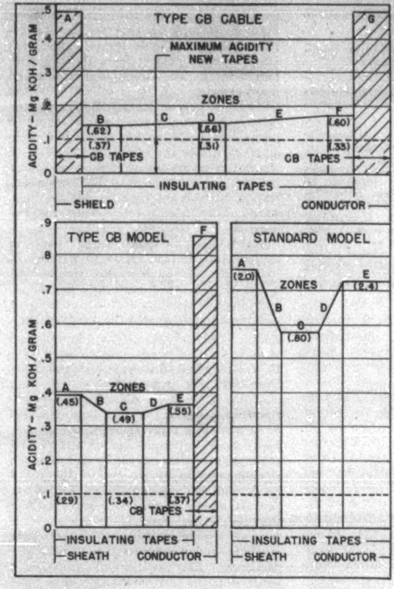

Figure 14. Acidity distribution of cables and cable models before and after aging

Bracketed figures are per-cent power factor taken from radial-power-factor tests

sidering these exceedingly small values of particle diameter and their degree of dispersion, it is evident that we are dealing with a true colloidal dispersion—detectable only by means of the ultramicroscope.

3. *Amount and Selection of Adsorption.* The integrated surface of such a disperse colloidal material as carbon black is relatively enormous. One cubic inch of solid carbon black has a surface area of six square inches. If the cube is subdivided so as to produce carbon particles having each a diameter of 1 micron (0.00004 inches), the total surface developed becomes 160,000 square inches, and if further subdivision is made to particle diameters of 100 millimicrons, the total integrated surface jumps to almost 2,000,000 square inches.

Other things being equal, the adsorbing power of a colloidal adsorptive depends upon its total surface free energy which is simply the same as the total surface developed by all the minute dispersed surfaces making up the material. For colloidal carbon the total free surface available for adsorption depends upon particle size, number of particles and their degree of dispersion. As we have seen above, there is thus ample explanation of the immense adsorption activity of colloidal carbons.

The *degree* of *selectivity* of adsorption depends upon the polar nature of the surfaces involved and the interfacial tensions between sorptive and sorbed materials. Colloidal carbon normally possesses a surface oxygen complex (C_xO_y) which influences this selectivity of adsorption to the greatest extent. Acidic or alkaline substances can be preferentially adsorbed depending upon treatment of the oxygen complex existing on the particle surfaces. High oxygen complex surfaces on the black are accompanied by low pH values and considerable preference for adsorption of basic material. Deactivated surfaces (caused by heating in absence of air) characterize the black with pH values over 7, low volatile content and definite preference for the sorption of acidic substances.

B. Fixation of Carbon Black in Cable Paper

1. *Incorporation of Colloidal Carbon Into Paper.* Colloidal carbon is incorporated into paper during the first operations in the manufacture of the paper. To the viscous slightly alkaline slurry of water and pulp in the beaters is added the proper amount of colloidal carbon. Continuous beating here and subsequent grinding action through the Jordan machines provide exceedingly efficient dispersion of the black and is actually in accordance with the most advanced ideas known for the preparation of complete dispersions.

2. *Stabilization of Colloidal Carbon in Paper.* Stabilization of the colloidal black within the structure of the paper is automatically effected during the course of the pressing, drying, and calendering operations incident to the formation of paper from pulp. Microscopic examinations show the colloidal carbon as an apparent continuous phase dispersed between, upon, and within the cellulose fiber structure and strongly bonded thereto. Properly prepared carbon black paper is absolutely nonmarking and can be boiled for 24 hours or more in water or in light oil without showing the slightest trace of carbon particle loss.

3. *Range of Control of Finished Carbon Black Paper.* It is thus noted that the two most important conditions for the greatest realization of the enormous inherent adsorbing power of the colloidal carbon, viz., complete dispersion and stabilization of dispersion, are fulfilled by carbon black paper.

By destroying the cellulose and properly filtering the resultant gel, one readily determines carbon content or "retention" in the carbon black paper. Advanced technique of manufacture indicates less than 30 per cent loss in percentage of carbon black to wood pulp from beater to finished paper. Considerable control in the important properties of the finished carbon black paper, i.e., density, air resistance, strength, electrical resistance, adsorbing power, etc., may be exercised by choice and amount of colloidal carbon and variation in the paper-making constants.

To the present, many types of colloidal carbon have been studied as incorporated into various types of pulps and manufactured to various paper specifications. Evaluation of these carbon black papers for paper cable application have been based on (1) insulating oil purification tests, (2) cable model accelerated life tests, (3) AEIC cold bend and high voltage time tests on full size cable, and (4) long-time cyclic aging tests on full size cable. *In most cases selections based upon the electrical tests have justified selections based upon colloidal theory.*

4. *Adsorption Properties of Carbon-Black Paper as Related to Purification of Insulating Oil.* Although having low pH values when measured in hot aqueous sludge, the high quality, low particle size colloidal blacks undergo surface changes in the process of incorporation into paper and subsequently into cable. In the beaters admixed with wood pulp and controlled water, the pH of the slurry is generally somewhat over 7 (slightly alkaline) and the finished carbon-black paper is essentially neutral. After application to cable the carbon-black paper is heated in the almost complete absence of air probably causing further deactivation of the surface oxygen complex on the carbon particles so that the final carbon-black paper is generally in a condition to preferentially adsorb acidic material.

Many tests in addition to those reported in the formal paper have demonstrated the substantial beneficial effects resulting from the adsorptive properties of carbon-black paper. In the type CB cable design, deterioration products generated within the cable oil due to simultaneous actions of heat and electric stress, further aggravated by paper catalysis and possible presence of oxygen, are preferentially adsorbed upon the surfaces of the carbon particles on and within the paper structure. Hence the organic acids, esters, organic metals and other aqueous electrolytic phases become distributed through and held within the carbon-black paper where they have no influence upon the cable's over-all dielectric behavior since they are effectively shielded from the electrical field by the high-conductivity particles to which they are adsorbed.

Two typical examples of the way in which carbon-black paper adsorbs acidic material during aging of impregnated paper cable at high temperature and stress are given in the accompanying figure 14. The data in the upper portion of figure 14 are for a lead-covered, three-conductor, 350,000-circular-mil, type CB cable having 130 mils total wall of impregnated-paper insulation, carbon-black tapes being present at both sheath and conductor. This cable was cyclically aged at a utility laboratory and analysis of the insulation made prior to and after aging. Data given in the lower portion of figure 14 pertain to a cable model electrically aged under advanced conditions of stress and temperature. Due to the comparatively small wall of insulation, 65 mils, this cable model contains carbon black only at the conductor. The data in each case show the radial distribution of acidity before and after aging for selected zones through the insulation wall. The power factor values associated with these zones are given by the bracketed figures.

The data on the cyclically aged cable (upper, figure 14) shows the carbon black tapes to contain more than three times the acidity of the insulating tapes, sheath and conductor carbon-black tapes being of equal acidity. The distribution of acidity through the insulating wall appears to be constant at a moderate value. The dashed horizontal line represents the *limit* of acidity in freshly impregnated carbon-black and wood-pulp cable papers (generally, values are about one-half this maximum). Hence we note that the cyclic aging tests brought about an increase in acidity of the carbon-black tapes by about ten times and only three times for the insulating tapes. It is concluded that the carbon black accounts for the difference by acting as a continuous adsorbing medium for the acidic deterioration by-products generated within the cable during aging. Radial power factor values are in agreement.

The lower portion of figure 14 again demonstrates the protective action of carbon-black paper. Here the acidity data is more complete. After aging the acidity of the insulation wall is found to have increased between three and four times its initial value, whereas the carbon black is found to have nine times its original acidity. On the other hand, an identical model unprotected by carbon black has an acidity increase *throughout the insulation wall* of between seven and eight times after the same aging. Radial-power-factor values also correlate excellently.

C. Design Considerations of the Type CB Cable With Reference to Oil Purification

The two important factors involved in design of the type CB protected cable are shielding of stress concentrations and continuous purification of the saturant. These considerations affect selection of the colloidal carbon, the desired properties and amount of carbon-black paper and the positioning of these papers within the cable structure. A satisfactory carbon-black paper must have properties which accomplish both its primary objects.

From the standpoint of oil purification, we are interested in the adsorption activity of a given carbon-black paper and the total carbon surface available for adsorption in any given cable. Carbon-black papers may be produced which have a maximum selective adsorbing activity for insulating oil deterioration products, i.e., organic acids, esters, and water. For a given carbon-black paper, one readily computes the adsorbing carbon surface area per inch of tape from knowledge of: (*a*) carbon particle size, (*b*) total number of carbon particles per unit volume of paper, and (c) dispersion of carbon particles.

As an example of the tremendous integrated surface of carbon incorporated into standard carbon-black paper, we note that using a colloidal carbon of 40 millimicrons particle size, each one inch length of $^3/_4$ inch by 0.005 inch tape having a gross area of only 1.5 square inches contains approximately 650 square inches of carbon surface. The amount of carbon black incorporated within a cable is subject to design and control and will naturally vary with the size and type of construction.

Philip Sporn (American Gas and Electric Service Corporation, New York, N. Y.): One of the compensations of working in a field that is as rocky as is the engineering field by and large, is the turning up on too-rare occasions of a paper on, or the coming across of a description of a new idea, a new view of an old phenomenon, or the logical working out of old and known principles to new uses. The paper of Mr. Rosch's illustrates perfectly the last of these occurrences.

The use of carbon in oil purification has been known for some time; so have the reasons behind insulation instability. It remained only for someone to put these ideas together in a workable and usable form and to bring about the improved cable described so well by the author. These improvements are logical and are well brought out by such data as figures 3 and 5, and most strikingly by figures 10 and 11 of Mr. Rosch's paper. It is to be hoped that this work will be continued and the original idea developed to the fullest. The result ought to be not only more reliable cable but less expensive cable. In both of these directions some progress has been badly needed for a long time.

J. A. Peterson (The Commonwealth & Southern Corporation, Jackson, Mich.): Anaconda Type CB cable has been tested and found superior to the standard type especially for service voltages over 10,000 volts. Tests by one of the large operating companies have shown that this cable has a much higher impulse voltage strength than the standard constructed cable. Other tests have shown type CB cable has better power factor and insulation resistance characteristics. In view of these facts, it appears that it might be possible to reduce appreciably the present insulation thicknesses as standardized by the AEIC if this new type of construction is generally adopted by the manufacturers. In fact, one of the metropolitan companies is installing, presumably for trial, type CB cable for 28,000 volts grounded neutral with insulation thicknesses much less than the AEIC standards.

Would it not be desirable to also consider using type CB construction on low-voltage belted cables, that is, using carbon-black tapes adjacent to the conductors and expect that the impulse-voltage strength would also be materially increased and that insulation thicknesses in this range could also be reduced?

If this type of construction is desirable on paper cables, it should also be desirable on varnished cambric insulated cables. It might be possible to reduce the present IPCEA standards for insulation thicknesses of varnished cambric cable.

This type of construction should eventually reduce insulation thicknesses with a corresponding decrease in cost.

The development of Type CB cable is undoubtedly a big step forward in cable design. However, in our particular position, it appears that the most essential fault in IPLC cable has been susceptibility of the lead sheath to corrosion. Our corrosion troubles have not been due to loading since corrosion has been just as severe on lead covered control cables as on power cables. We would like to see corrosion tests made on various types of lead sheaths, such as so-called common lead, both pure and copper bearing, also "Asarco" lead, calcium lead, etc., to see if there is any appreciable difference in corrosion resistance between these various types of lead sheaths.

S. J. Rosch: Due to the similarity of a number of points raised by several contributors, they have been grouped according to subject and discusser, as follows:

1. Conductor shielding: R. W. Atkinson, W. A. Del Mar, G. B. Shanklin, L. G. Smith, J. B. Whitehead.
2. Adsorptive and purifying effect of carbon-black paper: T. F. Peterson, A. Gemant, L. G. Smith, W. B. Wiegand, J. W. Snyder.
3. Protection from metallic soap formation: T. F. Peterson, G. B. Shanklin.
4. Electrode contact and characteristics: W. A. Del Mar, J. C. Balsbaugh.
5. Test conditions and limitations: H. Halperin, H. H. Race, G. B. Shanklin, E. R. Thomas.
6. The type CB cable design: J. F. Calvert, E. A. Hauser, T. F. Peterson, H. H. Race.
7. Possible economic advantages of type CB cable: H. Halperin, E. F. Nuezel, F. W. Nimmer, J. A. Peterson, P. Sporn, E. R. Thomas.

1. Conductor Shielding

Judging from the several discussions, the concept of conductor shielding seems to be somewhat confused. It is variously applied to designate:

(*a*). The elimination of field concentrations due to electrode geometry

(*b*). The elimination of destructive discharges from metallic electrodes

(*c*). The short circuiting of possible void spaces that exist or develop between conductor and insulation

These conceptions are not necessarily compatible, and in addition require different constructions and properties of materials to be realized to the fullest extent. It so happens that pervious carbon-black tapes, when considered from the restricted sense of shielding only, have inherent properties which permit an optimum compromise for all the conceptions listed above. The type CB construction thus automatically contains the benefits of conductor shielding in its broadest sense, and *in addition*, operates as a continuous oil purifying means.

Test 4 was one of several conducted to separate the effects of conductor shielding from oil impurity adsorption in the carbon-black tapes. Since these were hand-wrapped models and unbent in any way, gross contact differences between the smooth polished cylinder and the insulating paper were certainly as good as between the carbon-black papers and insulating papers. Secondary contact differences do exist in favor of the CB construction. However, since neither model showed the slightest trace of markings or damage to the insulation, we conclude that this was a small factor in the test. In addition, acidity measurements not included in the paper, confirm the adsorption picture by disclosing the degree of activity of the carbon-black papers.

Question has been raised concerning the high-voltage time tests described in test 6. It is stated that the results of this test did not correlate with the quantity of carbon-black paper in the various cable constructions, and hence conductor shielding effects predominated in producing the excellent results. In these short-time tests at room temperature, oxidation phenomena are limited and it is true that ionization probably plays an important role. Hence, positioning of the carbon-black tapes had a bearing from the standpoint of conductor shielding in its most general sense as outlined above. Adsorption phenomena contributed to the excellent results by adsorption of gases and water vapor generated during the ionization. This can be confirmed by acidity tests of the individual tapes removed after test.

2. Adsorptive and Purifying Effect of Carbon-Black Paper

Type CB cable has been generally constructed with carbon-black tapes adjacent to both electrodes. No such tapes were used in isolated form within the effective insulating wall. The question as to whether cable oil can sufficiently contact the carbon-black layers in order to permit adequate adsorption of impurities and generated deterioration products seems to be answered by radial power factor and acidity distribution determinations after aging on both models and cables. These indicate effective control of the acidic material throughout the insulation wall. There is every reason to believe that under long-time conditions oil diffusion within the cable structure follows the usual laws of liquid diffusion in porous media.

Many of our model aging and cable tests have been supplemented by chemical analysis of the insulation both before and after the electrical tests. The evidence indicates that carbon black adsorbs acidic material avidly and that the extent of this adsorption is potentially enormous. In Greenfield's discussion, are given two examples of the results of radial power factor and acidity measurements on aged and unaged cable, which bring out the points discussed.

Contributory evidence on the adsorption properties of carbon black has been presented by several discussers who are primarily workers in the fields of colloidal carbon development and colloid chemistry. Much of the future development of the type CB cable will be guided by theory and practice acquired from these fields.

Most of the model tests described in the paper were carried out under advanced thermal and air-exposed conditions so as to accelerate oxidation products. Effectiveness of carbon black as an adsorptive agent is best demonstrated by tests producing those materials which it is desired to adsorb. We have shown conclusively the carbon-black tapes do adsorb the acidic products. Furthermore, the result of such adsorption is that the dielectric losses and free acidity in the insulation are maintained at a minimum. Material removed and held in the carbon-black tape structure no longer contributes to dielectric loss because it is not in the electric field.

Reference to figure 6 shows that models E5 and E2, having adsorption indices of 75 and 95, had *lower* power factor after aging than initially, which is the opposite of that obtained with the standard models and carbon-black models having lower adsorption indices. Surely this indicates that improvement increases with adsorption index. It may also be pointed out that similar tests on standard models reported by Whitehead have never shown an improvement in power factor after similar aging.

3. Protection from Metallic Soap Formation

It has been suggested that the carbon-black tapes confine metallic soaps at the region of contact between the copper and the carbon-black tapes. This seems to be reasonable since reaction of any formed hydrocarbon acids with the copper conductor takes place at the high-voltage region. Here the carbon-black tapes are in position to immediately adsorb and retain such products in a region shielded from the electric field.

It has been emphasized by one discusser that oxidation products such as organic acids, esters, soaps, water, etc. are not a problem in cable operation today and that gaseous ionization is the main problem. It is felt that this statement is not entirely substantiated by experience with both oil-filled and solid-type cable. It is also felt that the complete divorcement of oxidation effects from ionization destructiveness is not possible, the two being dependent and interrelated when solid losses reach a certain point. Excessive solid ionization is as destructive as gaseous ionization and although less frequent, becomes more and more a factor as better cables are produced and stresses and temperatures elevated. Adsorption of electrolytes produced in the oil as a result of oxidation reduces solid ionization. This function of carbon-black protection is particularly applicable to oil-filled cable design.

4. Electrode Contact and Characteristics

Under consideration of conductor shielding, it has been mentioned that conductor-to-insulation contact may have profound influence on cable properties entirely outside the question of geometry and maximum stress. Several points have been raised concerning the benefits accruing from nonmetallic ("inert") electrodes as well as the more perfect and intimate contact which carbon-black paper makes against insulating paper as compared with metal shielding tapes or smooth cylinders.

It is quite true that on theoretical grounds, a nonmetallic electrode possessing an appreciable electrical resistance can damp high frequency discharges much in the same way that any properly designed series resistor can damp the high frequency oscillating components of a circuit in ionization or other unstable equilibrium. In the case of the type CB cable, this series resistance is distributed but the effect should be the same.

The beneficial effects described above are inherently obtained with the type CB cable so that these are advantages in addition to those described in the paper.

5. Test Conditions and Limitations

The cable models were kept continuously in oil and free from contact with air or other gases. The oil in which these models were submerged for temperature control was exposed to air and hence deterioration greatly accelerated. The tests conducted on the models and cables show the differences that exist between standard and type CB cable under controlled conditions.

In test 8, the conductors were of the compact construction, both cables being manufactured under identical conditions. They were simultaneously dried and impregnated in the same tank and leaded in the same press. All the refinements of the most modern impregnating system were used to remove air and moisture. The treating procedure was controlled by routine electrical measurements on the cables. Every effort was made to remove all traces of impurities, and except for design, both cables were comparable as indicated by the initial characteristics shown in figure 9. Therefore, it is concluded that the changes in properties during the cyclic aging test were a result of the electrical stress and extremely high temperatures.

In figure 12, it is seen that the standard cable continued to show pressure changes from below to above atmospheric pressures on each load cycle, whereas the type CB cable changed from this type of characteristic to one of changes in pressure above atmospheric. With the data available at present, it is impossible to state whether or not this is an inherent characteristic of type CB cable.

Since all tests are comparative with standard constructions, it is obvious that the addition of other variables such as longitudinal migration would tend only to complicate the problem and the results.

6. Type CB Cable Design

The carbon-black paper we use *does not* contain rosin size or sodium abietate to hold the colloidal carbon in suspension. This paper, without the use of a binder was developed for use in type CB cable in order to avoid the corrosive effects such materials would have on the copper conductor. The adsorptive effect of carbon black is not peculiar to that material alone. Silica or alumina, activated clays, etc. could be used except that due to the dielectric nature of these materials, the adsorbed products would be acted upon by the electric field and thereby overcome the advantages gained by using a material which is both conducting and adsorbent. We have no data on the distribution of oxygen from the electrodes to the center of the insulation; however, a review of Greenfield's discussion will show the distribution of acidity through the insulating wall, which is a comparative measure of the distribution of oxygen. The amount of carbon black incorporated within a cable is subject to design and control and will naturally vary with the size and type of construction.

7. Possible Economic Advantages of Type CB Cable

The answer to higher operating temperatures and reduced insulation thicknesses with type CB cable will eventually be obtained by the various utilities investigating the economic advantages in a very practical way on their cable systems. There is little doubt that these investigations will show type CB cable to be more reliable and less expensive, as well as simple to install and splice.

The author takes this opportunity to thank all those who have contributed to this discussion for their encouragement, criticisms and helpful suggestions.

Modern Rail Transport

Discussion and author's closure of paper 40-122 by A. M. Wright, presented at the AIEE summer convention, Swampscott, Mass., June 24–28, 1940; published as an article in ELECTRICAL ENGINEERING, October 1940, pages 400–06; and reprinted in AIEE TRANSACTIONS, 1940, pages 1306–12.

D. R. MacLeod (General Electric Company, Erie, Pa.): The high cost of wayside equipment is one reason why the potential economies of electric operation cannot be realized on some railroads. In this country we have established high standards for wayside construction since we are always striving toward the ideal of 100 per cent reliable operation.

The figure given by Mr. Wright in his paper may prove to be high in some cases, but it emphasizes the great need for engineering study to reduce this part of the capital outlay. Very often we find that the traffic requirements are such that only $^1/_{10}$ locomotive is required per track mile. This means that the cost of the wayside equipment is usually the major part of the initial outlay for electrification.

Various attempts have been made to reduce the cost of the wayside equipment by electrical design methods. Among these attempts are the higher-voltage trolleys mentioned by Mr. Wright. All attempts along this line have been disappointing, because the cost of the wayside equipment is principally due to the cost of installation on a busy railroad. Work trains can work only for a fraction of the time that they are on the job, and construction must be carried on without seriously impeding traffic. Great improvements have been made in the methods of construction as a result of the installations which have been made during the last two decades. A great deal of the experience has been lost, however, because none of the projects have been continuous and it is not always possible to reassemble the skilled workers once they have been dispersed. Standardized construction will remove some of the engineering uncertainties so that less margin of safety must be taken not only in design, but also in contracting for the job. As the volume of electrification business increases it will become more and more possible to keep experienced gangs at work continuously so that the cost will be further reduced by the improved efficiency of the construction forces.

The added cost of the high-voltage transmission which parallels the low-voltage trolley and supplies power to it is a small part of the total cost of electrification. The use of a high-voltage transmission line enables large blocks of power to be transmitted at relatively low power factor with high efficiency and low voltage drop. Too high a voltage increases the cost of the substations more than necessary, while too low a voltage limits the capacity of the system and ultimately hampers the schedules that can be made by the trains. It is surprising what a small difference there is in the cost of the single-phase two-wire transmission lines having different transmission voltages, but with the same contact line construction. It should, therefore, be possible to standardize on one type of construction for all electrifications using the same system of distributing power.

E. W. Brandenstein (General Electric Company, Erie, Pa.): Mr. Wright's paper is a very comprehensive analysis of modern rail-transportation problems. There is no doubt but that long distance mass transportation can best be taken care of on rails. It is also evident that electric locomotives can handle long-distance high-speed mass transportation much more economically than any other type of motive power.

We have recently made improvements in electric locomotive designs which permit a horsepower ratio of 80 pounds of locomotive weight per continuous horsepower. In other words, it is practical to build a 2-C+C-2 passenger or freight locomotive weighing 480,000 pounds and rating 6,000 continuous horsepower. This not only cuts the weight horsepower ratio but also cuts the cost per horsepower. This locomotive will handle either freight or passenger trains with gearing for 90 miles per hour top speed. This universal engine permits transferring the motive power from freight to passenger service or from passenger to freight service depending on which type of traffic is experiencing a peak.

Mr. Wright refers to the advisability of going to trolley voltages higher than 12,000 to cut down the cost of substations. Our past record over a period of 10 years with 25-cycle substation transformers is almost perfect. It has been found unnecessary to duplicate transformers in substations. Single transformers located about 15 miles apart are adequate for most installations. This drastically cuts the cost of the steel work and reduces installation labor as well as eliminating transformers. On a two-track railroad the 12,000-volt substation costs total approximately from 10 to 20 per cent of the total roadside equipment, i.e., everything excepting locomotives. Our recent studies indicate that a higher voltage trolley ordinarily adds as much to the cost of the locomotives as it saves in substations. There is little object, therefore, in changing the established standard.

Mr. Wright's analysis of modern railway problems is very stimulating and indicates that further study should be made by railroad operating men to determine whether or not there is any motive power, other than electric, which will meet the demands of modern high-speed mass transportation. We, in the electrical industry, will be glad to meet that challenge.

Sidney Withington (New York, New Haven & Hartford Railroad Company, New Haven, Conn.): Mr. Wright's valuable paper discusses a number of highly controversial points of interest in both the economic and technical fields. There is no question that with the mechanical developments which have been brought about in the past few decades, the entire system of transportation is subject to drastic revision and much of the capital now invested in railroad facilities must be retired and written off the books, tragic though this may be; and much new capital must be made available to take care of developments in the interest of safety and efficiency. That the problem is not new is indicated by an editorial in the *American Railroad Journal* of June 30, 1832, more than 100 years ago, which concluded with the following comment: "It will be a little singular if *steam carriages on common roads* should treat the railroads with as little ceremony as the railroads are treating the canals."

Opportunity is taken to point out a few minor items which Mr. Wright has mentioned upon which some exception may be taken. It is agreed without qualification that Mr. Wright's contention is entirely logical that there are undisputed points of superiority of electric motive power as compared with steam, and that electric locomotives may be found to be the solution of certain problems in railroad operation.

In connection with the loss of freight traffic to the highways, there has been much discussion as to the advantage of revision of railroad rate structures, and it is quite possible that a rational revision may tend to bring certain kinds of traffic back to the railroads, though without question certain kinds of traffic are permanently lost to the railroads.

With regard to railroad consolidation, which Mr. Wright suggests as a solution of the railroad problem, it is probable that large scale abandonment through consolidation cannot in general be brought about satisfactorily, since each existing line serves its own community, and the abandonment of its tracks would leave the community in many cases without service. For instance, it is not conceivable that the Pennsylvania Railroad between New York and Chicago could be abandoned and its traffic transferred to the New York Central, because the latter does not cover the intermediate territory served by the Pennsylvania.

Mr. Wright mentions a figure of 60,000 gross ton-miles per train-hour as a measure of railroad operating effectiveness. It may be pointed out in this connection that in 1939 only four railroads in this country achieved a record of more than 50,000 gross-ton-miles per train-hour, (the average being 32,808) and that these four railroads are all coal or ore roads with uniform heavy specialized freight tonnage. Mr. Wright also says that trains are "easily capable of removing freight from a terminal at the rate of 10,000 net tons per hour. At 30 tons per car, a figure of 10,000 net tons means three trains of 111 cars each must leave each hour. This is a possibility, but not an easy performance for continuous operation.

Mr. Wright mentions "freight and passenger trains at hourly intervals . . . 24 freight and 24 passenger trains per day in each direction" as the maximum traffic on a hypothetical two-track railroad, and assumes that this theoretical capacity on account of "incidental delays and track limitations" would be cut in half. The actual 24-hour capacity of a railroad of this type would usually be sadly limited by traffic demands. Under present conditions it is to be noted that people insist on traveling over the railroads at such times as they want to travel, or not at all; and that freight in increasing degree must be handled at the convenience of the shippers or consignees. This means in general that railroads are subject to heavy loads during a few hours of the day and are quite deserted for the rest of the time because there is no business offered. Mr. Wright's estimate of the capacity of his hypothetical railroad, however, is very conservative as to weights of trains and locomotive capacities. He mentions 3,000-ton freight trains and 450-ton passenger trains. Many railroads now are regularly operating, by steam locomotives, freight trains up to 5,000 or 7,000 tons, and occasionally much higher, and normal modern passenger trains often may run to 1,500 tons or more. Speeds higher than 40 miles for freight trains and 70 miles for passenger trains also are common, even with steam operation. It is generally true that the limitation in most cases is set in freight car capacities and track restrictions, rather than in those of motive power. There is some question in this connection as to the practicability of increasing the capacity of rolling stock in the form of larger freight cars, as Mr. Wright suggests. Traffic may not be offered in sufficiently large units to utilize effectively the added capacity. There is, for instance, a general trend away from the older 70-ton hopper cars, and 50-ton cars of this type are more popular today on this account.

It is possible that Mr. Wright's analysis of cost of electric locomotives as compared with steam locomotive costs for equivalent work, may be criticized, and also his estimate of the relative availability for duty of the steam locomotive at 50 per cent. There is still an important spread in motive-power costs as between steam and electric power, and steam-locomotive operation has made remarkable progress during the past few years as regards length of run and availability. Traffic demands now often being at relatively low load-factor, much of the steam-locomotive outage for boiler washing and other maintenance can be matched with the valleys in traffic demands. A record recently quoted (*Railway Mechanical Engineer*, June 1940) refers to a freight locomotive which operated in 31 days a mileage of 9,700, changing crews 79 times in this period without dumping the fire.

Mr. Wright mentions the cleanliness of Diesel-electric locomotives as compared with steam. The development of modern air-conditioned passenger equipment, with sealed windows, forced ventilation, and filtered air, has changed the situation in this respect of recent years so that in the modern train, passengers often do not know nor care whether the motive power is steam or not.

Another small point in Mr. Wright's paper to which some exception can perhaps be taken, is that the modern coach weighs one-half as much as former designs of all-steel passenger cars. When modern equipment is considered, a weight reduction of perhaps 30 per cent is more accurate as a general estimate.

Mr. Wright's analysis of electric locomotive efficiency in weight and in power production is of interest. The low thermal efficiency in the conventional type of steam locomotive is more fundamental than merely "imperfect combustion." The high exhaust pressure of steam is even more vital, and it is not to be expected that a thermal efficiency of anything like 20 per cent, which Mr. Wright mentions, can be obtained without radical change in boiler and furnace design, which will be necessary with increase in pressure, and in the utilization of steam. The application of hydroelectric power, or of high central-station thermal efficiency now available, and the very considerable concentration of horsepower readily available at the head-end of a train by the use not only of a single electric locomotive unit, but of multiple-unit equipment, is a recognized advantage of electric locomotives as compared with steam, and as trains increase in weight and speed, the electric locomotive is an obvious solution of many of the problems facing the railroads if its use can be brought about without undue correlated costs.

P. A. McGee (Electromotive Corporation New York, N. Y.): I believe Mr. Wright has very well presented the railway problem in both its economic and important technical phases. He has rightly stressed the fact that railways are primarily suited for mass transportation, and in this connection employed the most satisfactory transportation unit of ton miles per locomotive hour.

Finally, Mr. Wright considered a hypothetical case where the desirability of obtaining a 6,000-horsepower locomotive was indicated, and on this basis, a case for railroad electrification is considered.

I do not propose to go into the technical details of the various types of locomotives available for rail transport, but I feel that Mr. Wright, in order to justify the title of his paper "Modern Rail Transport", should have devoted more space to the question of Diesel locomotives.

As an indication of the modern trend in rail motive power, it should be recognized that the steam power available today is the result of a century and a quarter development. Electric locomotives were first applied a little over 40 years ago. The Diesel locomotive as a serious competitor in the rail transportation field dates back about five years. Today we have in the United States approximately 45,000 steam locomotives which are more or less interchangeable on the various lines of our rail system. After 40 years of rail electrification development, we employ today not over 850 electric locomotives of 100 tons or more and most of these locomotives are designed for some specific traffic problem, and very few, if any, of these locomotives, can be satisfactorily transferred from one electrified system to another. There are today some 750 Diesel switching locomotives of 100 tons and over, together with approximately 130 Diesel road units in service in the United States. These Diesel locomotives are interchangeable between railroads, and as a matter of routine operation, pass over as many as four or five lines. Due to the extensive use of these Diesel locomotives and the large mileage covered in daily road service, their yearly performance probably exceeds that of the electric locomotives. This is quite an accomplishment, considering the limited time that Diesel locomotives have been applied to heavy switching and road service.

Although a straight electric passenger locomotive can be designed considerably lighter than a Diesel passenger locomotive of equal horsepower output, the Diesel locomotive is certainly the answer to very high-speed trains where long distances are involved and complete interchangeability is required between the various rail systems.

With freight transportation it will be found that properly to exploit the advantages of individual axle drive, there will be no material difference between the weight of the electric and Diesel locomotive, or if there is, the added tractive power of the heavier locomotive will be a decided advantage.

In the hypothetical case employed for illustration where the production of 180,000 ton-miles per hour was obtained with a 6,000-horsepower locomotive, Mr. Wright showed that a steam locomotive of approximately 620 tons would be required as against an electric locomotive of 270 tons. With the 3,000-ton train the advantage of the reduced weight as such is of no great importance, except as to the amount of weight available for adhesion between the two locomotives. In this respect the electric locomotive may have a very great advantage over steam.

Actually there are many steam locomotives today in operation of approximately 600 tons weight, but none of these locomotives can under normal conditions produce, 6,000 horsepower, nor can they over a rolling profile consistently produce for a matter of 24 hours 180,000 ton-miles per hour.

It will be noted that the 180,000 ton-miles per hour were obtained by assuming a speed of 60 miles per hour. I believe that a more practical locomotive should produce these ton-miles per hour at a considerably lower speed.

This brings up the question of the locomotive characteristic throughout its operating range, where I feel that both the conventional electric and steam locomotives are at a decided disadvantage in comparison with the constant horsepower output of the Diesel locomotive.

Mr. Wright states that the first cost of the Diesel locomotive is about twice that of the electric locomotive. This estimate overlooks the really important items in the cost of railway electrification. Considering only the cost of the power plant to supply railway electrification, it is interesting to note that the cost of a Diesel locomotive fully equipped on the rails per horsepower output, is considerably less than the cost per horsepower of the power plant.

It is true that with a diversified load, it is not necessary to have the power plant capacity equal to the total nominal rating of the locomotives on the system. However, when traffic becomes congested due to conventions, sports meetings, special freight movement, or irregularities due to accident, the problem of peak power demand with electrification is a serious one.

Finally, if you consider rail transportation from a national viewpoint, it must be evident that the artificial concentration of movement on certain favored lines is on many counts not practical. If railways were considered according to a "Peace Economy" and without any thought to the effects of washouts, fires, derailments, and other accidents, it might be shown with a purely economic study that over half the railway lines in this country could be eliminated with great economic advantage to the retained lines, regardless of the type of motive power employed. With the national awakening to the importance of railroads for not only economic but also for strategic reasons, it is difficult to see how traffic could be concentrated on certain privileged routes.

Experience to date with electrification has very clearly brought out the inflexibility of this type of motive power in the event of the hazards just outlined. There are, of course, great advantages where high speed and large tractive power are required with the individual-axle electric drive. To obtain these advantages to the maximum and retain the present flexibility of the steam locomotive, the Diesel locomotive with an electric drive would appear to be the answer.

A. M. Wright: Some of the discussion has questioned the wisdom of consolidating traffic on certain favored routes between centers of population, both because some communities would be left without rail service, and because of possible dislocation of transportation in case of accidents or wrecks. It was not the intent of the paper to recommend that all routes but one be abandoned between, for example, New York and Pittsburgh, but a glance at a railroad map shows that not only do the main lines of the B. & O. and the Pennsylvania connect these cities, but that there is also a multitude of interconnecting branch lines whose operation is of questionable economic value, and which serve communities whose needs might just as well and more cheaply be met by road vehicles. Mr. McGee mentioned the strategic value of the railway system as being inconsistent with concentration of general traffic on certain routes, but I do not think the occupation of an area by enemy forces would be a disaster of less magnitude if that area were served by many railway lines. Peacetime economy requires that the transport system be operated on an economic basis, and it is to be hoped that the gearing of our economy to the whims of the megalomaniac gangsters of Central Europe will be a fleeting phenomenon. Any such program of consolidation as was suggested in the paper will be consummated only after years of preparation, and for strategic purposes the existing railway trackage is probably more than sufficient, particularly since moving armies rely almost wholly on motor vehicles for transportation in the zone of action. Mr. Withington's comment that the traffic density on the railways is more likely to be limited by the business offered than by the limitations of the tracks is unfortunately only too true at present, but it is the author's hope that by proper co-ordination, rather than competition, of road and rail vehicles, and the establishment of central freight depots in centers of population, the railroads will eventually be enabled to concentrate on the main line haul of passengers and commodities, and that road vehicles will be confined to pick-up and delivery. With each transport tool thus restricted to the business it is best fitted to perform, I think that a great many of our present difficulties will disappear.

Regarding the weight of modern passenger rolling stock, it must be remembered that modern cars are usually longer than those built ten years ago. The Reading Company's "Crusader" is a good example of a modern train, with appointments as luxurious and more comfortable than could be obtained in a Pullman car of ten years ago. This train with cars averaging 80 feet in length, weighs 1,250 pounds per foot, including a dining car and air conditioning equipment. A Pullman car of 1928 vintage, $75^{1}/_{2}$ feet long, with no air conditioning equipment, weighs about 2,200 pounds per foot of length.

Mr. Withington is correct in ascribing much of the inefficiency of the steam locomotive to high exhaust pressure. A locomotive with a boiler pressure of 250 pounds per square inch, and using steam at 150 deg F superheat, would have a theoretical thermal efficiency of 22 per cent if perfect adiabatic expansion of the steam could be obtained down to 15 pounds per square inch. If the back pressure could be reduced to 28 inches of vacuum, the theoretical efficiency would be raised to 36.3 per cent. Variable cutoff, heat losses, etc., would lower these figures considerably, and there would be a great increase in dead load due to the weight of the condenser. Other practical difficulties also militate against the use of condensers on locomotives. The combustion problem is, however, just as serious. It has been estimated that 50 per cent of the coal fired into a locomotive passes unconsumed through the smokestack. The shower of carbon particles which accompanies the passage of a steam locomotive supports this estimate, and Lipitz (ASME paper RR-56-6, 1934) quoted boiler efficiencies of from 42 per cent to 52 per cent, with over-all locomotive efficiencies of 3.8 per cent and 5.6 per cent. In past designs imperfect combustion was largely due to insufficient combustion space and to the sudden temperature drop experienced by the furnace gases as they entered the boiler tubes, where little further combustion occurs. In modern designs a generous combustion chamber is provided, but this has the effect of lengthening the boiler and increasing weight at a rate approaching the rate of increase of boiler output.

Mr. McGee commented on the noninterchangeability of electric locomotives and on the cost of the power supply facilities required for electric traction. We certainly cannot run electric trains on nonelectrified tracks, but apart from this, railway electrification engineers have been remiss in not agreeing on standards for electrification. If electric traction is ever to become an important economic factor in main line rail transport, the advantages of standardization of transmission and trolley voltages and locomotive types must certainly be applied. The achievements of Diesel-electric locomotives in recent years have indeed been impressive, but their success in handling long-haul trains in regions of sparse traffic density does not show that they will be equally successful in handling very dense traffic. The cost of power-supply facilities, as Mr. McGee rightly says, far outweighs the economy of electric locomotives on lightly loaded railways, and here the Diesel locomotive shows up to great advantage. But when the traffic becomes very heavy, the low operating cost of electric locomotives outweighs the cost of power-supply facilities, and electric traction is an economic proposition. Each type of motive power has its own field of application, and present indications do not show that one will displace the other from its own field. Mr. McGee's remarks are in general confined to conditions obtaining on light traffic railways; on such lines the rate of production of transportation by a train may be kept high, although train speeds are low. But on a congested railway low freight-train speeds are intolerable, and in such cases the rail power rating per ton of locomotive weight is of real importance. The poor weight efficiency of the self-contained locomotive is a great drawback where traffic density is high, although, as Mr. McGee says, it does not matter much where low train speeds are not objectionable.

The remarks of Mr. MacLeod and Mr. Brandenstein are of particular interest in emphasizing the importance of keeping down the cost of wayside equipment with electric traction. The lower this cost can be made, the lower is the traffic density at which electrification is feasible, and manufacturers of electric traction equipment are therefore affected by this phase of the problem quite as much as the railways themselves. The cost of labor and work train service affects the cost of installation, but perhaps not so much as Mr. MacLeod's comments would indicate. For catenary work, about 25 per cent or 30 per cent of the total cost is chargeable to labor and work trains, but for erection of steel supporting structures this figure is of the order of only 12 per cent. Concrete foundation work is not much affected by traffic, as the greater part of the labor cost is in excavation, backfill, placing reinforcing, etc., which is mostly done from the ground.

The figure of 100 pounds per rail horsepower of continuous rating given in the paper for electric locomotives is very conservative, as Mr. Brandenstein points out. As long ago as 1925 locomotive E-501 of the Paris-Orleans Railway was put in service, having a weight of 85 pounds per continuous horsepower. But even Mr. Brandenstein's 240-ton locomotive of 6,000-horsepower rating is not a record. A locomotive of the new "E-19" series built in Germany weighs only 50 pounds per continuous rail horsepower. Such locomotives are suitable for high-speed freight movements, but would, as Mr. McGee has implied, perhaps have difficulty in starting an extremely heavy train, even though the operation might be within the power capacity of the locomotive.

Mr. Brandenstein's comments on transformer reliability indicate that we can expect a less conservative substation layout in future electrification. But the other substation equipment affects the over-all cost in a very important way. Particularly is this true of high-speed circuit breakers. On a 4-track railway requiring a substation capacity of 200 kva per mile of track there would on this account be a great difference in unit cost per kva between substations spaced 10 miles apart and substations spaced 15 miles apart, although the total installed capacity might be the same in both cases. To take full advantage of transformer reliability it will therefore be necessary to raise the reliability of the catenary system to the same degree.

A High-Speed Differential Relay for Generator Protection

Discussion and author's closure of paper 40-103 by W. K. Sonnemann, presented at the AIEE summer convention, Swampscott, Mass., June 24–28, 1940, and published in AIEE TRANSACTIONS, 1940 (November section) pages 608–12.

L. F. Kennedy (General Electric Company, Schenectady, N. Y.): The two ideas incorporated by Mr. Sonnemann; namely, the use of a variable-ratio characteristic in a differential relay and its dependence upon phase angle, certainly provides a means for overcoming the tendency toward incorrect operation due to the shortcomings of the current transformers. I do not feel, however, that we can fully accept his statement "that when the restraining current is large, . . ., the sensitivity of the relay *should* be reduced to allow for greater shortcomings in current-transformer performance." A more accurate statement would seem to be one which conveyed the idea that a reduction in relay sensitivity may be an acceptable means of overcoming otherwise unavoidable current-transformer errors. While I feel that there is some real merit to be derived from a variable slope, I do believe that we should avoid giving the impression that it is a definite benefit under all conditions and that we are not interested in obtaining current transformers capable of reasonably good performance.

Giving the relay maximum sensitivity when the difference current is in phase with the restraining current and decreasing the sensitivity for angular shifts, such as would be caused by current transformer errors, would seem to be a further assurance against incorrect operation. The difference current which produces the operating force in the case of external faults is the vector difference between the output currents of the two current transformers used for the generator differential protection. It may therefore be close to 90 degrees out of phase with the restraining current when the two output currents are nearly equal in magnitude, but somewhat out of phase with each other. But when one of the current transformers has a large error then the difference current approaches an in-phase relation with respect to the restraining current. It appears therefore that this characteristic, while of some merit, is not of too great value in preventing incorrect operations on external faults and is obtained only at the expense of some complication.

There has been frequent expression, before the AIEE, of the idea that perhaps there has been too much emphasis on speed of relay operation with a resulting tendency toward incorrect operation due to transients. I, for one, while realizing the validity and seriousness of this thought, have felt, nevertheless, that the work which has been done toward providing reliable high-speed devices should be continued because we seemed to be so close to a solution. It is, therefore, with considerable regret that I see a new type of high-speed relay introduced, wherein considerable thought has been given to preventing undesirable operation on electrical transients, but which is in itself so mechanically unstable that it must have added to it a device for preventing unwanted operation due to vibrations or jars. It would seem that an opportunity has been missed here in not making a device of greater mechanical stability. Presumably this has been done to keep down the burden of the device, but if it is possible to include the burden of a small plunger device of adequate mechanical stability, it would not appear to have been too difficult to obtain a single device having the desired electrical characteristics and adequate mechanical stability as well.

Since a device of the type described is unstable in its operation, that is the operating force becomes greater and the restraining force less when the armature starts to move there would seem to be a real danger of false operation due to the balanced beam being in the operated position when a fault occurs and remaining there while the so-called fault detector picks up due to a small difference current flowing because of current-transformer inaccuracies. In other words, does not the final assurance against an incorrect operation depend on what is in reality a low-set instantaneous over-current relay?

P. O. Langguth and **S. A. Bottonari** (both of Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): Mr. Sonnemann's approach toward a more satisfactory relay for differential protection is very valuable in that it provides a relay which will give satisfactory performance without imposing too rigid requirements on current transformers. This is particularly important when relays operate from bushing current transformers housed in circuit breakers. Previous investigations have shown that in some differential-relay installations, current transformers having the necessary characteristics exceeded practical or economical limitations. Likewise, when differential protection is to be applied to existing systems, physical limitations in either breaker or structure may be encountered.

The effect of d-c saturation of current transformers due to offset current faults has been clearly brought out in past articles.[1,2] The approximate expression indicating the severity of current-transformer performance requirements to prevent d-c saturation is well illustrated by the factor $(1+wt)$. Unity represents the component of steady-state performance, and the term wt indicates the required factor due to the d-c transient component. The summation $(1+wt)$ is a measure of transformer performance required for the offset transient fault as compared to the normal a-c equivalent steady-state fault. Typically, a 60-cycle system having a time constant of 0.1 second would demand $1+(377)(0.1)$ or 38.7 times the normal size of transformer to prevent d-c saturation, as required to prevent saturation under the equivalent steady-state condition. Thus it is apparent that the steady-state requirements are negligible compared to that for the d-c transient, since the latter is many times greater.

Obviously, then, a relay which permits the choice of a transformer determined by the a-c characteristics alone, solves the relaying problem from a more practical, and economical point of view. The development of this relay also indicates that existing designs of bushing transformers may be suitable for high-speed differential protection. In this respect it is interesting to note that the author has compared current transformers on the basis of iron area or flux density instead of the conventional practice of using ratio curves. This is a good example of the limitation in bushing-current-transformer ratio curves. It seems that a saturation curve of each transformer involved would be more suitable for the application of relays for differential protection. Consideration should be given to supplanting the ratio curve for relay application work.

C. D. Hayward (General Electric Company, Philadelphia, Pa.): In the application of high-speed relays to generator differential protection serious consideration must be given to the saturation effects produced by the slowly decaying d-c component present in asymmetrical fault currents. In this paper the author has mentioned the extreme ratio breakdown effects caused by d-c saturation of the current-transformer cores, but no mention is made of d-c saturation effects within the relay itself. The whole theory of the relay as described in the paper and illustrated by figure 4 of the paper has been developed on the assumption of symmetrical sine-wave currents supplied to the relay by the current transformers. Actually, the currents are neither symmetrical nor sine wave as a glance at the oscillograms in the paper shows.

The neglect of the d-c component is particularly serious because the characteristics of the relay *depend* on saturation of the transformer element in the relay. Figure 1 of this discussion shows the relative magnitudes of core flux required to reproduce the a-c and d-c components of the current in the secondary circuit of a current transformer having an assumed burden

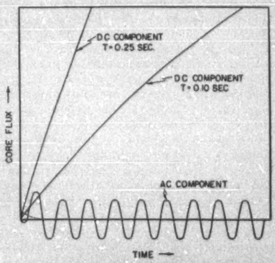

Figure 1. Relative magnitudes of current transformer core flux required for a-c and d-c components of an asymmetrical fault current wave

phase angle of 45 degrees. Curves are shown for the 60-cycle a-c flux component, the d-c flux component for a fully offset wave having a 0.10-second d-c time constant, and for the d-c component of a wave having 0.25-second d-c time constant. It is readily seen that the saturation produced by the neglected d-c component because of its greater core flux requirement, is much greater even during the first few cycles than that produced by the a-c component on which the design of the relay is apparently based.

The effect of the increased saturation of the transformer element by the d-c component would probably be to greatly increase the per-cent restraint. It would seem that this increase could easily be enough to prevent operation of the relay on an internal fault until the d-c component dies out, which would mean a time delay of many cycles. The relay characteristics shown in figures 3, 5, and 6 of the paper were apparently taken with steady-state symmetrical currents. It would be interesting to see a similar set taken with transient offset currents having long time-constant d-c components similar to those met in practice.

The oscillogram of one internal fault test is shown in figure 10 of the paper. Here due to a high degree of saturation of both current transformers the d-c component disappears in the secondary currents after a fraction of a cycle, and a high-speed operation of the relay is recorded. If the test had been made at a lower current, or with lower current-transformer burden, or with better-quality current transformers, the d-c component would have been reproduced more faithfully and the relay operating time would probably have been much longer.

Another point which should be considered is the possibility of the relay failing to operate at all on an internal fault in which the currents fed to the fault from the two directions are considerably out of phase. The relay would be restrained from operating under this condition because of its phase angle-restraint characteristic shown by figure 5 in the paper. There are a number of ways in which these two currents could get out of phase: for example, consider the case of a generator supplying a synchronous motor load. If a fault occurs near the high-voltage end of the generator winding, the generator itself will feed current to the fault from one side, while the synchronous motor load will feed back current from the other side. Since the induced voltage of a synchronous motor lags behind line voltage when acting as a motor but leads it when acting as a generator and since a further angle of lag would be added on by line reactance drop, due to the reversed direction of current flow, it would seem that the current fed from the synchronous motors might lag behind that from the generator itself by a considerable angle. Generator faults occurring during swing periods would also find the two currents out of phase depending on the swing angle. If the tripping of the relay is delayed due to saturation on the d-c component as described before, it is quite possible that the faulted generator itself would swing out of step with the system voltage during the delay by an angle great enough to prevent tripping after the d-c component has died out. A thorough study of the possibility of occurrences of this kind should be made before the relay is applied. No such study is described in the paper. In the one internal-fault test described the fault currents from the two directions were prevented from getting out of phase by the use of the same primary current, from a single source in both current transformers as shown in figure 7 of the paper.

W. K. Sonnemann: The author was gratified to note the approval expressed by Mr. Langguth and Mr. Bottonari of the method of comparing current transformers. Recent experience has indicated that this method, as well as the use of the saturation curve of the transformer is, in many cases, of considerably more value than the use of the conventional ratio and phase-angle characteristics.

Mr. Kennedy's first paragraph is quite interesting. The author is quite willing to soft-pedal the word *should* in favor of the statement that: "Variable ratio characteristics will, in many cases, allow the use of standard current transformers where otherwise super-quality transformers might have to be used."

Mr. Kennedy seems to doubt that the phase-angle characteristics described have the value which is claimed, and he cites cases where the differential current might be very nearly in phase with the restraining current. In a long series of tests of this relay, and in the development tests which preceded its final design, considerable variation in phase-angle relationships was observed. It was for this reason, as pointed out in the paper, that both the phase-angle characteristics shown and the variable-ratio characteristics were incorporated in the design. Both contributed to the satisfactory performance of the relay.

Mr. Kennedy's statement that the device is unstable in its operation because the operating force becomes greater and the restraining force less when the armature starts to move is quite an overstatement. There is a slight amount of this effect noticeable, but this does not exceed 25 per cent. Moreover, it does not render the relay unsatisfactory in the manner alleged. As a matter of fact, the adjustable weight placed on the back end of the beam is sufficient to keep it in the reset position even when the relay is totally de-energized. During the flow of a heavy external-fault current, the amount of restraint is a great deal more than any amount of additional weight which could be added to the beam in any practical design. For this reason it is not correct to assume that the beam could be in the operated position during the time that the sensitive overcurrent element (fault detector) is picked up because of an external fault.

The first portion of Mr. Hayward's discussion brings up a number of points which cannot be answered in the detail which is apparently expected and still keep the discussion within permissible limits of length. The author believes it is sufficient to say that the *effect* of the d-c component on the auxiliary transformer is known, and that it is favorable to the correct operation of the relay rather than unfavorable. The d-c characteristics of the relay cannot be expressed in curve form, however, because of the fact that an infinite family of curves would be required. That is, for a fully offset current wave, the d-c component begins at a maximum value and decreases instant by instant, until it finally disappears. At each succeeding interval of time, no matter how small, the d-c component of the main fault current is a lower percentage of the original value, and it is thus seen that to endeavor to show curves for every possible percentage of direct current would require an infinite family. The a-c characteristics of the relay discussed in the paper are primarily useful for two purposes and secondarily useful for a third purpose. First, they apply directly in the case of symmetrical fault currents. Secondly, they are a useful reference in checking the relay itself to determine that it is in satisfactory condition. The secondary purpose of these curves has been to serve as a guide in predicting the probable performance of the relay when the current wave is offset. Obviously, they could not be used in this fashion without proper interpretation, but the experience gained in development indicated that the type of curves shown were in the right direction. The author feels that the final answer with regard to the d-c characteristics lies in the fact that the relay met every test condition satisfactorily. These test conditions covered the range of fault currents from high to low values and from symmetrical faults to asymmetrical faults. In tests of this kind, it is the usual practice to make repeated tests until both a fully offset wave and a fully symmetrical wave have been obtained. In the course of such tests, a number of intermediate conditions were obtained. That is, some of the current waves were partially offset so that the per cent of direct current obtained in the whole series of tests ranged from 0 to 100 per cent. It is felt that, since this procedure was followed with both high and low and intermediate current values, the tests were complete.

Mr. Hayward places considerable stress in his last paragraph on the phase-angle characteristics of the relay. It seems he has completely overlooked discussion in the paper which points out in detail that these curves, figure 5 of the paper, are primarily for the through-fault condition. They do not apply directly for internal-fault conditions without proper interpretation because, (1) in the test setup in which the curves of figure 5 were obtained, the connections represented the through-fault condition in which the ampere turns in the restraining coils were additive, and (2) for internal faults to which the bus also contributes, the currents are in opposite direction and the ampere turns in the restraining coils are subtractive.

The worst condition emphasized by Mr. Hayward would be in the case of a bus contributing a current to an internal fault near the high-voltage terminals equal to the current contributed by the generator and slightly out of phase with it. The ratio of the current transformers used with a generator, combined with the subtransient reactance characteristics of the machine, will limit the current contributed by the machine itself to not over 60 amperes in terms of the secondary, and even this is an extreme case. If it is now assumed that the bus contributes 60 amperes also, and that this 60 amperes is 30 degrees out of phase with the generator current, the relay conditions are derived as follows. The effective restraining current being the difference between the two, there results a current value of $8+j30$ amperes having a scalar value of 31 amperes. However, since there are two restraining coils and the characteristics are based on the average of the two, it is necessary to divide the 31-ampere value by two and thus obtain an effective value of 15.5 amperes restraint on which to determine the relay characteristics. Referring to figure 5 of the paper, the nature of a 15.5-ampere restraint curve, falling between the 5-ampere and 25-ampere curves shown will be readily noted. It is thus seen that the operating current, equal to the vector sum of the two 60-ampere currents quoted and having a scalar value of 116 amperes, will be considerably more than sufficient properly to operate the relay.

There are theoretical considerations indicating that in extreme cases the two currents fed to an internal fault might be more than 30 degrees out of phase. However, the conditions that would allow this phase angle to be exceeded are such as to render the effect unimportant. Where generators are operating tied together with an extremely long tie line, it is possible for the generated voltage of one machine to run 30 degrees to 40 degrees or possibly even very slightly more out of phase with the other. However, in this case the impedance of the tie line will so largely reduce the amount of current which the distant generator can contribute that its effect would be negligible.

Computation of Accuracy of Current Transformers

Discussion and author's closure of paper 40-89 by A. T. Sinks, presented at the AIEE summer convention, Swampscott, Mass., June 24–28, 1940, and published in AIEE TRANSACTIONS, 1940 (December section) pages 663–8.

W. K. Dickinson (General Electric Company, Lynn, Mass.): It may be of interest to point out that the formulas given in Mr. Sinks' paper are not of interest simply from a theoretical point of view, but they have been used for some time as a valuable tool in current-transformer design.

An accurate method of calculation of the ratio and phase-angle characteristics is valuable not only in obtaining the optimum design for standard lines of transformers, but it becomes almost invaluable in the design of special transformers to meet exacting conditions, such as the operation of differential protective relays at very high currents.

In the days when 20,000 or 30,000 amperes was considered to be a lot of current, it was not particularly difficult to design adequate transformers. Now, with the great interconnected systems making it sometimes necessary to design for currents as high as from 120,000 to 130,000 amperes and with accuracy requirements to meet very exacting selective relaying, the transformer-design problem is much more difficult. Not only are the transformers large and expensive, but the cost of testing at these enormous currents is high.

Therefore, it became very necessary to predict accurately the characteristics of existing transformers which had not been tested at high overcurrents, and to design correctly, the first time, transformers to meet very exacting conditions.

It was to meet this necessity that the improved method of calculation was developed by Mr. Sinks and his method has proved of great value in a large variety of designs over a period of several years.

E. C. Wentz (Westinghouse Electric & Manufacturing Company, Sharon, Pa.): Mr. Sinks' paper is a most workmanlike exposition of a method for practical solution of a problem the complexity of which defies attempts at rigorously exact solution.

The proof that the leakage flux Φ_{L2} linking the secondary turns brings about a reduction of $\Phi_{L2}/3$ in the flux at the center of the core is a new and interesting idea, inasmuch as the method of calculation which we have used, although similar in general to that given by Mr. Sinks, has been based on division of the core into only two parts, one part corresponding to section 1–2 of figure 1 in Mr. Sinks' paper, the other part consisting of the remainder, and we have assumed that the average flux in section 1–2 is simply E_2/K (equation 5 of the paper). However, it does not seem that it should require quite so much mathematics to show that the effective linkages due to Φ_{L2} are $\Phi_{L2}/3$, and it seems obvious that Φ_C must be reduced from Φ_M by this amount.

I am personally glad to see that Mr. Sinks belongs to the small group of fundamentalists who do not believe in a mythical secondary leakage reactance. "Secondary leakage reactance" is a useless as well as an imaginary conception. Cutting right to the heart of the problem with analysis of real and measurable fluxes is a contribution to clear thinking about the whole problem.

The number of sections into which the core can be divided is quite arbitrary, because the only exact division is into an infinite number of sections. We have found during the past eleven years that a division of the core into two parts usually strikes a reasonable balance between the amount of work in calculating performance and the probability of error in the result. This method was described in a thesis for the University of Pittsburgh, "Iron Losses in Current Transformers, With Particular Attention to the Effect of Leakage Flux" (1936).

We have since worked out a method of calculation which allows the numerical work to be considerably reduced. The principle of the method is that the core divided into several sections, as described by Mr. Sinks, can be represented by the equivalent diagram in the accompanying figure 1. Each exciting branch represents one section of the core, and the series reactances are equivalent to the various leakage fluxes. The increment of exciting current which produces a certain per cent ratio error can be read directly from curves according to the method described by A. M. Wiggins in "Ring Type Current Transformers—Limitations in Design" (*Electric Journal*, Dec. 1927, page 621).

The method is simple enough that even one not familiar with transformer theory can still calculate ratio and phase angle in a few minutes, given the equivalent diagram with constants for a given transformer and the necessary curves. We have been considering giving this data to customers instead of the ratio and phase-angle curves. This method involves a return to fictitious secondary reactances and the whole equivalent diagram has no real existence in reality. However, it gives exactly the same result with much less numerical work.

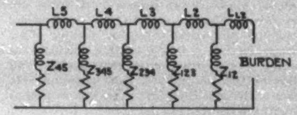

Figure 1. Equivalent diagram of current transformer

(All quantities referred to the secondary winding)

$L_{L2} = \dfrac{-N_2\Phi_{L2}}{3I_2}10^{-8}$ = equivalent inductance corresponding to leakage flux $\dfrac{\Phi_{L2}}{3}$ negative value

Z_{12} = exciting impedance corresponding to section 1–2 of the core. (See Sinks figure 1)

$L_2 = \dfrac{N_2\Phi_2}{I_2}10^{-8}$ = equivalent inductance corresponding to leakage flux Φ_2

Z_{123} = exciting impedance corresponding to core sections 1–2 and 2–3

$L_3, L_4, L_5 = \dfrac{N_2\Phi_3}{I_2}10^{-8}, \dfrac{N_2\Phi_4}{I_2}10^{-8}, \dfrac{N_2\Phi_5}{I_2}10^{-8}$

$\left.\begin{matrix} Z_{234} \\ Z_{345} \\ Z_{45} \end{matrix}\right\}$ Exciting impedances corresponding to core sections $\left\{\begin{matrix} \text{2–3 and 3–4} \\ \text{3–4 and 4–5} \\ \text{4–5} \end{matrix}\right.$

The best method we have been able to work out for calculating the leakage flux in bar type current transformers gives fair agreement between calculated and measured ratio and phase angle, but the measured fluxes in different parts of the core not only do not agree very well with calculations, but vary widely with the position of the primary conductor, much more than we have expected, even though the ratio and phase angle is not affected appreciably. I should like to ask if Mr. Sinks has been able to overcome this difficulty.

Duff and Price and other authors have written about "negative secondary leakage reactance" and have used it to show that the ratio error may be negative, that is, that a current transformer may actually deliver more secondary ampere turns than is put into the primary winding. If "secondary leakage reactance" is elusive, a negative value of it is one degree further removed from reality and I have never quite understood how the ratio error can be negative. However, we believe we have actually observed this effect on test although it is always very small and would like to have Mr. Sinks discuss this.

I should also like to ask if Mr. Sinks has a method for accurate calculation of the effect of Wilson compensation. Although theory of Wilson compensation has been described in the original paper, we have never been able to calculate the ratio and phase angle variations produced by Wilson compensation or any of the similar schemes which have been devised, with sufficient accuracy that we could use it with confidence for special transformers, the performance of which must be predetermined before they are built.

A. T. Sinks: Mr. Wentz's discussion brings out some important points, and the hypothetical circuit developed for purposes of calculation seems to have interesting possibilities.

As Mr. Wentz points out, the equivalent circuit method he shows is probably simpler after all the impedance values and curves are established than the fundamental method presented in the paper, particularly inasmuch as the former makes use of circuits more familiar to most engineers. However, it must be borne in mind that the determination of these hypothetical constants requires considerable preliminary work in the form of either tests or calculations of the kind presented in the paper. Moreover, once the leakage fluxes have been established the work of calculating the accuracy by the method given in the paper is not so great and the one set of figures for leakage is good for all burdens.

As Mr. Wentz suggests to simplify the calculation the core can be divided into two sections, and, in fact, even one section can be used by using a flux density equal to the average of the maximum and minimum calculated values which will usually occur at sections 1 and 5. However, the more the calculations are simplified in this manner the greater the likelihood of error and the more experience is necessary in order that one won't be misled by such considerations as nonuniform core cross sections and the changes in relative values of magnetizing forces accompanying saturation of points of high flux density.

With regard to Mr. Wentz's questions on variations in leakage flux in bar type transformers, I believe this problem is very closely related to the old problem of interference from the return conductors. On bar-type transformers the interference effect is, of course, more pronounced than on wound types. Many tests on bar- or window-type transformers were made by the Bureau of Standards by J. H. Park (see bibliography of paper) in which interference was investigated. These tests show considerable variation in accuracy due to effect of return conductors although no measurements of core flux were reported. However, tests on similar transformers and calculations on the "stray flux" show that the changes in core flux due to the return conductors must have been enormous, more than would be expected from changes in accuracy shown. These tests, therefore, are in agreement with Mr. Wentz's observations with this important addition, that when the flux densities are high enough to produce saturation in one or more parts of the core due to the stray field the change in accuracy may be quite pronounced.

The explanation of why large changes in flux density resulting from mechanical changes in conductor position usually do not produce correspondingly large changes in accuracy is probably that such mechanical changes increase the flux density in one part of the core about as much as they decrease it in another and that at low densities generally encountered in current transformer operation a given per cent change in flux density requires a smaller per cent change in magnetizing force. At high flux densities on the other hand, where a slight change of flux requires a large change in exciting current, the accuracy may be greatly affected by changes in flux resulting from mechanical changes in the conductors. This leads to the conclusion that interference from adjacent conductors is probably more important with respect to relaying applications than with respect to metering.

Mr. Wentz raises a question about the possibility of the ampere-turns in the secondary being greater than those in the primary, saying that he believes such a condition has been observed to a slight degree. We have also noticed this condition on a few occasions. I agree with Mr. Wentz that explaining this phenomenon on the basis of a "negative secondary reactance" is rather tortuous logic. Moreover, although such a concept might be used for purposes of calculation it does not clarify the physical situation until the negative reactance itself is explained. That the secondary ampere turns can be greater than the primary, however, can be proved from fundamental considerations rather simply.

To do so consider a toroidal core like a bushing-transformer core with a secondary winding equally distributed around the core and a round primary conductor straight through the center of its toroid. Consider, further, that the secondary is quite thick relative to the cross-sectional dimensions of the core. Due to the symmetry of this construction all flux lines will be circular and none will enter the core or leave it. Moreover, when the primary and secondary turns are exactly equal there will be leakage flux linking the secondary winding outside the core, and the density of this leakage flux will be zero immediately outside the surface of the core and will increase continuously to a maximum value at the outside surface of the secondary winding where the density will be determined by the primary ampere turns and the circumference of the flux circles. The direction and phase of this leakage flux will be the same as the magnetizing force produced by the primary current. Since this leakage, therefore, produces a voltage which is 90 deg out of phase with the primary and secondary currents this voltage in the secondary must be balanced out either by reactance in the external secondary burden or by flux linkages in the iron core opposite to the leakage. Consequently, if there is no external reactance, there will have to be flux in the core opposite to the direction of the primary magnetizing force and ampere turns opposite to the primary ampere turns will be required to produce the flux. Hence, the secondary ampere turns will have to be greater than the primary.

The conditions outlined may be considered as a negative reactance, but actually they are the result of superimposing a positive mutual inductance on a somewhat smaller positive self inductance.

It is interesting to note that if the windings on the transformer in the paper are spread out uniformly around the core and the latter made circular, the quantity Φ_{LT} in equations 7 to 10 disappears and the equations all become the same, and if L_s is then taken as the mean length of magnetic circuit, the resulting formula will give the flux for the toroid just discussed. Moreover, if the external reactance X_B is taken as zero, following through the calculations will show that the ratio correction factor will be less than unity if (R_B+R_2) is not too great. In bushing transformers the secondary windings are usually so thin and the distance around so long that the effect of leakage is not detectable and it would probably be necessary to build a very special transformer to measure the effect under discussion.

To answer Mr. Wentz's last question the Wilson Compensation has been calculated with fair accuracy, but it hardly seems practical to do so ordinarily because empirical data has pretty well established the limitations of this compensating scheme and also determined the best position of the hole. This is all that it is really essential to know in design work since the number of turns and the resistance of the short-circuited turn in the compensating windings can be readily adjusted after the transformers are built to get the exact value of compensation desired.

New Instruments for Recording Lightning Currents

Discussion and authors' closure of paper 40-90 by C. F. Wagner and G. D. McCann, presented at the AIEE summer convention, Swampscott, Mass., June 24–28, 1940, and published in AIEE TRANSACTIONS, 1940, pages 1061–8.

J. H. Hagenguth (General Electric Company, Pittsfield, Mass.): The paper is of considerable interest, as it presents a variety of instruments for measuring lightning currents and charges. Although considerable progress has been made in our knowledge of lightning currents, there still remains considerable work to be done before lightning is fully understood.

Before discussing the instruments, a survey of established facts and further desirable information is useful. Some known facts are the following:

1. A considerable amount of records have been obtained concerning amplitudes of lightning currents on transmission lines, distribution circuits, and through station-type and distribution-type lightning arresters. Distribution curves of these currents with respect to frequency of occurrence of any given amplitude have been obtained principally by means of the magnetic link method in several countries and these curves in general show good agreement with each other.

2. Current wave shapes involving relatively high amplitudes and short time duration have been recorded in a relatively few instances by means of the cathode ray oscillographs. The number of records is too few to allow a safe estimate on the limits of front and tail length of high current lightning discharges and further investigation in this field is required.

3. Long-time or continuous lightning discharges have been observed first by Walters photographically. These discharges have been proved to be produced by actual current flow first by Dr. K. B. McEachron

in his investigations on the Empire State Building using simultaneous records by means of the oscillograph measuring the current in the stroke and the photographic camera taking a photograph of the same stroke using a moving image. Further, the existence of such continuous discharges has been proved by comparing the effects of laboratory discharges with lightning traces obtained in the field on counterpoise gaps, on metal parts of airplanes, distribution line conductors, and others. From Dr. McEachron's oscillograms and the other evidence mentioned, a fairly good estimate of the total charge in a single lightning stroke can be made. It is found that approximately 50 per cent of all strokes have a charge of between 15 and 30 coulombs, while 10 per cent exceed 50 coulombs.

4. One oscillogram is available showing the rate of rise of voltage on a transmission line. This oscillogram was taken close to the point of the stroke contact with the line. Although this was taken early in the art of impulse measuring when methods of measuring were not as well understood as today, this oscillogram probably gives a fairly good indication of the severity of the voltage wave of a lightning stroke to transmission lines.

Today the principal points of interest to the apparatus engineer concerning the lightning stroke probably are the following:

(*a*). The fronts of the high current discharges

(*b*). The tail of the high current discharges

(*c*). Total charges in a lightning discharge

(*d*). Distribution of total charge in a lightning discharge on transmission and distribution circuits

This is probably the most important information for improvement of continuity of service on overhead systems.

Of the instruments described in the paper, the cathode ray oscillograph is the only one which can give accurate records of the current wave front and tail. Although the high speed fulchronograph would fundamentally be capable of distinguishing between a wave tail of 40 microseconds or longer, the properties of the magnetic link method are such that a number of links will be subjected at varying degrees at the same time, so that even with the wheel stationary, a relatively long front and a long tail are obtained (see figures 9 and 13 of the paper). The apparent time from zero to zero from figure 13 would have been 200 microseconds for a 20,000-ampere crest. Most of the lightning records obtained with high speed oscillographs show fronts of 2 to 12 microseconds and tails of 30 to 100 microseconds. The usefulness of the high-speed fulchronograph for obtaining such detailed information is therefore doubtful. For measurements concerning the duration and amplitudes of the low current discharges or continuous discharges the "slow-speed" fulchronograph should be a very suitable and relatively inexpensive instrument. The "high-speed" fulchronograph would undoubtedly give a confusing picture of a discharge consisting of several multiple strokes connected by low-amplitude continuous current flow, if the total discharge time is longer than 17,000 microseconds—which corresponds to one revolution of the wheel. Maey strokes with duration longer than 50,000 microseconds have been observed photographically at locations other than the Empire State Building. For this reason the slow speed fulchronograph, or the magnetic oscillograph as used by Dr. McEachron, should prove the more useful instrument as regards the continuous discharges while the cathode ray oscillograph appears to be the only solution to measure the fronts of the current waves. It is surprising to learn that the speed of rotation of the film for the oscillograph has been chosen as low as five revolutions per minute or 12 seconds per revolution.

If the size of the film shown in figure 13 is the actual size, this would mean, that the zero point of the oscillogram moves 1 mm on the circumference in 27,300 microseconds.

In the New York and Pittsfield lightning investigations by the company with which I am associated, it was found that successive peaks of relatively high amplitude could occur at as short times as 500 microseconds and times of 30,000 microseconds are very frequent, which should cause considerable overlapping of successive waves on the film and would make it extremely difficult to obtain proper separation. The selection of logarithmic sweep for the purpose of obtaining lightning current waves appears to be excellent, since it provides a good time scale for the front as well as for the tail.

With the exception of the oscillograph, the instruments described by the authors make use of the magnetic link. During the investigations on transmission lines and other places, it was found that the results of measurements have to be interpreted with great care. The magnetic link reading is easily affected by surges of opposite polarity, by magnetic induction from nearby conductors. The authors probably are too optimistic in stating that the over-all accuracy of the measurements are about 10 per cent. However, the instruments, if placed in numerous locations, should enable the authors to obtain statistical data. It would seem that the greatest reliability should be obtained from the "slow speed" fulchronograph records.

C. M. Foust (General Electric Company, Schenectady, N. Y.): This paper is interesting reading to all those who have struggled with this problem of devising suitable instruments and methods for this difficult field of measurement. That it is a difficult field of measurement is easily proved by a few generally accepted facts. The time intervals under consideration range from one microsecond to one second, a range of a million to one. Current values of interest range from 10 to 150,000 amperes, a ratio of 15,000 to 1. The time of occurrence of a stroke is, I believe you will all agree, most unpredictable except that it should come sometime during the period of a lightning disturbance. Suppose we assume a passing lightning disturbance of about two hours duration. The lightning technician must be ready to start a record in any one of the 7,200 million microseconds in this two-hour period with no warning as to which one it will be, or how long a time duration this particular record should have, or for what amplitude of current or shape of wave he should be prepared.

In the period of investigational work extending over the last 10 or 15 years, the instrument problem has been the outstanding one and the progress which has been made toward a better understanding of lightning, which I believe is substantial, has been achieved almost wholly because measurement instruments of greater effectiveness have been developed.

To one whose efforts and confidence have for some time been invested in the new sealed-in type cathode-ray oscillograph and the magnetic, surge-crest ammeter, it is more than gratifying to read of Messrs. Wagner's and McCann's use of these methods. Since 1936 we have been using a similar hot-cathode oscillograph for both laboratory and field work. Vacuum pumps are not required; permanent photographic records are taken outside the tube and simultaneous visual observation of the wave shapes under investigation are made. The authors of this paper have pointed out that the grid control of the electron gun provides for ready initiation of the cathode beam. Details of such a technique for automatic operation of the hot cathode-ray oscillograph are contained in a paper presented by Mr. N. Rohats and myself at Minneapolis and Scranton last summer.

I assume, as indicated by the laboratory record of figure 3 of the paper that the amplitude deflection is at right angles to the calibrated time axis, but this assumption has made it difficult to interpret the field record of figure 4. The vertical deflection seems to be associated with the rotary motion of the disk and is suggestive of too early tripping.

The magnetic link method of surge-current measurement has moved steadily forward since our introduction of it in 1932. This method is directly adapted to the measurement of crest current values of unidirectional surges and has been used for thousands of lightning surge-current records on this basis. Multiple link stations, described at Ithaca in 1935, have been in extensive use since then. Experience has shown us that such a combination of several links, each located at different distances from the conductor, will provide records which discriminate definitely between single unidirectional polarity surges and oscillatory or repeated surges. Also, further classification can frequently be made into oscillatory surges of constant decrement or repeated surges of opposite polarities.

The authors' experimental work on the fulchronograph is very interesting. Possibly the principal disadvantage of the moving link recorder is, as pointed out by the authors, its inability to measure high rates of change of current. As indicated by the slope of the distribution curve in figure 9 of the paper, 200 amperes per microsecond would be the upper limit of current slope which can be recorded. While the authors state that the accuracy of the device is of the order of 10 per cent, possibly much greater error than this may be introduced because of magnetic distribution. Three variables—current amplitude, time, and link position are involved and only when current amplitudes change slowly relative to link velocity, is link position negligible. In other words, a considerable number of links must record along any particular current slope to achieve this 10 per cent accuracy figure. This is illustrated in figure 15 of the paper where a laboratory calibration record is reproduced. The agreement between oscillograph and fulchronograph is good for the slope shown which is 800 amperes in 2,000 microseconds or 0.4 ampere per microsecond. It is apparent, however, that accuracy will decrease as current variations become more rapid. Further comment from the authors as to accuracy variations with different wave shapes would be helpful.

The necessity of assuming a time zero based on the nature of the record and the magnetic distribution curve is somewhat unsatisfactory. In this connection I would like to ask if the fulchronograph is equipped with an automatic means to take it out of the circuit after the first record is obtained. If this is not done, composite records such as are often indicated in surge-crest ammeter field data are a real probability.

The field records of figures 13 and 14 of the paper are interesting. The smooth line drawn through the points involves an assumption of current continuity. It might be well to bear in mind that similar records could be obtained by a series of impulses distributed throughout the same time period. Further interpretation of these records would be helpful.

That the moving link surge-current recorder falls far short of attaining the qualities of precision, magnitude, and wave shape recording inherent in the automatic cathode-ray oscillograph is quite apparent. However, the reduced cost warrants some sacrifice and the authors are to be congratulated on their progress in this experimental lightning measurement work.

W. A. McMorris (General Electric Company, Pittsfield, Mass.): The paper presents several very interesting adaptations of magnetic links to obtain much-needed data on the wave shapes and total charge of lightning discharge currents. It is hoped that the installations of these instruments will be in sufficient numbers, under a wide range of conditions, to yield a valuable addition to the data now available.

The current wave shown in figure 14 of the paper is referred to as that of a typical lightning-arrester discharge current. It would be expected from what data have been published that the current magnitude, charge and duration each might vary over a range of several hundred to one, and would be influenced by the locality and the circuits involved. In order to select a record of wave shape that is typical in all of these respects with any degree of certainty, it would obviously be necessary to have a large number of records obtained under a wide range of conditions.

It would therefore be of considerable value in establishing the degree of confidence that can be placed in the wave of figure 14 as a typical arrester discharge current, if Messrs. Wagner and McCann would inform us how many such records were available when their paper was prepared, the localities and types of circuits involved, and the maximum, minimum, and median values of crest current, charge and duration.

It is stated in the paper that the magnetic surge front recorder is not sufficiently accurate if the slope of the tail of the wave exceeds 20 per cent of the slope of the front, due to the effect of the reversal of current in the auxiliary coils. By using two or more magnetic links for each coil, as indicated in figure 17 of the paper, with ranges which overlap sufficiently, it would be possible not only to detect when current reversals of appreciable magnitude had occurred, but also to obtain an accurate measurement of the crest current in the coil even though the reversal has partially demagnetized the links. The method by which this may be done was described in a paper presented at the 1935 summer convention—"Direct Measurement of Surge Currents" by C. M. Foust and J. T. Henderson, Electrical Engineering, April 1935 (AIEE TRANSACTIONS 1935, volume 54), pages 373–378.

There are serious objections to the interpretation of the magnetic link readings on the basis of magnetization tests made with unidirectional currents. First, the hypothesis that the slope of the tail of a wave will not exceed 20 per cent of the slope of the front and large current reversals therefore will not occur in the auxiliary coil, does not appear to be justified. Some of the oscillograms obtained by Dr. McEachron fall outside this limit, and the wide variety of wave shapes recorded suggest that almost anything can happen. Also a flashover on the tail of the wave, which shunts the major part of the current around the recording equipment, may result in a tail which is steeper than the front.

The effect of current reversals on magnetic links, like the effect of vibration illustrated in figure 11 of the paper, is a function of the degree of magnetization. If the method of Foust and Henderson is not used, the degree of reversal that could be tolerated at the higher flux densities would be quite small, possibly of the order of two per cent.

J. H. Goss (General Electric Company, Schenectady, N. Y.): This paper presents an interesting discussion of the methods available for the measuring of lightning discharge currents.

The authors do not discuss the wave shape used in calibrating the device, figure 8, and show only one wave shape in comparison to the cathode-ray oscillograph, figure 15. Figure 15 shows a very slow wave and low crest value and the calibration shown apparently gives one point of the fulchronograph record at the peak and the balance of the points on the tail of the wave.

It has been determined from various tests with surge generators, as shown by Messrs. Foust and Kuehni in the *General Electric Review* for December 1932, that permanent magnets exhibit an effect which can be attributed to eddy current shielding which is dependent upon the speed of the wave.

The authors state that magnets 9 mils in thickness were used but do not state the composition of the permanent magnet material. It would be expected that the calibration curve shown in figure 8 would vary appreciably depending upon the wave shape used to obtain the calibration.

It is also an established fact that masses of highly conducting material in the field of a lightning surge have a pronounced influence upon the shape of the magnetization field and consequently upon the degree of magnetization encountered by a permanent magnet. While it is not possible from the description in the article or from figure 5 of the paper to evaluate exactly the amount of conducting material in the field of the magnetizing coil, it appears there is a considerable amount of aluminum and other material within this field. I should like to ask the authors if they have evaluated the effect of various wave shapes with a given crest value upon the calibration curve and if they have evaluated the effect of the highly conductive material in the field of the magnetizing coil.

The mechanical vibration is shown by figure 11 of the paper to have a pronounced effect in demagnetizing the unit magnets. This effect might be expected to vary depending upon the permanent material used and to be less for a high coercive force material such as Alnico than for lower coercive force material such as chrome steel. I should like to ask the authors if this effect has been evaluated for different permanent magnet materials and if they have found it to be important.

C. F. Wagner and **G. D. McCann:** As stated in the paper, each of the instruments described has certain advantages and also certain limitations. It appears to be generally agreed that the cathode-ray oscillograph is the best available means for measuring wave form. However, its cost sets a very definite limit to its applicability. In the fulchronograph the authors have attempted to develop an instrument that is simple, reliable, rugged, and cheap. It is capable of determining certain characteristics of lightning that are felt to be controlling in the design of protective equipment and at the same time it is sufficiently low in cost to be used in large enough quantities to provide statistical data regarding these characteristics.

It is recognized that the limit of analyzing ability of the fulchronograph does not extend to waves of duration less than 50 microseconds although it will register the presence of such waves in crest magnitude. However, from the standpoint of protection, a knowledge of the wave shape of surges of less duration than these are not of very great importance. The cathode ray oscillograph using a logarithmic sweep loses a certain portion of the record during the charging period of the sweep circuit. The fulchronograph is capable of identifying multiple strokes having very small time intervals without the loss of the dead portion characteristic of the cathode ray oscillograph circuits described to date.

Mr. Hagenguth is of the opinion that the high-speed fulchronograph will give a confusing picture of a discharge consisting of multiple strokes if the total discharge time is larger than one revolution of the wheel. This would undoubtedly be true if the slow-speed fulchronograph were not also used as is our practice in all important installations. In applying the information obtained from these investigations it is desirable to know the duration of the high current components, a time which is usually not greater than 500 microseconds. This interval covers only about three per cent of the periphery of the high-speed wheel. The likelihood of two components in different revolutions of the wheel falling within this same three per cent of the periphery is very small and of course the components may be much shorter than the three per cent assumed. As an example, one record obtained having a total duration of $^{1}/_{3}$ second contained 22 components and it was possible to distinguish each of these on the high-speed wheel. A record of such a large number of components is quite unusual. A record of fewer components should, in general, offer no confusing picture of the discharge. The low current components are of importance only as their duration is sufficiently long to measure on the slow-speed wheel.

Mr. Hagenguth also states that in their investigations with the stationary links they found that the link was easily affected by surges of opposite polarity and induction of nearby conductors. In the case of the fulchronograph these factors have been largely eliminated because of the rotation of the wheel, the shielding provided by the steel cover, and the greater frequency with which the fulchronographs, being smaller in number, can be and are inspected.

Mr. Goss raises the question of the wave shape of the calibrating current and the effect of neighboring conducting masses. Tests made on the magnetic material by means of chopped wave fronts as short as $^1/_2$ microsecond showed no eddy current effect. The supporting blocks for the coils are micarta so that aside from the laminations of the magnetic circuit of the high sensitive coil and the aluminum of the wheel there are no large conducting masses close to the links. The links are mounted in an aluminum disk $^1/_2$ inch thick and the disk is approximately $^1/_8$ inch from the end of the magnetizing coil. Tests made with different wave shapes during preliminary design of the instrument showed that the presence of the aluminum had no effect on the calibration. The mechanical vibration tests described in the paper were made only for the particular material which is being used.

Mr. Foust states that with the use of several links located at different distances from the conductor, records are provided "which discriminate definitely between single unidirectional surges and oscillatory or repeated surges". Perhaps he did not mean exactly what was said. Of course the demagnetizing effect of a current in the opposite direction following the original current permits an evaluation of the magnitude of the reversal in current but if the original current is followed by a repeated surge of the same polarity, the link will record only the magnitude of the greater. As stated previously, all fulchronograph installations are inspected either after every storm or at least once a week and the chance of obtaining more than one stroke on the wheels is very small.

Mr. Foust questions the justification of drawing a smooth line between the points on figures 13 and 14 of the paper. The time intervals between these points are 43 microseconds as the possibility of any of the points being obtained on successive revolutions of the high-speed wheel is eliminated by the record obtained on the slow-speed wheel. From the standpoint of the performance of protective equipment this interpretation of the tests is certainly satisfactory and it is highly improbable that successive impulses would occur at time intervals as small as 40 microseconds.

Mr. McMorris infers that the field record of figure 14 is intended to be representative of arrester discharge currents. This paper is confined to a description of the instruments developed for the recording of lightning surges. Figure 14 is merely illustrative of the type of record obtained.

The inability of the fulchronograph to record wave fronts has been mentioned in the paper and reiterated by several discussions. The surge-front recorder provides a means of measuring this property of the surge. It is recognized as stated by Mr. McMorris that the effect of a rather fast decay of current on the tail of the wave causes a reversal of current in the auxiliary coils of this instrument. Two magnetic links in different parts of the field of these coils serve not only to increase the recording range of the instrument but also detect the presence of such a reversal of polarity. Furthermore, from the readings of these two links, it is possible not only to determine the front of the wave but also the maximum rate of change of current on the tail of the wave. These considerations are based on the presence of only one component of surge current which can be verified by the simultaneous record obtained by the fulchronograph. For cases in which the effect of the tail of the wave may be neglected, the instrument will record the order of magnitude of the rate of change of current of that impulse in the train for which the rate of change is maximum.

The Output and Optimum Design of Permanent Magnets Subjected to Demagnetizing Forces

Discussion and authors' closure of paper 40-91 by A. J. Hornfeck and R. F. Edgar, presented at the AIEE summer convention, Swampscott, Mass., June 24–28, 1940, and published in AIEE TRANSACTIONS, 1940, pages 1017–24.

H. T. Faus (General Electric Company, Lynn, Mass.): A fundamental reason for the difficulty of making accurate calculations of the performance of permanent magnets is that the effect of magnetic leakage is so difficult to estimate. In the case of magnets of irregular shape adjacent to iron, accurate calculations are almost impossible. The problem is analogous to that of an electrical circuit comprising metallic conductors immersed in salt water.

A relation which I have found useful in arriving at a first approximation of a design is that the air gap reluctance should equal the magnet reluctance. The reluctance of the magnet is estimated on the basis of the maximum permeability of the material from which it is made. In the case of a magnet of uniform cross section having an air gap area equal to the cross section of the magnet, the length of the magnet should equal the length of the air gap multiplied by the maximum permeability of the material. For Alnico I, this value is 12, for Alnico II, it is 10, and for chrome magnet steel, it is 100. This method provides only for the magnetomotive force to overcome the air-gap reluctance. Magnetomotive force to resist other demagnetizing forces must be provided by increasing the magnet length.

In many problems of magnet design, there is little incentive to attempt a detailed calculation of the performance, either because mechanical features limit the magnet to a particular size and shape, or because so little work is involved in determining the best proportions by cut-and-try methods. However, there is an increasing number of applications requiring more accurate methods of calculation, which makes this paper a very timely one.

A. J. Hornfeck: We wish to thank H. T. Faus for his pertinent remarks. Relations such as he suggests are very useful in the design of permanent magnets. It is very desirable, of course, to have such relations supplemented by theoretical considerations such as those outlined in our paper, so as to facilitate their application to structures of different shapes and sizes.

In planning this paper we considered devoting some part of it to magnetic-leakage calculations. However, such calculations were not included for fear of unduly lengthening the paper. They seem a proper subject for separate discussion. Magnetic leakage is obviously a function of the geometry of the structure. It is entirely possible that general methods of including leakage in design calculations without requiring complicated mathematical analysis or flux maps may be worked out for certain types of magnetic structures. Dimensional analysis and the theory of models should be particularly useful in this work.

It is believed that the continuing improvement of present alloys and the development of new alloys of even greater available energy will stimulate new uses for permanent magnets at an accelerated rate. Unless engineers and designers have reliable methods of calculating a permanent magnet for a particular application, considerable waste in the utilization of such materials will result. It is hoped that our paper will serve some purpose in enabling the engineer to understand the operation of a permanent magnet under a variety of conditions and to choose the best design for his own application. Also, we hope that further work will be stimulated in the field of permanent magnet theory and design.

Performance of Traveling Waves in Coils and Windings

Discussion and author's closure of paper 40-102 by Reinhold Rüdenberg, presented at the AIEE summer convention, Swampscott, Mass., June 24–28, 1940, and published in AIEE TRANSACTIONS, 1940, pages 1031–40.

L. V. Bewley (General Electric Company, Pittsfield, Mass.): Professor Rüdenberg has presented an interesting analysis of traveling waves in windings, in which, by means of a Fourier integral, he represents the incident wave as an infinite series of sinusoidal components, and then determines from the differential equation in what fashion these sinusoidal waves can enter the winding. He finds that there is a critical (or cut-off) frequency beyond which an applied sinusoidal wave cannot penetrate the winding as a wave, but can nevertheless establish an exponential distribution which decays in place. This method of analysis, while little used by power engineers, is quite familiar to communication engineers in connection with filter theory (see, for example, chapter XI, volume II, of Guillemin's "Communication Networks").

Previous writers on the subject of transients in windings have, so far as I am aware, followed K. W. Wagner ("Progress of Waves in Windings", *Elecktrotechnik und Maschinenbau*, February 1915) in regarding the matter from the point of view of standing waves oscillating about a final, or steady-state condition, and dependent in magnitude on an initial condition (the method of "normal functions").

It is of interest to examine Dr. Rüdenberg's method in comparison with prevalent theories.

Does the New Method Confirm or Disprove Previous Conclusions?

The traveling-wave theory, as presented by Dr. Rüdenberg, does not disclose any new or unknown facts about transients in windings; nor does it lead to any different conclusions as to ways and means of suppressing or controlling these transients. Starting from a given differential equation, a permissible solution in terms of either traveling or standing waves must be equally valid, and as either method permits the calculation of any number of instantaneous space distributions, it is hardly to be expected that something will show up by one method which remained masked in the other. There will be, of course, a different "interpretation" of certain aspects, but the facts themselves must be identical.

Is the New Method Quicker?

If the *exact* solution of the differential equation in terms of traveling waves is compared with the exact solution in terms of standing waves, there is a distinct advantage in favor of the latter; because each harmonic space wave, vibrating at its own natural frequency, makes its contribution, and it is not necessary to include more than a dozen or so of these harmonics; whereas there are theoretically an infinite number of traveling wave components included in the Fourier integral specification of the incident wave, and the frequencies of these traveling wave components differ from each other by infinitesimal amounts. However, if we were to accept, tentatively, Dr. Rüdenberg's approximations (particularly the assumption that all sub-critical waves travel at the same velocity) then the traveling wave theory would present a marked advantage as a means of obtaining the instantaneous distributions. For then it would only be necessary to move a rigid distribution along the winding, at a constant velocity, and superimpose a decaying fixed distribution, in order to find the instantaneous distributions. This would be a particularly easy way to compute gradients. If this procedure were perfectly valid, it would also greatly facilitate the calculation of neutral transients; for if a winding acts like an ideal transmission line, except that it will not permit the passage of waves having a frequency higher than a certain critical value, then the whole of the theory of traveling waves on transmission lines would apply without modification.

It is interesting to note at this point that waves of arbitrary shape are taken care of by means of Duhamel's theorem if the solution is in terms of normal functions; but must be specified in terms of a Fourier integral if the traveling wave solution is given. This may or may not lead to greater complications.

Does the New Method Offer a Better Physical Picture?

It is difficult to make a choice in this respect, as each point of view has its advantages. The traveling wave theory explains the negative polarity loops near the neutral end as due to the progress of the "forerunners" in front of the traveling wave. The standing wave theory explains the same thing as due to the rapid reversal of the higher harmonics. The traveling wave theory explains distortion as due to a slight difference in velocity of its sinusoidal components. The standing wave theory explains distortion as due to a difference in frequency between its space harmonics. The traveling-wave theory explains the initial distribution as the superposition of its traveling wave (already partly protruding into the winding) and its decaying fixed exponential distribution. The other theory invokes the physical fact that the current cannot initially enter the inductive paths, and therefore the initial distribution is simply a matter of the capacitance network (this, I think, is a much simpler concept than that offered by the traveling wave theory). The traveling-wave theory makes no specific mention of a "final distribution" but supposes that such a final state will be realized following the subsidence of the traveling wave. (In his paper Dr. Rüdenberg states that the wave front of the traveling wave tends to flatten out indefinitely, on account of the difference in speed of the harmonic waves. If this were so, the final distribution in the winding would be zero. Nor must it be inferred that any such progressive flattening of the wave front is responsible for the realization of the actual final distribution—a straight line from zero at a grounded neutral to E volts at the line terminal. The only way in which the transients can possibly degenerate to the final distribution is through the agency of energy losses.) The traveling wave point of view presents, in my opinion, a much clearer picture of the gradient, as the slope of the advancing wave front is a direct measure of this gradient. The only way to find this gradient with standing waves is to compute it.

Is the New Method More Adaptable to Refinements?

Both Wagner's and Rüdenberg's theories are based on the assumption of a simple idealized winding without losses, without mutual coupling with other windings, and an infinite rectangular applied wave. Actually, however, the losses play a very important part in the transient behavior of a winding; being responsible for the realization of a final distribution, limiting the excessive gradients to the ends of the windings, and greatly reducing the envelope of oscillations. When resistance elements are introduced into the circuit, the differential equation is more complicated. Decrement factors and displacements are introduced into the solution for standing waves, and the harmonic oscillations are superimposed as before. Dr. Rüdenberg has not indicated how he would take losses into account in his theory. Of course each sinusoidal component wave will decay in magnitude, a relative displacement will be experienced, and finally the velocities of the component waves will be different. It may be that these distorting influences can be accounted for by reasonable approximations.

How Accurate Is the New Method?

Dr. Rüdenberg's solution is based on the identical differential equation used by K. W. Wagner, which is

$$\frac{\partial^2 e}{\partial x^2}-LC\frac{\partial^2 e}{\partial t^2}+LK\,\frac{\partial^4 e}{\partial x^2\partial t^2}=0$$

Wagner's equation assumes a uniform self inductance per unit length of winding, just as for a transmission line. Indeed, analytically Wagner's differential equation is the same as for a no-loss transmission line having axial capacitance in parallel with the inductance. It ignores the variation of the mutual inductance along the winding. Dr. Rüdenberg has endeavored to show that this variation is of little consequence; but his demonstration rests on the investigation of an interior section of an infinitely long winding.

Over twenty years ago, Blume and Boyajian, following an extensive experimental investigation of transformer transients by Weed, Blume, and others, concluded that the Wagner formula did not give sufficiently accurate results and that the trouble was in its failure to take into account properly the mutual flux leakages.

They then extended the analysis to more nearly include the mutual inductance (Blume and Boyajian, "Abnormal Voltages Within Transformers," AIEE TRANSACTIONS, volume 38, 1919). This differential equation is

$$\frac{\partial^4 e}{\partial x^4}+LC\,\frac{\partial^2 e}{\partial t^2}-LK\frac{\partial^4 e}{\partial x^2\partial t^2}=0$$

Now the solutions of both differential equations, in terms of standing waves, give the same initial and the same final distribution, and the same amplitudes for the space harmonics. But the natural frequencies of oscillation are quite different.

Thus, while Wagner's formula shows a ratio of harmonic frequencies (s = order of space harmonic)

$$\frac{f_s}{f_1}=s\sqrt{\frac{1+\pi^2/\alpha^2}{1+s^2\pi^2/\alpha^2}}$$

the Blume and Boyajian formula gives a ratio of

$$\frac{f_s}{f_1}=s^2\sqrt{\frac{1+\pi^2/\alpha^2}{1+s^2\pi^2/\alpha^2}}$$

in which $\alpha=\sqrt{C/K}$.

Thus the simplest test for the relative correctness of the two equations is to measure the harmonic frequencies. The most reliable way to do this is to apply a long sharp front wave and take oscillograms with the cathode-ray oscillograph. For a grounded neutral, an oscillogram taken at the midpoint of the winding will give the fundamental with a pronounced ripple, which is principally the third harmonic. This third harmonic is easily segregated. An oscillogram taken between the 25% and 75% points gives the second harmonic having the sixth harmonic as principle ripple (the fourth harmonic is zero at each of these points, and all odd harmonics—1, 3, 5, etc.—cancel out between these two points). Thus two oscillograms will yield four harmonics—1, 2, 3, 6.

Figure 1 of this discussion shows the tracings of oscillograms taken with the transient analyzer on a 3-phase 5,000-kva, 12,000-volt transformer with grounded neutral, and with the secondary either grounded at one or both terminals. This transformer had an α-factor of 11. The comparison between the frequency ratios as given by the two formulas and test is:

Space harmonic	1	2	3	4	5	6
Wagner	1	1.8	2.4	2.8	3.0	3.1
Blume and Boyajian	1	3.6	7.1	11.0	15.0	19.0
Test	1	3.3	7.2			13.0

These results are typical of those obtained over a 20-year period by many investigations on numerous transformers.

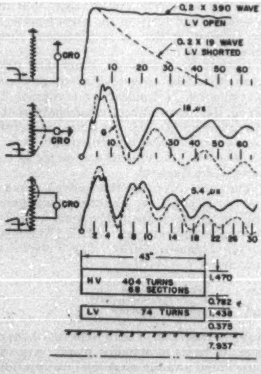

Figure 1

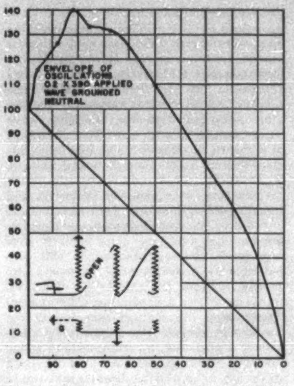

Figure 2

A further comparison is offered by the envelope of oscillations and the instantaneous distribution at different points along the winding. A typical example is given in figure 2 of this discussion. It will be noted that whereas Rüdenberg's theory specifies a maximum value of 118 per cent for the envelope of oscillations, and the extension of this crest far into the winding, the Blume and Boyajian theory gives a crest of 140 per cent confined to a short portion of the winding about 15 per cent in from the line end. Furthermore, the instantaneous distributions agree well with the Blume and Boyajian predictions.

L. F. Blume (General Electric Company, Pittsfield, Mass.): It is the rule rather than the exception that the solution of an engineering problem is greatly facilitated by finding the appropriate approximation. The validity of an approximation is determined solely by whether the reliability of the quantitative results obtained are good enough for the practical purposes concerned.

Dr. Rüdenberg, starting out with a theoretical analysis, develops, by making certain approximations, a simplified solution to the abnormal voltage transients within coils and windings, and reduces the transient to a wave of constant shape, traveling at a uniform velocity throughout the winding. This major simplification is brought about, first, by the neglect of a component of mutual inductance. Although the differential equations employed contain terms concerned with mutual inductance, these, in the course of the development become restricted, or so modified that the relation between the order of harmonic and its frequency becomes more nearly a constant value; so much so in fact that Dr. Rüdenberg feels justified in making the second approximation of assuming a linear relationship between them. By these approximations constant velocity is obtained for all the harmonics, and from this it follows that the penetration of the wave within the winding occurs without distortion. The interesting and very practical question is, do these several approximations introduce appreciable errors in the distribution of the maximum voltage stresses?

It is difficult for me to be sure that a correct quantitative solution can be arrived at by using the approximations which Dr. Rüdenberg employs. Transformer coils in a winding are physically so close together that the fluxes produced, and the voltages induced become much more of a community phenomena, rather than a self-induced phenomena, and it therefore seems that it is necessary to integrate the current in the turns, or coils, to obtain the flux at any point, and again to integrate the flux distribution to obtain the induced voltages. It would seem that the neglect of this fact would result in very appreciable errors.

The method which has been successfully used in America for many years (Blume-Boyajian paper "Abnormal Voltages Within Transformers," AIEE TRANSACTIONS, 1919, pages 577–614) in the predetermination of abnormal voltages within transformers, is mathematically equivalent to the one developed by Dr. Rüdenberg excepting for the treatment of mutual inductance, and I believe it represents more closely the phenomena under consideration. It uses exactly the same method which transformer designers have employed in the calculation of mutual inductance or the reactance volts of interleaved transformer windings, assuming that the much higher frequencies involved do not affect its validity. By this method a close correlation has been obtained between test and calculated values.

The results obtained by this method which differ from that obtained by Dr. Rüdenberg are:

1. There is no simple relation between wave length and frequency, and in consequence the wave undergoes a continual distortion of shape as it penetrates the winding.

2. There is no critical frequency, and therefore the distinction between a super and a subcritical frequency is not valid.

3. It is rather surprising that in spite of these wide divergencies, the quantitative values of voltage stress distribution are not so far apart. Dr. Rüdenberg's method gives somewhat smaller values of voltage stress to ground.

It is difficult to gauge the accuracy of the approximations which Dr. Rüdenberg uses by a theoretical discussion alone. An examination of a large amount of relevant test data is also essential, such as those presented by Mr. Bewley. This task, however, is made difficult as a general problem, owing to the fact that there are so many types of windings to be considered. Mathematical treatments assume a rather simple arrangement of windings and coils, as compared with what often exists in practice, and for this reason test results must be interpreted with considerable caution. So many diverse arrangements of coils make up transformer windings that it is impossible to say that any one method of analysis is sufficient for all practical purposes.

A. Boyajian (General Electric Company, Pittsfield, Mass.): I welcome this paper by Dr. Rüdenberg as a valuable contribution to the literature of transients in transformers, presenting, as it does, a point of view on which relatively little is to be found in the Institute records. I welcome it even though its point of view diverges a great deal from mine: the literature of no subject may be considered adequate until the major alternative points of view have been adequately covered in it.

The prevailing point of view on the oscillations of a transformer winding is that of standing waves, while Dr. Rüdenberg's view is that of traveling waves.

It might appear at first blush that the traveling wave concept must be the simplest, the most direct, physical way of considering the transformer phenomena resulting from disturbances at the terminals of a winding: thus, one might think that a wave traveling on a transmission line reaches the terminal of a winding, part of the wave enters the winding, travels along the thousands of turns of the winding until it reaches the neutral or the other end of the winding; there, part of the wave is reflected, etc., etc.; that this to-and-fro travel of the wave within the winding constitutes the transformer phenomena; and that it would then be for the mathematician to calculate the velocity of the wave along the turns of the winding, whether or not the wave undergoes any change of shape.

We may concede that this point of view can be developed mathematically, but we may well consider what price it demands.

According to the traveling-wave conception, current and voltage waves travel together, and accordingly we will have to assume that when the entering wave has reached in course of time the mid-point of the winding, the second half of the winding is as yet entirely free from current and voltage, and knows nothing about them. But how shall we fit this with our physical conception that a sudden current in the first turn must induce a voltage in the last turn by mutual induction, without requiring the current to travel to the last turn? Mutual induction between turns and windings is the most characteristic feature of a transformer, and a mathematics which does not explicitly recognize this does some violence to our physical picture, even if it should in some cases give correct final numerical values to the stresses.

Now, it may require appreciable time for the current in the first turn to travel the miles of intervening conductor to reach the last turn according to the traveling-wave theory, but the flux generated by the sudden current in the first turn need travel only 5 to 10 feet to cut clear across all the turns of the winding and induce voltages in them before any current has reached them. Thus, the simple traveling-wave conception does not fit very well a winding with closely coupled turns.

The mathematical formulation attempted in the earlier part of Professor Rüdenberg's paper, which could be said to be based on traveling waves and which would give correct results is one which involves the Fourier integral and implies a series of waves of infinite wave length coming from both sides of the winding, not merely from the point of disturbance: a type of waves which are altogether foreign to ordinary conceptions of traveling waves and are of no help to the average engineer in forming a physical picture of the phenomena.

In the latter part of his paper, Dr. Rüdenberg does describe the progress of a slowly traveling wave in a winding, a wave similar to the common conception of a traveling wave, but this result is secured on the rather over-simplified assumption that up to a certain critical harmonic all harmonic waves travel with the same velocity in the winding, assuming that the inductance of any portion of the winding is directly proportional to its length, just like a transmission line, and that the mutual effect of one portion on the other can be ignored.

In contrast with this, the standing wave conception assumes that the dielectric field, in which the winding is immersed, establishes a voltage distribution throughout the winding at the very first instant of the impact of the disturbance, and imposes thereby a certain pattern of standing harmonic waves on the winding at the instant of the impact of the wave. The winding oscillates to each such space harmonic at whatever frequency may be associated with that space harmonic in that particular winding. Thus, successful application of this theory in a relatively simple manner does not place any restriction whatever on the frequencies of various space harmonics and therefore lends itself not only to a clearer understanding of the phenomena consistent with our standard notions, but also to more precise predictions, as various experimenters have verified.

Finally, the standing wave conception has justified itself by that very important test, namely, ability to point out how the apparatus can be improved. This has been accomplished by the development of the shielded nonresonating windings and the sinusoidally shielded windings.

J. F. Calvert (Northwestern Technological Institute, Evanston, Ill.): Doctor Rüdenberg has presented a very interesting mathematical concept, and the appearance of the calculated results show the same general type of voltage variations as are obtained by test. The question naturally arises can this analysis be applied to specific machines in the design stage so as to predetermine all the oscillations and their frequencies? If this can be done, much more can be calculated concerning the higher harmonic oscillations than has been possible heretofore, especially with regard to rotating machinery.

This brings up the very vital question of the calculation of the machine constants—particularly the inductance calculations where iron is present. So much time and effort have been expended upon the calculation of the 60-cycle inductance constants, that it would be very desirable if those required under impulse conditions could in any way be correlated with some of the 60-cycle values. However, whether or not this can be done, clearly defined methods are needed, and in view of the marked difference in the physical proportions and iron and copper arrangements of inductance coils, core type transformers, shell type transformers, and rotating a-c machines, I believe that the method of treatment for each type should be made available by the author for impulse and switching problems.

From that part of a paragraph which appears directly below equation 7 of the paper, one would judge that the author assumes the iron to act almost as a perfect damper or electric shield rather than as a magnetic material. No flux penetration into the iron seems to be the assumption there. This, I am inclined to believe is not always the correct viewpoint to take, and I would be interested to see the evidence available—theoretical or experimental—for the range of frequencies met with in the harmonic analysis of lighting and switching surges. In the tests which were reported in the paper "Protecting Machines From Line Surges", ELECTRICAL ENGINEERING, 1934, pages 139–46 (reference 12 of the paper) we found one or two things which bear on this point. When a $1^1/_2$x40-microsecond wave was applied across the armature winding of a synchronous machine, then despite the presence of a squirrel cage damper winding, an electromagnetically (and not electrostatically) induced voltage of very appreciable magnitude appeared in the field winding of that machine. Also the impedance function (impedance-frequency curve) for the armature winding was affected not only by the terminal connections of the armature winding, but also by the number of stator parallels, rotor position, etc.

To summarize: (1) I hope the author will indicate in his closing discussion exactly what assumptions he makes for the calculation of the inductance and capacitance constants under impulse conditions for reactors, core-type transformers, shell-type transformers, high-speed turbine generators, salient-pole synchronous machines with and without damper windings, and for induction motors. (2) I hope that the author will show in more detail his calculated and his test data on a representative group of specific machines on which his work has been applied. (3) I hope that the author will submit a subsequent paper, to show in some detail how the author's constants should be computed for these cases.

I believe that if the method of calculation of these constants is presented and the results of check tests up to and including the higher harmonics are given, then the usefulness of this very able theoretical analysis will be greatly enhanced for the electrical machine designer who, I believe, is the man most to be benefited immediately by this particular type of investigation.

V. Karapetoff (Cornell University, Emeritus): Dr. Rüdenberg's paper is both valuable and stimulating for further research. The remarks below are intended more as an indication of the next natural steps, rather than a criticism of his methods or results.

1. With discrete coils, the problem seems to require a combination of differential equations within each coil with finite-difference equations for the whole winding consisting of separate coils.

2. The assumption of constant parameters for the partial inductances and capacitances seems to be too far from the actuality. Equations with variable parameters should be tried, or else the elementary magnetic linkages and electrostatic fluxes used directly in the equations. This will constitute a closer approach to the actual phenomena.

3. With simpler wave phenomena, a classification into standing and traveling waves has been fairly adequate, but for the transients analyzed in the paper one or more advanced, more general concepts are desirable. Thus, as an analogue, with the advent of phase or frequency modulation in radio the concepts of sine waves and their harmonics has become inadequate and the radio man will have to learn to think in terms of Bessel functions. With ultrahigh-frequency oscillators, shapes of bodies will probably be used requiring spherical har-

monics and other specialized functions. This tendency toward higher and higher mathematical concepts and operations seems to be irresistible and we simply shall have to have a specialized group of experts to handle these problems, or at least to know how to translate them into the language of pure mathematicians.

4. Much progress in pure mathematics has been due to the stimulus of astronomy, physics, biology, etc. Even though the equations in the form proposed above may seem at first unsolvable they will signalize a distinct progress in our account of the phenomena involved. Later they will undoubtedly stimulate practical and theoretical mathematicians to develop approximate solutions: analytical, graphical, electrical, or mechanical. I should rather see an expert mathematician simplify an originally unsolvable equation than an engineer make an inadequate simplification from the start.

5. The problem of waves and oscillations in coils and in windings is an excellent illustration of the need for closer co-operation among pure mathematicians, applied mathematicians, mathematical physicists, experimental physicists, mathematically inclined engineers, experimental engineers, and designers, all working toward the same end and none capable of solving the problem alone. It is for the executives of industrial concerns and of institutions of higher learning to see to it that such a co-operation be established on an efficient and permanent basis.

R. Rüdenberg: A large part of the items brought up in the discussion pro and contra the analysis chosen in my paper can be arranged in three groups, and I believe they will be clarified to some extent by the following remarks:

1. Standing or Traveling Waves

Although it is certain since the investigations of D'Alembert, Bernoulli, and Dirichlet more than a hundred years ago that solutions by standing and by traveling waves are equivalent and can be mathematically transferred into each other, their physical conception is different and therefore it is sometimes convenient to clarify technical questions with the one and sometimes with the other form of analysis. I feel that the experimental result expressed by figure 8 of the paper concerning the velocity of propagation of surges along wires of transformers approaching the Maxwellian velocity of light, can be more easily understood by the conception of traveling waves, and brings these phenomena in closer contact with similar fields of science.

The fact that many experimental results of other investigators also agree well with the wave propagation shown in figures 16 and 17 of the paper may be proved by the accompanying figures 3 and 4, of the former representing the successive voltage distributions over a transformer with grounded neutral (taken from reference 14 of the paper), the latter showing the distribution over an alternator with insulated neutral (taken from reference 12 of the paper). Magnitude and position of the maximum voltage, mentioned by Professor Bewley, depend upon the ratio of head length and winding length and in figure 3 are closer to figure 16 of the paper than in Bewley's figure. If waves such as those of figures 16 and 17 travel repeatedly over the winding to and fro with increasingly flattening front, the final distribution does not approach zero, as Professor Bewley has guessed, but is given by the average of the initial traveling wave shapes over a period and coincides with the final distribution usually assumed.

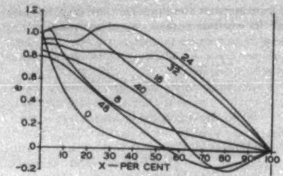

Figure 3. Consecutive distributions of voltage measured in a transformer with grounded neutral

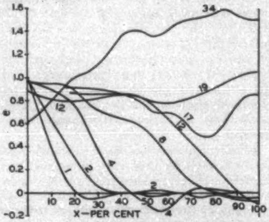

Figure 4. Consecutive distributions of voltage measured in an alternator with insulated neutral

In principle there exists a difference of much deeper significance in the two conceptions: Traveling waves can be developed with respect to the frequencies contained within the wave, forming a continuous spectral distribution, or a Fourier integral, which is well known for most of the interesting wave shapes. This spectral distribution, and therefore the actual wave shape, can be modified substantially only by refraction of the wave at the terminals of the winding, due to the difference of the interior characteristics of the winding and the exterior characteristics of the network. Within the winding the spectrum and the wave shape remain substantially unchanged, however, and suffer only a slight distortion by dispersion, caused by lack of constancy of the velocity. Therefore we can consider separately the propagation of the surge within the winding and the reflection and refraction at the ends. Thus the external network influences only alterations of the wave shape by refraction but not by propagation and reflection. Magnitude and distribution of the natural frequencies play no part in this analysis and therefore are entirely irrelevant in the performance of traveling waves.

Standing waves, on the other hand, enter if the phenomena are developed with respect to the natural frequencies of the winding. These frequencies, however, depend not only on the winding proper, but quite as much on the external system connected to the terminals. Thus they are by no means constant parameters of the winding. All standing waves, which give by summation the voltage along the winding, are dependent therefore on the characteristics both of the winding and of the exterior network. This interaction, which refers to amplitudes as well as to frequencies and wave lengths of standing waves, is in contrast to the analysis by traveling waves, where the internal and external characteristics enter separately and, in my opinion, this facilitates the survey.

These differences may be responsible for the fact that the magnitude of the internal stress of the interior coils can be computed much more easily by the conception of traveling waves, giving, moreover, a simple expression for the highly important duration of the internal stress.

The differences of the two conceptions are also evident in the method for obtaining the initial and the final distribution of voltage over the winding. With traveling waves these distributions result from the solution of the differential equations for any form of incident wave without further hypothesis. With standing waves the distributions are derived only with additional static considerations, foreign to the differential equation, and then are used as boundary conditions for determining the constants of integration. With this procedure, the standing-wave conception naturally gives identical initial distributions and identical final distributions for every differential equation.

There is no difficulty in applying the traveling-wave conception to the Blume-Boyajian differential equation, given by Professor Bewley in his second equation. The correlation of velocity and frequency then gives, using the statement of equation 17 of the paper but with Bewley's notation,

$$\omega = -\frac{v^2}{\sqrt{\frac{1}{LC}-\frac{K}{C}v^2}} \tag{a}$$

while Bewley's first equation, due to Wagner and which I prefer, gives

$$\omega = \sqrt{\frac{C}{K}\left(\frac{1}{LC}-v^2\right)} \tag{b}$$

corresponding to equation 26 of the paper. The two relations are represented in the accompanying figures 5 and 6 for different capacitive ratios K/C. We see that the traveling velocity of harmonic waves along wires of transformers, according to Wagner's and my equation, starts with the velocity of light and decreases steadily to zero with in-

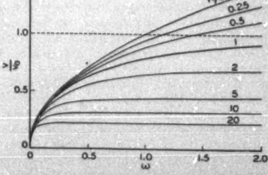

Figure 5. Wave velocity against frequency according to the Blume-Boyajian differential equation

creasing frequency. But according to the Blume-Boyajian equation the wave velocity starts with zero and increases steadily up to a limiting value.

Experimentally, my own tests, some of them given in figure 7 of the paper, are decisively in favor of the accompanying figure 6. Theoretically, sudden impacts, according to Fourier's theorem, always comprise the range of the high frequencies up to $\omega=\infty$, and since for high frequencies the velocity in the accompanying figure 7 becomes constant, there is the cogent conclusion that, according to the Blume-Boyajian differential equation, steep impacts should propagate without dispersion and thus without distortion throughout the winding. This seems in contrast to expectation and to experimental results. This discrepancy, I dare say, was one of my reasons for a revival of this old but not obsolete problem. A second reason was to show how the traveling-wave conception, so fruitful in other fields, works out with closely-wound windings.

2. Inductive Interaction

In the discussion was said rightly that in equation 10 of the paper there is neglected a remainder of the mutual inductance of all turns and that the differential equation is derived for a relatively long coil. It is possible, however, to state the conditions under which these approximations are valid.

For oscillations of any frequency forming harmonic waves along the winding, the current within the elements of the winding is

$$i_m=I\cos(\varphi+\alpha mw)\cdot\epsilon^{j\omega t} \qquad \text{(c)}$$

φ being an arbitrary angle, α the wave density in space, and m the distance between the elements. For $m=0$ we have the current within the element n under consideration

$$i_n=I\cos\varphi\cdot\epsilon^{j\omega t} \qquad \text{(d)}$$

The second difference of the currents in the elements with distances $\pm m$ from the element n considered becomes, therefore,

$$\begin{aligned}\Delta^2 i_{n,m}&=i_m-2i_n+i_{-m}\\&=2I\cos\varphi\cdot(\cos\alpha mw-1)\cdot\epsilon^{j\omega t}\end{aligned} \qquad \text{(e)}$$

The mutual inductance μ, decreasing with the distance between the elements, can always be approximated within the most important range by an exponential expression

$$\mu_{n,m}=\mu_n\epsilon^{-\eth mw} \qquad \text{(f)}$$

in which μ_n is the maximum value and $\eth$ the rate of decrease.

For evaluating the summations in equation 10 of the paper, we replace them by integrals since the number of elements is large. The first member of the right-hand side then becomes, computed for both sides of a long winding, including the self-inductance, and with abbreviation $x=mw$,

$$i_n\Sigma\mu_{n,m}w=2i_n\mu_n\int_0^\infty\epsilon^{-\eth x}dx=2i_n\frac{\mu_n}{\eth} \qquad \text{(g)}$$

For the second member we obtain, with use of equations *e* and *f*,

$$\begin{aligned}\Sigma\mu_{n,m}w\,\Delta^2 i_{n,m}&=2I\cos\varphi\cdot\mu_n\epsilon^{-j\omega t}\times\\&\qquad\int_0^\infty\epsilon^{-\eth x}(\cos\alpha x-1)dx\\&=2i_n\mu_n\frac{-\alpha^2}{\eth(\eth^2+\alpha^2)}\end{aligned} \qquad \text{(h)}$$

The ratio of the two members of equation 10, which was neglected in the fundamental equation 12 of the paper, is, therefore,

$$\eth=-\frac{\alpha^2}{\eth^2+\alpha^2} \qquad \text{(i)}$$

This ratio is always negative, depends only on wave density α and on attenuation $\eth$ of the mutual inductance, and forms a correction factor to the first member. With regard to the change in space, $\eth$ is the reciprocal of the space constant of the mutual inductance, while α is the reciprocal of the wave length $\lambda/2\pi$ of the oscillation.

The mutual inductance between two equal circular coaxial rings in air is given by the accompanying figure 7 as function of the ratio of distance y and radius r. The average subtangent of this curve forms the space constant of an equivalent exponential curve, and within the important range the subtangent is smaller than the turn radius r.

The mutual inductance of two turns or coils due to the air flux in the region beside a screening core is given by a well-known picture, as in the accompanying figure 8, with two conductors over a perfectly conducting ground. This figure shows the mutual inductance as function of the ratio of distance y and height b. The average subtangent of this curve within the most important range is at maximum of the order of the height, which equals in our problem the insulating distance b of the turns or coils from the secondary or the ground.

Therefore the correction factor ρ in equation *i* is small for all oscillations the wave length λ of which is substantially larger than the space constant, just determined for two important cases. This gives the condition

$$\lambda>2\pi r \quad\text{or}\quad \lambda>2\pi b \qquad \text{(j)}$$

Thus we see that for reactor or transformer windings the fundamental equations 11 and 12 of the paper are valid down to short waves, the length of which in axial direction approaches the order of the radius for air-core windings, or of the insulating distance to the secondary or to the iron for steel-core windings.

For machine windings the mutual inductance decreases rapidly according to the slot pitch, and therefore the limit of wave length corresponds here to 2π times this pitch.

We have considered preponderantly the air flux of the winding because the core flux in steel sheets has only moderate significance for the rapid variations here in question and may be considered, if necessary, by an addition to the distance b in the accompanying figure 8. In transformers or machines under actual operating conditions, the core flux vanishes almost completely by the action of the secondary windings. Only with special terminal conditions may a core flux common to all turns be produced. However, it will then be so large compared with the air flux that it forms an extra oscillation of its own with low frequency, which scarcely interferes with the dangerous rapid oscillations released by the action of travelling waves. Such a relatively slow oscillation can be treated separately in a quasi-stationary manner using lumped constants of the winding.

We see therefore that equation 12 of the paper with the definition in equation 11 comprises completely the mutual inductance of all turns or coils under the conditions just derived.

The influence of the ends of the winding, and of the core flux as well, can be further clarified by the accompanying figures 9 and 10, in which the primary and secondary windings of a transformer are shown within the gap between steel core and tank. In figure 9 the magnetic lines of force are drawn radially through the primary coil of finite length. The magnetic lines of force pass undisturbed across the secondary winding and end perpendicularly at the iron surfaces through which they close themselves unrestrained by eddy-current formation. This

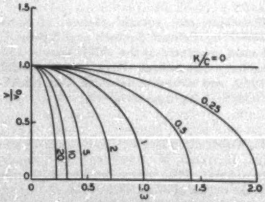

Figure 6. Wave velocity against frequency according to the paper

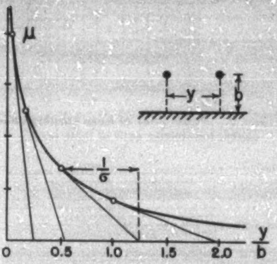

Figure 8. Mutual inductance of turns around a screening core dependent on their axial distance

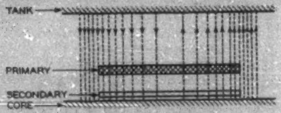

Figure 9. Radial lines of force crossing concentric transformer coils of finite length

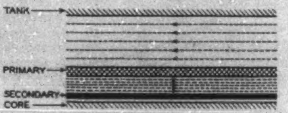

Figure 10. Axial lines of force flowing parallel to long concentric transformer coils

picture corresponds to the Blume-Boyajian equation. In figure 10 the lines of force are drawn axially to the coils which are long compared with their distance of insulation. Eddy-current formation in the iron or secondary currents in the closed low-voltage winding shield the core completely. This picture approaches the conceptions for the differential equation of this paper.

If the secondary is open and the coils are short axially, figure 9 may give an adequate picture for low natural frequencies. If the secondary is closed, either directly or through a low impedance, and if the insulating distance between the windings is small compared with their axial length, figure 10 will be nearer to reality. In some cases a superposition of both assumptions concerning the lines of force may be useful and it might be a rewarding task to pursue such a problem further. If the low-voltage winding under operating conditions is near the short-circuit state for the wave frequencies here in question, as is the fact with most larger transformers, it does not seem probable that turns or coils lying far apart from each other have a mutual inductance considerably larger than indicated by figure 7 or 8, as is assumed by Mr. Boyajian. The core flux is then suppressed, as in figure 10, and the effective l is constant and is proved, I think, for the first time in this paper, to be given directly by the regular self-inductance of the entire primary winding under operating conditions.

If, on the other hand, the closing impedance of the secondary is so high and the frequency so low that in spite of eddy-current screening a considerable core flux develops, closing itself either through the yoke or only locally as in figure 9, a substantial dependence of self-inductance on frequency will occur, due to the varying depth of penetration of the flux into the steel sheets. This must lead to a relative decrease in the value of the lower natural frequencies. The differences in the spectral distribution found by various experimental investigators may possibly find their explanation in these facts.

3. Capacitive Interaction

It is certainly remarkable that the various assumptions about the flow of the magnetic lines of force, or about the inductive coupling of each and every turn, do not influence considerably the results of the different theories with respect to the internal stress in the winding. The reason for this is the agreement of all investigators about the capacitive coupling, qualitatively as well as quantitatively, and that the internal stress in all theories is dependent mainly on the capacitive relations and not on self- or mutual inductance. Therefore the practical means for improving transformers with regard to surges are nearly identical according to all these theories. Actually, a striking success from increasing the internal capacitance k of transformers was secured as far back as 1914 (see reference 1 of the paper), when for the first time I published the mechanism and the effects of the internal interaction in coil-windings without, at that time, giving details of the calculation.

The great improvement of transformers by external shielding, as developed by Messrs. Blume, Boyajian, Bewley, and their collaborators, is based materially on static considerations of capacitive networks without regard to waves, be they standing or traveling, or to magnetic interaction of any character. Thus the present practical consequences are not influenced by preferring either one or the other theory. However, knowledge of the more detailed phenomena will be increased by viewing them from different angles and this may lead to further improvements.

4. Additional Queries

The discrepancy about the lowest natural frequency, mentioned by Professor Bewley, which appears when comparing the theories as well as the experiments of different investigators, certainly needs further elucidation. Although these slowest oscillations are important in other directions, it is well to have in mind that they play practically no part in the internal stress of the winding, which is preponderantly affected by the higher frequencies. In some cases terminal capacitance may add to the lowering of the fundamental frequency, due to the bushing or to the first coil side opposite a ground ring or to the surge generator during testing. Such extra capacitance can even produce a low frequency oscillation of its own.

The effect of energy losses in windings, which Professor Bewley mentioned, can be treated in the traveling-wave theory in the same manner as energy losses in smooth lines are usually treated. They result in a further flattening of the wave front which adds to that caused by internal capacitance. With regard to the remarks by Mr. Blume and Mr. Boyajian, I think that the last section of my paper shows that I never supposed the velocity of all harmonic travelling waves to be constant. The flattening of the wave front is derived from the variation in velocity of the partial waves. However, the entire group of waves proceeds with fairly constant velocity, though its shape is slightly distorted. I think, therefore, that the advantages which Professor Bewley tentatively credits to the travelling-wave theory really exist.

It is relatively simple to derive from the conceptions of the paper numerical values of the surge constants for various types of windings, as Professor Calvert suggests. This will be dealt with in a subsequent publication. Furthermore, the problem of the different natural frequencies of a winding under various conditions of operation, such as star or delta connection, isolated or grounded state at one or more poles, first or last interruption at the grounded pole by the circuit breaker, can easily be treated in the light of the traveling-wave conception.[a]

The problem of discrete elements, mentioned by Professor Karapetoff, can be solved rigorously in the manner suggested by him. It can be extended to the interaction of different groups of elements such as turns, layers, and coils in real windings.[b] As long as the magnetic fields are preponderantly in air, the use of constant parameters has its merits. Then it is possible to solve the problem of the inductive interaction of all turns of a uniform coil by the powerful method of Maxwell's equation.[c] However, where the iron part of the field is deciding, and eddy-current formation plays a part, Professor Karapetoff's suggestion of variable parameters is certainly important, although the calculations may become complicated.

The comprehensive theoretical solution of our problem has been attempted repeatedly by mathematicians.[16,d,e,f] However, in spite of the application of very powerful methods of analysis, such as integral equations and the like, no practical results have been obtained thus far. My impression is that comprehensive experimental investigations on different types of coils, windings, and transformers, such as are now under way at the Pittsfield Works of the General Electric Company as well as at the Graduate School of Engineering of Harvard University, may be helpful in advancing our knowledge of the questions still open.

Effective Resistance to Alternating Currents of Multilayer Windings

Discussion and authors' closure of paper 40-99 by Edward Bennett and Sidney C. Larson, presented at the AIEE summer convention, Swampscott, Mass., June 24–28, 1940, and published in AIEE TRANSACTIONS, 1940, pages 1010–17.

E. Weber (Polytechnic Institute of Brooklyn, Brooklyn, N. Y.): The most important result of the very valuable contribution of the authors is their figure 4 which demonstrates the need for careful design of windings, particularly at higher frequencies. As shown in one example, an increase of copper thickness, although decreasing the d-c resistance, increases the a-c effective resistance considerably more than proportionally, so that instead of obtaining lower losses with more copper, one thus obtains very much higher losses with the attending problem of heat dissipation. With the data of this paper available, it is now possible to design strip copper windings for higher frequencies which give the lowest losses with a minimum of copper weight; that is, the most economical winding for each individual case.

Although the authors mention the additional edge effect due to the finite width of the copper strips, it would be interesting to know the limitations of the present formulas, and particularly the relative values of width and total coil thickness for which the edge effect might become appreciable. My second question is closely related to the first one and concerns the distribution of the magnetic field within and between copper sheets. The assumption of parallel field lines is a rather rough approximation and it will be interesting to have an indication of how the current distribution might be affected by a different assumption concerning the magnetic-field distribution. One might have the possibility of superimposing upon the case considered by the authors, the effect of a transverse magnetic field.

Finally, have the authors tried to obtain a solution in the case of parallel combination of n-laminae without the rather difficult ideal transposition? In such a case the current would distribute nonuniformly over the n-laminae and a very much higher resistance increase would take place. It might be well to emphasize that parallel subdivision of large conductors would not help at all in reducing the total a-c losses.

Edward Bennett: Several questions have been raised in Professor Weber's discussion. The first may be put in this specific form: Over what proportion of the width of a layer at its two ends does the "edge effect" cause the loss to substantially exceed the loss as computed from the equations for the mid-portions of the layer? We have not attempted a mathematical treatment of the edge effect for a coil of any dimensions. From general considerations and from experimental observations of the heating, we know that at the ends of the layers, the current densities may be double those near the mid-portions. In figure 2 the distance, D, (not shown on figure 2) back from the ends of the layers over which the current densities substantially exceed those near the mid-portion may be expressed in the form $D=K(MM)$. In this expression (MM) (as shown on figure 2) is the separation between the outer layers which carry currents in opposite directions. My judgment would be to assign the value 2 to the factor K. It should be borne in mind that our equations are derived for the case in which the width of the layer (W, in figure 2) is many times (say 20 times) the distance MM. These statements should also serve as a response to the second question raised by Professor Weber.

The third question is: What is the solution for an n-layered winding with the n layers all in parallel, but with no transpositions? An n-layered solenoid as in figure 2, or an n-layered primary or secondary as in figure 1, each layer of thickness b, and all layers connected in parallel and with no transpositions, will have the same properties as a single layer winding having the thickness nb.

An Extension of the Method of Symmetrical Components Using Ladder Networks

Discussion of paper 40-98 by Waldo V. Lyon, presented at the AIEE summer convention, Swampscott, Mass., June 24–28, 1940, and published in AIEE TRANSACTIONS, 1940, pages 1025–30.

C. Concordia (General Electric Company, Schenectady, N. Y.): In connection with the method of analysis given in this paper it may be of interest to recall a somewhat similar method presented a few years ago ("Overvoltages Caused by Unbalanced Short Circuits," by Edith Clarke, C. Concordia, and C. N. Weygandt, AIEE TRANSACTIONS, 1938, volume 57, pages 453–66; see appendix B). This previous method (see latter part of appendix B of the paper referred to) is applicable to the determination of harmonic voltages and currents of an unsymmetrical system containing any number of machines having unsymmetrical rotors, and has been used for the solution of a problem involving two such machines supplying a system with an unbalanced short circuit.

The more general, but related, problem of the complete solution of the circuit equations to obtain both transient and steady state currents and voltages is also treated in the first section of appendix B of the 1938 paper previously referred to.

Transient Starting Torques in Induction Motors

Discussion and authors' closure of paper 40-100 by A. M. Wahl and L. A. Kilgore, presented at the AIEE summer convention, Swampscott, Mass., June 24–28, 1940, and published in AIEE TRANSACTIONS, 1940 (November section) pages 603–07.

S. B. Crary (General Electric Company, Schenectady, N. Y.): As stated by the authors the derivation of the equations for electrical torque were simplified by making certain assumptions in order to avoid "cumbersome" expressions. As these assumptions necessarily limit somewhat the generality of the results, it may be in order to indicate a more complete solution for the case of simultaneous application of the three-phase voltages but which still can be written in compact form.

From the equations of Park's "Synchronous Machines—I" for the conditions of a symmetrical stator and rotor, with no initial currents or voltages, the machine at standstill and with suddenly applied three-phase voltages, that is, $x_d(p)=x_q(p)$, $p\theta=0$, $e_d=-e\sin(t-\delta_0)1$, $e_q=e\cos(t-\delta_0)1$

$$\left.\begin{aligned} e_d&=p\psi_d-ri_d\\ e_q&=p\psi_q-ri_q \end{aligned}\right\} \quad (1)$$

$$\left.\begin{aligned} \psi_d&=-x_d(p)i_d\\ \psi_q&=-x_q(p)i_q \end{aligned}\right\} \quad (2)$$

$$T=i_q\psi_d-i_d\psi_q \quad (3)$$

where

$$x_d(p)=\frac{x_d'T_0p+x_d}{T_0p+1}$$

Solving the above equations for the torque,

$$T=-\frac{e^2(x_d-x_d')}{x_d'^2T_0(m^2+1)(n^2+1)}\Big[(1+\epsilon^{-mt}\epsilon^{-nt})-(\epsilon^{-mt}+\epsilon^{-nt})\cos t-\frac{mn+1}{n-m}\times(\epsilon^{-mt}-\epsilon^{-nt})\sin t\Big] \quad (4)$$

where

$$m=\frac{1}{2x_d'T_0}\left[x_d+T_0r-\sqrt{(x_d+T_0r)^2-4T_0rx_d'}\right]$$

$$n=\frac{1}{2x_d'T_0}\left[x_d+T_0r+\sqrt{(x_d+T_0r)^2-4T_0rx_d'}\right]$$

Equation 5 can be written with the same notation as that used in the paper, or

$$T=T_s\Big[(1+\epsilon^{-\lambda_1t}\epsilon^{-\lambda_2t})-(\epsilon^{-\lambda_1t}+\epsilon^{-\lambda_2t})\times\cos\omega t-\frac{(\lambda_1\lambda_2+\omega^2)}{\omega(\lambda_2-\lambda_1)}(\epsilon^{-\lambda_1t}-\epsilon^{-\lambda_2t})\sin\omega t\Big] \quad (5)$$

where

$$\lambda_1=\frac{1}{2(L_1L_2-M^2)}\left[L_1r_2+L_2r_1-\sqrt{(L_1r_2-L_2r_1)^2+4r_1r_2M^2}\right]$$

$$\lambda_2=\frac{1}{2(L_1L_2-M^2)}\left[L_1r_2+L_2r_1+\sqrt{(L_1r_2-L_2r_1)^2+4r_1r_2M^2}\right]$$

The above equation has the term $\epsilon^{-\lambda_1t}\epsilon^{-\lambda_2t}$ instead of $\epsilon^{-\lambda_2t}$ as given in the paper and more complete expressions for the decrement factors. On the basis of the assumption made in the paper that the magnetizing reactance is large compared to the leakage reactances, λ_1 is small relative to λ_2 and the term

$$\frac{\lambda_1\lambda_2+\omega^2}{\omega(\lambda_2-\lambda_1)}\cong\frac{\omega}{\lambda_2}\cong\frac{x_1+x_2}{r_1+r_2}$$

Also the term

$$\epsilon^{-\lambda_1t}\ \epsilon^{-\lambda_2t}\cong\epsilon^{-\lambda_2t}$$

For these approximations equation 5 of this discussion reduces to equation 11 of the paper, that is,

$$T_1=T_s\left[1+\epsilon^{-\lambda_2t}-\frac{\epsilon^{-\lambda_2t}\cos(\omega t+\phi)+\epsilon^{-\lambda_1t}\cos(\omega t-\phi)}{\cos\phi}\right]$$

R. Rüdenberg (Harvard University, Cambridge, Mass.): May I ask Mr. Kilgore whether he found that the doubling of the starting torque by action of the transients was advantageous for overcoming the considerable friction at rest which prevails with many motors, if one includes their machinery of supply?

A. M. Wahl and L. A. Kilgore: The authors agree with Mr. Crary that the assumption made in the paper that the magnetizing reactance is large compared to the leakage reactance, tends to limit to some extent the generality of the results. In their experience, however, they have not known of any induction motors where this assumption did not hold true.

The authors were very much interested in the solution derived by Mr. Crary from Park's original equations for the case of simultaneous application of voltage on all three phases and note that it may be expressed in relatively compact form. It is also of interest that this equation reduces to equation 11 of the paper where the magnetizing reactance is large compared to the leakage reactance. However, the authors are wondering whether or not such a compact solution could similarly be found for the case of nonsimultaneous voltage application, that is, voltage applied to α axis 90 degrees later than that applied on β axis. Since higher torques are set up under these conditions, this solution is perhaps of more importance from a practical standpoint. It should also be noted that if the electrical torque expression becomes too complicated, considerable difficulty may be had in integrating equation 5 of the paper in order to obtain the shaft torques.

In answer to Doctor Rüdenberg's question, it is true that the high transient torques developed may be of advantage in certain cases, particularly where static friction is high. However, where such loads must be started and stopped frequently, care must be taken that the mechanical stresses in the connected equipment set up by such torques do not exceed the allowable endurance values. The object of this investigation was primarily to give the designer sufficient information to enable him to make a rational design of equipment subject to such conditions.

Progress in the Production and Application of Light

A. L. POWELL
FELLOW AIEE

For at least three decades, light sources and their application continuously have undergone rapid changes. To provide the Institute membership with a record of these developments, it has been the policy of the AIEE committee on the production and application of light to prepare at periodic intervals reports reviewing the progress achieved during those intervals. The 1939–40 committee* presents in this report a summary of the epoch-making advancements since 1936, when the last previous report was published,[1] prepared by a member and former chairman of the committee.

THERE have been numerous developments in the art of lighting during the past three years, but to the illuminating engineer this is nothing unusual. For at least three decades light sources and their application have always undergone rapid changes. It is true that the whole field of electrical engineering, being young and with a tremendous horizon, is in a constant state of flux, but those working in lighting have reason to feel particularly proud of the way that new frontiers have been attacked. To say the least, lighting is not static and those engaged in it are constantly experiencing the thrill that comes with change.

During the period under consideration there have been some epoch-making developments and numerous others that were foretold in the previous report. These take the nature of refinement and expansion of ideas promulgated several years ago.

In the last report it was pointed out that during the year 1935 more than 700 million incandescent lamps were sold, which was then a new high record. In 1936 this figure was exceeded, the total reaching 880 million. The year 1937 saw an all-time high of 955 million, and in 1938 there was a falling off to approximately 800 million; of this total, 60 per cent was what are called large and 40 per cent miniature lamps. The rate for 1939 to date indicates that this figure will be exceeded.

New Incandescent Lamps

Lamps for Photography

There probably has never been a period that has shown such a great growth in public interest in any hobby. Almost everyone is a camera enthusiast. The development of numerous types of inexpensive miniature cameras, of new types of film, of practical color film, and simple movie cameras has contributed to this end. Most of the amateur photographers are not content with natural light, but are riding their hobby for 24 hours a day. The so-called photoflash lamp has completely displaced the old magnesium flash bag, and the news and commercial photographers are requiring many forms of flash lamps. The new varieties of color film have presented lighting problems. The miniature camera has greatly increased the importance of enlarging. As a result of all this, the line of lamps designed especially for photography has grown by leaps and bounds.

The photoflood lamp series has been supplemented by three sizes, 250, 500, and 1,000 watts in blue bulbs for use with "regular" Kodachrome film. These also find application in indoor photography where artificial light is required to supplement daylight.

A 500-watt photoflood lamp with an inside aluminized reflecting surface is on the market and proves very convenient and compact.

Three years ago three sizes of photoflash lamps were listed which had bulbs loosely filled with very thin sheets of aluminum foil in an atmosphere of oxygen. This general form has been supplemented by lamps using extremely fine aluminum wire instead of foil, and the entire line has been expanded so that now no less than eight types and sizes of photoflash lamps designed for particular operating conditions are available. Space does not permit an analysis of details of their characteristics.

For amateur and professional photoenlarging there is now standardized a line of seven lamps in special white bulbs varying in size from a tiny *S*-11[†] bulb emitting 1,125 lumens to a *PS*-30 bulb emitting 15,800 lumens.

Since color photography requires light of a definite spectral composition for proper rendition, it has been necessary to make available lamps standardized to operate at a predetermined color temperature, namely, 3,200 degrees Kelvin. These, again, are of various forms and sizes (500 to 5,000 watts) and are 13 in number.

Certain classes of color photography require light sources at a still higher color temperature and five lamps (1,000 to 10,000 watts) are available that are designed to operate at 3,380 degrees Kelvin.

Lumiline Lamps

These tubular lamps with contacts at both ends are still quite popular where structural conditions make neces-

---

Paper 40-1, recommended by the AIEE committee on production and application of light, and presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940. Manuscript submitted October 24, 1939; made available for preprinting October 31, 1939.

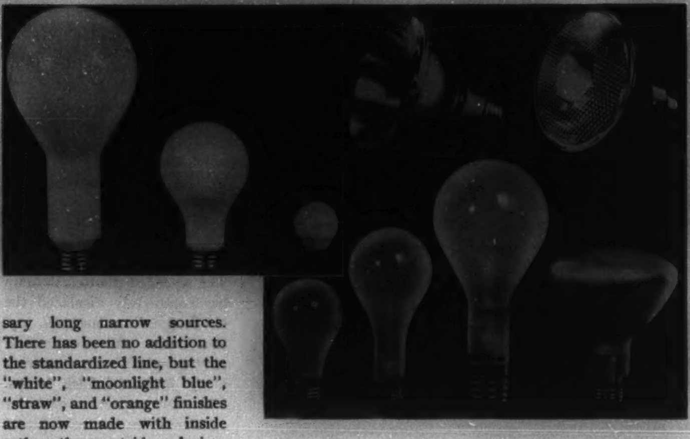
A. L. Powell was supervising engineer in the lamp department of the General Electric Company, New York, N. Y., at the time of his death, August 21, 1940.

*Personnel of AIEE Committee on Production and Application of Light: D. W. Atwater, *chairman;* S. K. Barrett, Robin Beach, W. T. Blackwell, H. B. Dates, E. E. Dorting, C. L. Dows, L. R. Gamble, C. A. B. Halvorson, Jr., L. A. Hawkins, S. G. Hibben, W. C. Kalb, R. D. Mailey, P. S. Millar, G. T. Minasian, L. C. Porter, A. L. Powell, E. M. Strong, and I. A. Yost.

The author acknowledges the co-operation of various members of the committee in supplying data and checking the manuscript.

[1] For all numbered references see list at end of report.

[†] In bulb designations the letter indicates the shape and the figure the maximum diameter in eighths of an inch.



Three sizes of photo-enlarging lamps, from the largest to the smallest (left group); photoflood lamps of the regular and reflector types (lower right group). At the upper right are (left) a typical spot lamp and (right) a typical flood lamp of the projector type

sary long narrow sources. There has been no addition to the standardized line, but the "white", "moonlight blue", "straw", and "orange" finishes are now made with inside rather than outside coloring, because of greater ability to withstand weather conditions.

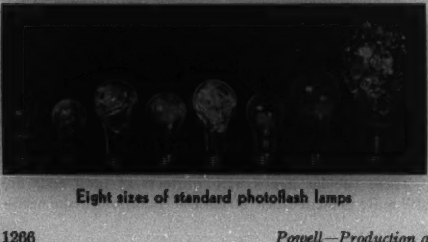
Three-Light Lamps

A considerable number of sizes of low-wattage medium-base three-light lamps have been offered for sale. In certain sizes the differences between the various steps are too small to be entirely practical and the combination of low-efficiency small filaments does not make a lamp that has much economic justification. Their novelty has given them a certain amount of popularity, however.

To meet the demand for a light source to provide higher levels of illumination from indirect portable luminaires in the home, a 200–300–500-watt *G*-40 bulb mogul-base three-light lamp has been made available.

Reflecting Processed Lamps

For several years rather large quantities of lamps with a silver coating on the hemispherical bowl of the bulb have been used for indirect lighting. The next step along this line was to coat the side walls of the bulb with reflecting material and use the lamp itself without external reflector to direct the light where needed. For this purpose, at first standard shapes of bulbs were employed, but these obviously were not designed to produce desirable distributions of light, so special filament mountings and bulbs of suitable contours were a logical step. Recently several new designs have appeared.



Eight sizes of standard photoflash lamps

Filaments of 150- and 300-watt ratings are mounted in bulbs 5 inches in diameter by $6^{1}/_{2}$ inches over-all with part of the inner surfaces given a special process mirrored finish of aluminum. These are available in two light distributions known as "spot" and "flood." The former is more concentrated and the latter of wider spread. This construction gives the following candle power readings at the peak of the beam:

300-watt spot	16,000	150-watt spot	7,000
300-watt flood	3,000	150-watt flood	1,200

The reflecting lamps just discussed have bulbs of ordinary glass and must be protected from the weather, but some new lamps known as projector lamps are made of heat-resisting glass. In these the bulb is made in two parts, the cover being fused to the bulb after the high-efficiency concentrated filament has been positioned. Two types of cover plates are used, one to give a flood and the other a spot distribution. In the 150-watt size the flood type gives a maximum candle power of 3,500 and the spot type 10,500.

Tubular-bulb lamps of various sizes with half of the bulb having a reflecting coating are available for show-cases and other places where space is limited.

Drying Lamp

In many industrial processes radiant energy has been found to be most effective for drying purposes. Synthetic enamels and many lacquers can be dried in from 10 to 15 per cent of the time required by other methods. For this purpose a 250-watt *PS*-30 bulb tungsten-filament lamp has been developed. The filament is operated at an abnormally low temperature or efficiency ($7^{1}/_{2}$ lumens per watt), which avoids the production of unnecessary visible radiation and gives a very long lamp life. As a supplement there are on the market several types of concentrating reflectors for directing radiant energy to the surface to be dried. Most of these are finished with electrolytic gold because this is efficient in reflecting the near infrared energy, permanent, and easily cleaned.

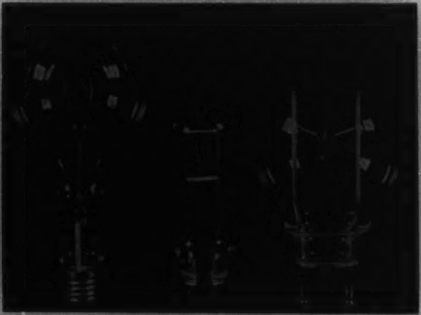
Projection Lamps

A rather startling advance has been made in this field with the development of 1,000- and 1,200-watt T-12 bulb biplane-filament lamps with a rated life of ten hours. The filaments and filling gas of these lamps incorporate improvements resulting in large increases in screen illumination and more uniform screen brightness. With the 1,000-watt lamp, for example, the lumen output is 32,000, and with a 16-millimeter motion-picture projector there is a gain of 50 per cent in light on the screen over lamps of previous design of the same wattage. In this field, also, improved optics have been introduced which make still further increases in screen brightness over that obtained with old style lenses and the same lamps.

With projecting lamps it is often necessary to prevent the light from escaping upward, and heretofore small metal caps have been used to slip over the ends of the tubular bulbs. Now the T-12 bulb 750-, 1,000-, and 1,200-watt projection lamps are regularly supplied with opaque end coatings.

An interesting medium-size projection lamp is the 300-watt T-8$^{1}/_{2}$ bulb lamp. This has a high-efficiency coiled-coil filament and a single-contact prefocused base. Being only 1$^{1}/_{16}$ inches in diameter and 4$^{1}/_{2}$ inches long it enables a source of 300 watts to be placed very close to the condensing lens and increases the amount of light entering the optical system of 8-millimeter motion-picture projectors.

During the past two or three years a considerable number of quite inexpensive toy projectors have been placed on the market. These are far from optically perfect, but they require brilliant concentrated light sources of decidedly low cost. For this purpose there has been standardized a line of several sizes and types of toy-projector lamps which retail at very low figures.



Left to right: old style 1,000-watt PS52-bulb lamp; 1,000-watt T24-bulb medium bipost lamp; and a mogul bipost lamp for projection service

Bipost Base Lamps

The mogul bipost construction has become the accepted design for new types of high-current lamps. The medium bipost construction has been applied to the T-20 bulb 500-watt and the T-24 bulb 750- and 1,000-watt lamps for general lighting service, as well as to a considerable number of types of projection lamps.

A few of the projection lamps now available

The small over-all size made possible through the use of hard glass and the medium bipost construction has enabled designers to make commercial fixtures for high-wattage lamps of attractive proportions. A number of excellent designs along this line are on the market.

Important Changes in Standard Lamps for General Lighting Service

The standard life of 200- and 300-watt lamps has been reduced from 1,000 to 750 hours in line with production of light at minimum operating cost. The 300-watt lamp is now made in a shorter bulb with a medium screw base and 750-hour rated life. The 50- and 60-watt lamps are now standard in A-19 rather than A-21 bulbs.

In the last report mention was made of the application of the coiled-coil filament to projection lamps. This construction makes possible increased efficiency in certain sizes of the regular lamps. The use of this coiled-coil principle has been extended first to the 60-watt size and here a 10-per cent increase in light output resulted. The uncoiled wire from such a lamp is 20 inches long, and with double coiling this is compressed to only $^{5}/_{8}$ inch. Since the filament is so concentrated the cooling effect of the filling gas is minimized. This construction was next applied to the 50-watt lamp, then to the 100-watt size, and a program is under way to expand its use as manufacturing facilities permit.

Flashlight Lamps

To permit accurate placement of flashlight filaments at the focus of reflectors, a simple type of prefocused base has been developed and applied to lamps of several sizes. Such accurate control, combined with die-cast reflectors, prevents distorted beams, provides more uniform and brighter spots of light, and materially increases the seeing range for general flashlight service.

SEALED AUTOMOBILE HEADLIGHTS

A most radical innovation in automobile headlights has taken place. In the past a typical assembly consisted of a plated parabolic spun reflector, an adjustable socket, a refracting cover glass or lens, and the necessary supports and housing. For accurate light control it was necessary to maintain three elements—the lamp, reflector, and lens—in exactly their proper relative positions. Even with rigid assemblies and careful workmanship, this was difficult because of the vibration and shock incidental to car operation. When these elements were out of optical adjustment a distorted and glaring beam resulted. In order to replace the lamp, it was necessary that the lens or cover glass be removable, and, in spite of attempts properly to gasket the joint, dirt and moisture accumulated on lamp bulb, reflecting surface, and cover plate. This accumulation materially reduced the light output.

"Sealed beam" automobile headlamp

Automobile manufacturers realize that with increased speeds safety in night driving required good headlighting and have been anxious to find some way of overcoming the two major difficulties just mentioned, produce something in which the human element of adjustment and maintenance was minimized, and obtain higher beam candle power. Work along this line has been proceeding for several years and has resulted in the development of two types of "sealed beam" headlamps, essentially the same in principle but different in structural details. These are entirely interchangeable, standard as to dimensions, and have the same light output and beam pattern. In one type there is a plated spun metal reflector to which a conventional-type two-filament bulb is soldered with the filaments in their correct positions. The lamp has three contact lugs so arranged that it cannot be inserted incorrectly in the receptacle. Across the mouth of the reflector is hermetically sealed a refracting-type cover glass. The maximum diameter is seven inches and the over-all length or thickness five inches.

The other type of sealed-beam lamp is similar to the projector spot and flood lamps in general construction features. The lamp bulb itself (Mazda lamp number 4030) is the complete unit. The shape is known as the *PAR*-56. Essentially it consists of an accurately designed pressed hard-glass parabolic section with aluminized coating on the inner surface; a refracting cover plate is welded to the back half of the lamp. In it are mounted two 6–8-volt filaments: one taking 40 watts is positioned for the so-called country beam; the other consuming 30 watts is positioned to produce a lower and sidewise-directed traffic beam.

Practically all the 1940 model cars have this new sealed-beam headlamp. An ingenious mounting arrangement has been designed and a standardized and universal switching arrangement for the two beams will be found. Since the new country beam is more powerful than previous types of "high" beam, there will be a campaign of education to make sure that operators switch to the traffic beam when meeting oncoming cars. It is anticipated that this radical development will be a tremendous factor in safe night driving.

Gaseous-Conduction Lamps

Continued research and development has made possible quite a number of new types of these lamps. The high-intensity mercury-arc lamp line, of which three sizes were mentioned in the previous report, namely, 400-watt (type *A-H*1), 250-watt (type *A-H*2), and 85-watt (type *A-H*3), now has in addition a 100-watt lamp (type *A-H*4), which emits 3,500 lumens, has a rated life of 1,000 hours, is made in a *T*-10 bulb and provides a low-wattage small bright source. The 250-watt size is also made with a smaller arc stream. This is known as the type *A-H*5, emits 10,000 lumens, has a rated life of 1,000 hours, and is a medium-wattage small bright source useful for floodlighting, and other purposes. Details of the theory and construction of these new lamps have been published in ELECTRICAL ENGINEERING.[2,3]

The water-cooled lamp has now been placed in production and is finding numerous and interesting applications. It is designed to operate at 1,000 watts and emit 65,000 lumens. The lamp itself is a small quartz tube with an arc stream $1^1/_3$ millimeters wide by approximately one inch long. This tube is placed in an outer jacket through which a flow of water of approximately three quarts per minute is necessary. Some special jackets have been made in which three lamps are placed side by side in one container. A rather special control system is necessary to make sure that the lamp will not be lighted before the water is flowing properly, that the water will be turned off if the lamp or power fails, and, further, that no voltage is applied in case of lamp failure. This lamp, known as type *A-H*6, is proving most useful in photoengraving, contact printing, high-power enlarging, copy-board illu-

A photoengraving unit employing the 1,000-watt A-H6 water-cooled high-intensity mercury-arc lamp

mination, oscillograph lighting, and other fields where an extremely brilliant and concentrated light source is required.

In Europe the 400-watt hot-cathode mercury lamp with a certain amount of cadmium added is on the market, fitted with an exterior envelope or bulb, the inner surface of which is covered with fluorescent material. This combination produces a whiter light at no loss in efficiency.

The standard low-pressure mercury-vapor lamp (Cooper-Hewitt) has been provided with an improved circuit which enables the complete unit to produce the same light output with a 22 per cent reduction in power.

Fluorescent Lamps

The last report mentioned that phosphors were being applied to the high-voltage cold-cathode type of gaseous-conduction lamp and that work was under way toward the production of standardized replaceable lamps for operation on commercial voltages incorporating the fluorescent principle. This is now an accomplished fact and is one of the most important innovations in recent years.

Lamps are now standard in 18-, 24-, 36-, and 48-inch sizes, which have a uniform rating of 10 watts per foot. In brief, an arc stream of low current density passes through mercury vapor to which a small amount of argon has been added for ease in starting. A slight amount of visible radiation (three to four lumens per watt) of the characteristic mercury color is generated, but this is accompanied by a considerable amount of radiation at 2,537 angstrom units. This ultraviolet radiation impinges on phosphors coated on the inside of the tube and is transformed into visible radiation at surprisingly high efficiencies in most colors.

One of the most outstanding features of this development has been the production of new types of phosphors which have proved very effective. There are now standard phosphors radiating green, pink, and blue light. By mixing these a white light very closely approximating, 3,500-degree-Kelvin black-body radiation can be produced. Another mixture gives an artificial daylight good enough for most purposes equivalent to that of a black body at 6,500 degrees Kelvin. If the tube coated with pink phosphor has also a layer of red lacquer, through selective absorption a red light is produced. Similarly, if the white tube has a coating of yellow lacquer, a golden light results. Thus seven colors are on the market.

Efficiencies vary somewhat, depending on the tube dimensions and color, but are of the following order:

White	35 to 47 lumens per watt
Daylight	30 to 40 lumens per watt
Blue	21 to 26 lumens per watt
Green	60 to 75 lumens per watt
Pink	20 to 25 lumens per watt
Gold	25 to 31 lumens per watt
Red	3 to 4 lumens per watt

At each end of the tube is a small coiled coated electrode. In operation these electrodes are first heated and when the electron emission reaches the proper point, the arc is struck and the electrodes are de-energized.

Since these are essentially arc lamps, every lamp requires some device in series with it to act as a ballast. Choke coils and small capacitors are used for this purpose. The ballast and a switching arrangement for energizing and turning off the electrodes are combined in auxiliary devices. These are of several types and sizes and in certain forms the controls for two lamps are included in one casing. Work is still under way on auxiliaries, and each month or two sees the introduction of new designs.

The tube or lamp has a cap at each end on which are placed two small pin contacts across which the electrodes are connected. A special lampholder is required. Space does not permit a complete discussion of the operating characteristics, of the factors that influence lamp performance, and of the specialized applications of this new illuminant. Some of these features have been described in previous articles and papers.[4–6]

The principle of fluorescence has also been applied to the standard low-pressure (Cooper-Hewitt) mercury-arc lamp. Here a rectifying type of a-c operation is used and a high-efficiency fluorescent material coated on the inside of a 52-inch tube. The lamp and auxiliary consume 100 watts and produce 5,000 lumens. Although the color of the light is similar to that of the Cooper-Hewitt lamp, the fluorescence adds a considerable amount of red and color rendition is decidedly improved, although no claim is made for white or daylight color quality. This lamp finds particular use for high-level industrial illumination with units mounted relatively low.

Ultraviolet Sources

In the sunlamp class one lamp has been developed known as the *S*-4. This is the same as the 100-watt *A*-*H*4 lamp discussed under "Gaseous-Conduction Lamps" except that it is fitted with an *A*-21 bulb of special transmitting glass. It has a somewhat greater output of ultraviolet radiation in the anti-rickitic region than the *S*-1 lamp and consumes only one-quarter the energy. The fixtures for the *S*-4 sunlamp are smaller, lighter, and easier to handle.

In the germicidal type, the "Sterilamp,"[7] a high-voltage cold-cathode type, is now made in 10-, 20-, and 30-inch sizes with ratings from about 10 to 20 watts. The following additional units have been made available:

Watts	Bulb	Base	Necessary Auxiliary	Life (Hours)	Microwatts Per Sq Cm of 2,537 A Radiation at One Meter
8	*T*-4	Radio type	Separate reactor	1,000	3–4
5	*T*-10	Medium screw	None required	1,500	1
15	*T*-8	Fluorescent	Same as for 15-watt fluorescent lamp	1,500	15–20
5	*T*-6½	Candelabra screw	Separate resistor	4,000	0.5
16	*T*-4	2-pin special	Separate reactor	1,500	15–20

These various germicidal tubes are finding considerable application for destroying bacteria. They have been experimentally installed in air ducts to kill air-borne bacteria; they are being used as a preventative to the spread of disease in hospitals, and for food preservation by various industries. Sanitization of drinking glasses and sterile storage of previously sterilized utensils are applications for these lamps which are becoming more popular every day. The relatively small size of some of the new tubes and simple control devices make them suitable for installation in places where space is limited.

A very useful new source for producing ultraviolet radiation for fluorescent and phosphorescent purposes is a result of modification and adaptation of the 100-watt type *A-H*4 lamp. This is made with a *T*-16 bulb of natural red-purple glass and emits a considerable amount of radiation of the type required for producing fluorescence, at the same time screening out most of the visible radiation. It is known as the type *B-H*4 lamp.

The Uviarc, a powerful source of ultraviolet radiation for industrial purposes, has been adapted for a-c operation. An entirely new line of these lamps with oxide electrodes and a limited amount of mercury has been introduced.

Carbon Arcs

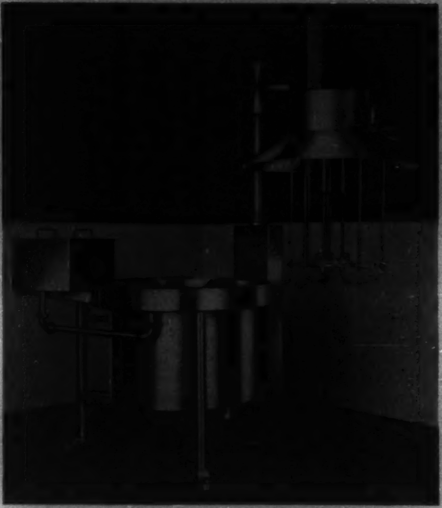
An improvement in carbon arc lighting for the motion-picture studios has been effected since the previous report of this committee through the development of a broadside lamp with motor-driven carbon-feeding mechanism. This development gives improved steadiness of light and a much lower sound level than lamps with solenoid-operated feed mechanisms.

A new super high-intensity carbon, 11 millimeters in diameter, provides an intrinsic brilliancy of 1,200 candles per square millimeter at an arc current of 135 amperes.

The development of carbon arc lamps for 16-millimeter motion-picture projection is extending the scope of the 16-millimeter film in educational and commercial fields, permitting the projection of a brilliant, sharply defined image on a much larger screen than has heretofore been practicable.

Three ultraviolet lamps of the germicidal type

The 3-phase carbon arc has been adapted to modern requirements and applied to a number of industrial uses. A 12-kw lamp, burning six carbons on a wye circuit, is being used for the vitamin-*D* activation of milk. For purposes of illumination this lamp provides a light source of one million lumens. A one-kilowatt, three-carbon delta-connected lamp is used in a new accelerated-fading-test unit. This lamp, equipped with carbons giving a spectrum similar to sunlight, is also used for illumination on applications requiring high-intensity light of daylight quality, free from the stroboscopic effects sometimes experienced with the single-phase arc.



A 12-kw arc lamp burning six carbons on a wye circuit being used for vitamin-D activation of milk

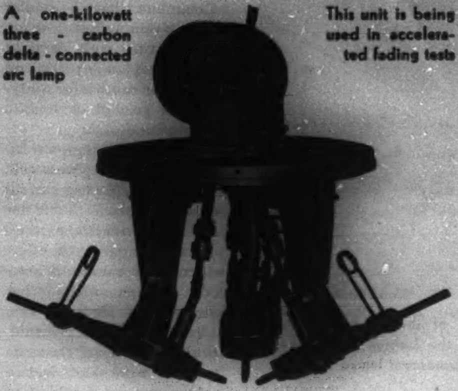
New Materials for Lighting

Glass blocks or bricks as structural elements have seen somewhat more extensive use during the past few years. Since these are translucent they offer opportunities for novel lighting effects, and quite a number of colorful schemes have been applied.

A new form of tempered glass has been introduced, and to this enamel of various colors is applied. This material is suitable for special effects in luminous store fronts and the like. In the same field different forms of weather-resisting metals lend themselves to interesting design in co-ordination with light and color. Mat and polished finishes, as well as porcelain-enameled corrugated metal are available to the designer.

Under normal conditions it is difficult to control the light reflected from a ceiling, for with plaster, sound-proofing materials, and other coverings diffuse reflections result. One manufacturer of metal ceilings has placed on the market sheets so formed that controlled or regular reflection results. This is known under the trade name of Parab-O-Lume.

A colorless transparent plastic known as Lucite has found certain interesting applications. This material has the property of retaining a beam of light through in-



A one-kilowatt three-carbon delta-connected arc lamp

This unit is being used in accelerated fading tests

ternal reflections in much the same manner as a quartz rod. It has been applied to curved dental and surgical lighting devices where the beam is bent around the corner to illuminate some cavity.

Notable Lighting Installations

During the period under consideration there has been relatively little new building, but considerable revamping and modernization of existing structures. Practically all the leading shops on Fifth Avenue, New York, State Street, Chicago, and similar merchandising centers have installed unique and effective up-to-date lighting within the last few years. Many public rooms in hotels, restaurants, night clubs, and cafes are completely changed in appearance, and some of the most ingenious lighting to be found anywhere may be noted in this class of service.

It is impossible to tabulate the number of larger department stores that have discarded old systems and installed illumination schemes to take advantage of the most recent developments. As representative of this field we might mention: Gimbels, New York, N. Y.; Marshall Field, Chicago, Ill.; Kauffman's, Pittsburgh, Pa.; J. L. Hudson, Detroit, Mich.; Orecks, Duluth, Minn.; Z. C. M. I., Salt Lake City, Utah; Saks, Los Angeles, Calif.; Roos Brothers, San Francisco, Calif.; T. Eaton Company, Toronto, Ontario, Canada.

Remarkable advances have been made in illumination of banking institutions, and both the Los Angeles and Toronto stock exchanges have been completely relighted. The new service building of the Detroit Edison Company is an example of the application of many new principles of illumination, and the main office building of the Commonwealth Edison Company has an entirely new system.

Details of new and novel lighting installations are discussed in each issue of the Illuminating Engineering Society *Transactions* under a section conducted by the society's committee on the co-ordination of light and architecture. Those desiring to keep in touch with the most modern practice should refer to that publication.

There have been a number of international expositions or world's fairs, and, of course, in these the latest developments in lighting are always incorporated. Details of the Texas Centennial,[8] Great Lakes,[9] Paris,[10] and Golden Gate,[11] expositions have been reported in ELECTRICAL ENGINEERING and in other publications.

A manuscript describing and giving technical details regarding the lighting installation at the New York World's Fair 1939 is under preparation and is scheduled for publication in ELECTRICAL ENGINEERING when completed (included in this volume, see pages 1288–1305).

Lighting Instruments

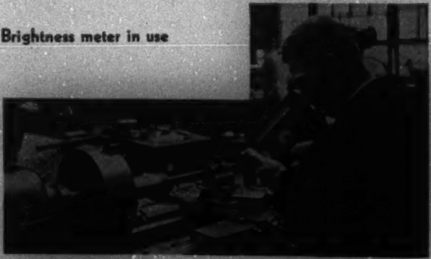
Not long ago the rather cumbersome bar photometer with grease-spot screen was the only light-measuring device. With the development of the art of illumination the need for additional measuring instruments has grown apace, and each period has seen new types made available.

One rather interesting device, first developed in England, has been introduced in the United States, known as a light selection recorder. The observer, or subject, has a means of varying the illumination level on a test object and eventually selecting the amount of illumination he prefers. At this point he presses a button and on a printed scale is indicated the result of his choice.

With the growing appreciation of the importance of brightness measurements, some special meters have been developed for this purpose. A rather expensive and accurate type is known as the Luckiesh-Taylor brightness meter. A less expensive and more simple instrument, known as a model *L-H*, was developed by Luckiesh and Holladay.

Baumgartner has developed a light-cell reflectometer[12] and a light-cell distribution photometer. This latter device enables one to obtain a candle-power distribution curve in an extremely small fraction of the time required by the older method.

The widespread use of photoflash lamps has made it necessary to find some means of checking the setting of camera shutters in relation to the peak of light output. For this purpose a rather simple device known as the "synchrograph" was introduced. Another instrument along this line is known as a "flashograph," which traces



Brightness meter in use

on a moving film the performance of photoflash lamps. The lamp is flashed in a small sphere which has a photoelectric cell mounted on it. The amplified output of the cell is applied across a small Rochelle-salt crystal oscilloscope. The deformation of the crystal in reflecting a beam of light across the aperture of a drum traces the candlepower-time relation on film.

With the development of the ultraviolet lamp of the germicidal type (Sterilamp) the need arose for an instrument that would provide an exact quantitative measurement of the abiotic radiation from these lamps. The instrument developed to meet this need is an ultraviolet meter embodying a tantalum photoelectric cell, which has a wave-length response to ultraviolet radiation similar to the lethal action of these radiations upon bacteria. With the aid of this device, it has been possible to determine the abiotic energy necessary to kill any chosen micro-organism, and sterilizing installations may be planned with an exactness approaching that of the normal lighting installation.

Interior of the lounge car of the "John Wilkes," remodeled express train of the Lehigh Valley Railroad, lighted by fluorescent lamps

Transportation Lighting

Real progress has been made in this field. Some of the tendencies have previously been reported.[15] New cars and busses, in general, are quite up-to-date from the lighting standpoint, and much work has been done in revamping and modernizing old vehicles.

With the coming of the fluorescent lamp the railroad engineers were among the first to consider its use. Since these lamps require alternating current for most efficient operation, the first step was the development of a vibrator inverter for operation on the storage-battery circuits. This device has worked out well in service. In some cases a small motor alternator set is used. The New York Central Railroad was the first to put in operation a fluorescent-lighted car. The Burlington Lines "General Pershing" Zephyr and the Lehigh Valley remodeled express train "John Wilkes" were the first two trains to be lighted throughout by fluorescent lamps.

Light in Horticulture

There is considerable interest on the part of various agricultural experimental stations in growing plants entirely under artificial light for the purpose of eliminating variables in order to study the effect of different chemicals, both for nutrient solutions and soil growth.

At Cornell University, Ithaca, N. Y., there is a room equipped with 24 1,000-watt lamps and a water filter, as well as humidity control. Ohio State University, Columbus, has a similar installation and is now experimenting with daylight fluorescent lamps producing 1,500 foot-candles for studying the growth of tomato plants.

The Boyce Thompson Institute for Plant Research, Yonkers, N. Y., has carried on continuous work and has recently conducted a series of tests comparing the effectiveness of various fluorescent lamps with other sources for plant growth. The University of California, Berkeley, is doing the same type of work and had a rather impressive exhibit at the Golden Gate Exposition during the 1939 season.

The color value of the daylight fluorescent lamp is apparently more suitable than that of filament lamps for stimulating plant growth. It gives much less radiant heat per foot-candle, and there is every indication that it will be an important factor in this field.

A notable installation of carbon-arc lamps for stimulating plant growth has been made at the field station of the United States Department of Agriculture, Beltsville, Md.

Sports Lighting

All the American Association baseball fields are now lighted for night playing and the "big" leagues are gradually recognizing the fact that night games pay well. Ebbets Field in Brooklyn, N. Y., has installed a total of 615 1,500-watt incandescent floodlights, and the Cleveland Municipal Stadium has now 712 units of the same size.

Show-Window Lighting

More than two decades ago the idea was promulgated that the show window was a miniature stage and that all the effects used on the latter would find application for the window display. It finally appears that the more progressive merchants are appreciating the logic of this approach. In the more artistic type of window spot lamps equipped with color mediums, flood effects, colored illumination of background, and combinations of all these are being applied with splendid results.

Street and Highway Lighting

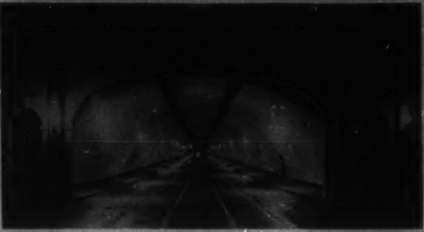
Each year shows a growing public appreciation of the advantage of highway safety lighting even if one considers only the dollars and cents involved. New tests constantly show that the cost of this lighting is soon offset by decrease in accidents. In several states modernization plans are under way; in certain instances the installations are owned by the state. Many of the important cities have shown marked improvement.

There have been a number of new forms of street luminaires, most of which incorporate efficient Alzak reflectors. A rather novel feature in one type is the reflector spun onto the globe providing a weatherproof seal and greatly reducing glassware breakage.

Sodium lighting with its distinctive color has proved useful as a caution signal for safety-island beacons, as well as for especially dangerous intersections. The two new large bridges in California, the Golden Gate and the San Francisco-Oakland, as well as the Blue Water Bridge over the Saint Clair River between Michigan and Canada and the new Main Avenue Bridge in Cleveland, Ohio, are all lighted by the sodium system. This efficient light has also proved very acceptable for underpass and tunnel lighting, notable installations being the Two Rock Tunnel on the Columbia River Highway in Washington, the Liberty Tunnel in Pittsburgh, Pa., the Stockton Street Tunnel, San Francisco, and the McCallie Avenue Tunnel, Chattanooga, Tenn.

Aviation Lighting

Improved efficiency in the design of conventional types of aviation lighting equipment and the introduction of new types of lights have combined to make the past four years a period of important progress. The trend in beacons has been a return to the 24-inch size but the design has been "streamlined." The trunnion arms have been eliminated, reducing the area exposed to wind and the risk that ice and snow may interfere with smooth rotation. The base has been redesigned to afford better access to the mechanism for maintenance. A new lamp changer eliminates the shadow of the reserve lamp from the beam. Another form of this beacon is also available in which the drum has been replaced by a glass dome, the rotating parts thus being completely enclosed. To provide a beacon with more frequent flashes, an oscillating beacon has been developed. In this unit a lamp moves up and down on the axis of a cylindrical Fresnel lens giving 80 flashes per minute. This beacon also has more candle power at high angles than the 24- or 36-inch beacons.



Stockton Street Tunnel, San Francisco, Calif., lighted by 10,000-lumen sodium-vapor units

An experimental boundary-light circuit in which the lamps are fed by a 550-volt multiple circuit through individual transformers has been installed at Washington (D. C.) Airport. The circuit is less expensive than a series circuit and the voltage drop is much less than with an ordinary multiple circuit. It is well adapted for use on fields that do not have sufficient night traffic to warrant the outlay required for a series circuit.

Floodlighting is being designed with greater attention to the avoidance of glare. This has led to the development of an improved 90-degree unit employing four 1,500-watt lamps each in a separate Fresnel lens. The four separate sources give insurance against a sudden interruption of the illumination by the burning out of a lamp.

The development of the approach-and-contact-light system has largely taken place in the last four years. This system was originally designed to supplement radio aids in fog, but its use in good weather has found much favor. The approach lights are located outside the landing area and are accordingly red. Neon lamps approxi-

Shibe Park, home field of the Philadelphia (Pa.) baseball club of the American League, illuminated by 780 1,500-watt floodlights mounted high above the field on eight towers, one of which is shown at the right

mately six feet in length, with suitable parabolic reflectors, give an intensity of 1,000 candles and, by their elongated shape, establish a horizontal plane of reference to guide pilots in approaching the runway. The contact lights are arranged along the two sides of a runway to show its location and indicate the ground level. These units project less than two inches above the runway and are available in two types. Heavy-duty units are used on runways that are in line with approach-light systems or furnished with radio aids for instrument landings. Normal-duty units are used on other runways. Contact lights are lighted on only one runway at a time. The approach-and-contact-light system, in addition to being one of the most satisfactory aids for night landings, is also the most effective means available for giving an airport a distinctive appearance at night; this is a great aid to a pilot looking for an airport with which he is not familiar.

There has been marked progress in the development of traffic-control lights. Lights visible only along the runways are being installed at several airports to control taxiing movements and take-offs. For controlling landings, 90-foot arrows composed of red and green marker lights are being installed at the ends of the runways. A green arrow indicates that landings may be made from the end of the runway so marked. A red arrow shows the landing end of a runway that must not be used at the time.

The growing overseas air traffic is necessitating equipment for use as seaplane-channel marker lights. Some very interesting experiments have been conducted with battery-operated coiled-tube fluorescent lamps mounted on resilient rubber floats to meet this need. The Civil Aeronautics Authority expects to establish specifications for seaplane-channel lights when these experiments have yielded sufficient data.

Electrical Advertising

The most novel feature in the incandescent-lamp type of sign is noted in the further development of the "motion picture" type of display. In such a sign moving images from a motion-picture projector are thrown upon a screen made up of photoelectric cells which, in turn, light up a huge bank of incandescent lamps in accord with the light and shade of the projected image.

In the gaseous-conductor type of display the familiar orange-red of the neon and the blue of the mercury have become so common that in many cases the colors lose their appeal and attracting power, and the variety of effects possible through fluorescent lamps are indeed welcome to this industry. It is reported that a very high proportion of all new work incorporates fluorescent tubing.

In the smaller type of displays many very unique features have been incorporated. One popular and inexpensive form uses letters or emblems made up of glass tubing in which volatile liquid is placed. There is a reservoir or small bulb at the bottom. The heat from concealed lamps causes a continuous moving bubble effect and the fluid itself is luminous from the light emitted by the lamps.

Another type of sign has a message formed by a thin wire which serves as a negative electrode for an electric discharge in a helium-filled tube. Still another takes advantage of the phenomena of high-frequency discharge. Changeable letters are filled with neon or other gases. An oscillator is placed in the base of the sign or nearby. There is no electrical connection, yet the letters glow with a fair luminosity. Standard colored low-voltage fluorescent lamps have been effectively applied to a number of signs based on the edge-glow and transparent-mirror principles.

Lighting Standards

The Illuminating Engineering Society as the guiding body has continuously conducted researches into various fields of practice. From the industrial angle the special requirements of different processes have been studied and these findings have been reported from time to time. The philosophy behind this procedure has been discussed in ELECTRICAL ENGINEERING[14] and in IES *Transactions.*[15]

Codes applying to airport,[16] highway,[17] and schoolroom[18] lighting have also been published.

Polarized Light

Polarized light is as old as time itself, but has never been a very useful tool for the lighting engineer because of the expense and complication in producing it. Its properties are well known to all who have studied physics, and obviously if it could be made available simply, many valuable and practical effects would result. For several years investigators have been trying to produce a synthetic medium which when placed before a light source would act as a polarizer. Such a material (known as Polaroid) is now available in sheets of considerable size.[19] To the unaided eye it appears as a sheet of thin gray or neutral-colored gelatin filter. Structurally, however, in this sheet are innumerable small microscopic slivers, practically all pointed in one direction. When two sheets of Polaroid are placed with these needle-like particles parallel, maximum light transmission results. When placed at right angles to this position, practically all the light is cut off.

Polaroid mounted between pieces of protecting glass has found rather wide use in sun spectacles. Placed before the openings of reflectors directing light on paintings it provides a means of reducing specular surface reflections to a minimum. Desk and reading lamps have been equipped to furnish polarized light. Beautiful decorative effects for the theater and advertising purposes result from the action of polarized light on cellophane and similar materials.

One of the most interesting fields for the application of the polarizing principles is in connection with automobile headlights. Here the proposed scheme polarizes the light from the headlamp in a 45-degree angle and places on the windshield an analyzer at the same angle. Thus there is minimum reduction in visibility of the beam from one's own headlights, yet the light from oncoming headlights being at right angles to the analyzer, is scarcely visible.

The transmission for unpolarized light incident on the sheet is of the order of 40 per cent. Hence, special beams for city use are indicated in order that the street need not be viewed through the analyzer, for this would reduce the brightness of the street and obstacles thereon by approximately 60 per cent and greatly increase accident hazard; also for the protection of pedestrians who might not wish to provide themselves with special polarizing spectacles.

The reduction in brightness of the interurban or rural highway and obstacles thereon as seen through the analyzer varies greatly depending upon the degree of depolarization caused by reflection from these surfaces. Fortunately, light reflected from the darker surfaces suffers less depolarization and thus the brightness of the most hazardous obstacles is much less impaired. The polarizing materials available until very recently lacked the necessary thermal and solarization properties. Now it is announced that a new polarizing material obtained by suitable processing of polyvinyl alcohol sheets obviates the former difficulties. This makes the prospect for the application to motor car headlights more promising.

Lighting Control

The thermionic-tube control combined with saturable reactors has been improved in certain details. In the first stages of development it was necessary to have a reactor with a rating approximately equal to that of the load to be delivered. Thus a reactor rated for 5,000 watts would not function with a load of one kilowatt. Now, however, reactors are available that will operate over the following load ratios: 1–1, 2–1, 4–1, 10–1, and 30–1.

When this system was first introduced, it was necessary to connect reactors in cascade, which meant that different sections of an installation being thrown on the line would come up to full brightness at slightly different intervals. Now reactors are operated in parallel eliminating this distracting feature.

There has been announced a four-circuit thyratron reactor mounted on a single chassis for mobile light control.

Photoelectric relays for lighting control have been improved and a new circuit used for the control of street and floodlighting. Less equipment and smaller space is required. The new relay is much more sensitive and turn-off and turn-on values can be very close together. Automatic control for the schoolroom has long been desired, for the teacher with her mind on a multitude of other things very often neglects the matter. Such a scheme is not practical, however, unless a decidedly inexpensive and simple photoelectric device is available. This is now the case.

Fluorescent lighting in a New York, N. Y., fur shop

Meeting of the International Commission on Illumination

The International Commission on Illumination, familiarly known to English-speaking people as the "ICI", to the French as "CIE", and to Germans as "IBK", convened for its tenth session in Scheveningen, Holland, June 11 to 20, 1939.

It drew an attendance of over 500 including 11 delegates and 9 guests from the United States. In addition to the 14 member countries, several others were represented, two other applications for membership being received.

From the American viewpoint, the session was probably one of the most interesting and productive of the ten sessions that has been held. Without neglecting standards and other basic questions, an increased amount of attention was devoted to the interchange of information and opinion on the late developments and trends in the art and science of illumination, ranging from laboratory investigation and field surveys to views as to future trends on lighting practice.

Reports covering 32 main topics were presented by 24 technical committees; the two United States secretariats submitted four of these reports. In addition to these, 34 papers by individual authors were presented for discussion, none of these being by American authors.

Among the fundamental questions taken up were the "new" candle, and the several topics arising out of the application of luminosity factors to photometry and colorimetry. Nearly all practical photometry throughout the world is now carried on by physical methods, even to the checking of visual standards.

Some additions were made to the English-French-German lighting vocabulary, which had been printed since the 1935 sessions. Arrangements were also made for the inclusion of equivalent terms in other languages in addition to Spanish and Italian.

Much information on the new electric discharge lamps was brought out as well as data on the recent developments of other illuminants. In the fields of illumination, street lighting, automobile lighting, aviation lighting, railway lighting, and school lighting, the United States Committee contributed information on a relatively extensive scale.

At the conclusion of the technical sessions, a program was adopted for the ensuing three years, 25 secretariats being allotted to the several national committees. In addition a plan was adopted for the presentation of individual papers at the 1942 sessions.

Officers were elected including Doctor Halbertsma of Holland as president and E. C. Crittenden (A'19, M'22) of the United States as one of the three vice-presidents. The invitation of the French committee to hold the 1942 Session in Paris was accepted, while an invitation from the Polish committee to hold an intermediate meeting of the aviation lighting committees in Warsaw was deferred for later action.

Now that Warsaw is in ruins and the great countries of Europe are too busy with destruction to give attention to co-operation on constructive effort, these plans presumably are canceled.

General

It is believed that the above data are a truly remarkable record of progress in an art in a very short space of time. It is impossible to give due credit to the many workers in the field of lighting. They are legion, and here and there without fanfare or publicity, without public recognition, these individuals advance the art here a little, there a little. The cumulative effects are of vast importance to the public. This work is often not sufficiently spectacular to receive much publicity, but it is none the less important and of a nature that is appropriate for engineers to recognize.

Progress in Power Generation—1933–39

This report of the AIEE committee on power generation* reviews practices and developments in this field since 1933, when the last progress report of the committee was published. It divides itself naturally into three main parts discussing steam, electric, and hydroelectric plant practice. A comprehensive bibliography is appended.

DURING the past six years the most important advances in power generation have been made in the use of 3,600-rpm high-temperature high-pressure steam-turbine hydrogen-cooled generators of large size. Boiler design and construction has been changed to insure sufficient circulation, and welding has taken an increasingly important part in almost every part of the plant equipment, both mechanical and electrical. The period has marked the installation of many superposed units whereby the capacity of existing plants has been increased and the thermal efficiency materially improved. Because these stations are largely located near load centers from which distribution districts are served, there has been much rebuilding and extension of switching facilities of improved design and layout. These changes have greatly lessened the possibility of service interruptions from fire or other causes. Hydraulic power projects have been largely in the hands of Federal agencies. The output of existing hydroelectric plants in many parts of the country has been severely reduced owing to lack of rainfall during the past year.

With the European war there arises the prospect of extra demands on the electric-power systems for manufacturing purposes. For present requirements ample generating capacity is available with a sufficient margin to meet a considerable increase in load. To maintain this margin for growth much new capacity is under construction. In addition, since the beginning of the war about 400,000 kw of steam turbine-generator capacity has been ordered. It is interesting to note that this further expansion is being carried out along the same lines as would normally be followed. It is simply a quickening of the pace of construction, all consistent with earlier prepared plans for plant extension.

Equally careful to the steps being taken to insure an adequate power supply must be the attention given to the physical safety of the plants in operation and under construction. This means special guarding and other precautionary measures.

Steam-Plant Practice

Since 1933, and as predicted then, practically no new large generating stations have been built and very few small ones. Activity has been confined to rehabilitation, principally in the form of superposition of existing capacity. There have also been a number of condensing additions to existing stations.

Development of metals has resulted in an increase of operating steam temperatures from a maximum of 850 degrees Fahrenheit then to 950 degrees. This increase has made possible the superposition of nominal 1,200-pound units on existing 200-pound capacity without the complication of reheat, and consequently this type of installation has been more attractive than heretofore. Also, curtailed economic activity and limited load growth made the relatively small capacities obtainable by this method more in line with requirements. As a result 1,200-pound pressure has become quite common. There has been little tendency to go further in pressure as with present steam temperature limitations reheat would be required. One utility installation, however, is proceeding with a 2,500-pound plant; also, an industrial installation is in operation at this pressure. There has been no commercial installation of any appreciable size for higher pressure than 2,500 pounds, as this is now considered the limit for natural boiler circulation, and forced circulation is as yet untried in the United States for large units.

BOILERS

Boiler sizes have not increased since the last report of this committee, remaining at a maximum of about 1,000,000 pounds per hour. Recent large installations have indicated that the sectional-header boiler is not as desirable for high pressure as other types because of improper distribution of water circulation between individual tubes in the vertical headers. Practically all new high-pressure boilers now under construction are of a type in which the boiler surface proper is either eliminated entirely or disposed nearly vertically with individual tubes entering the steam drum. Welded steel drums are almost universal. All high-temperature installations employ superheat control, consisting of some form of gas by-passing part or all of the superheater surface. Higher pressures have increased the problem of obtaining pure steam. Recent developments indicate that washing is unnecessary, providing either a suitable scrubber or baffling is installed and precautions are taken to hold proper boiler water level in the steam drum. One very satisfactory method of accomplishing this, which has been developed recently, is by means of cyclone separators installed on the outlet of the circulating tubes entering the steam drum.

The trend toward pulverized coal for large boiler units has persisted. Direct-fired systems have been improved to a point where it is difficult to justify the additional expense of a storage system. This has stopped development of large pulverizer units, about 25 tons per hour

---

Paper 40-6, recommended by the AIEE committee on power generation, and presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940. Manuscript submitted November 16, 1939; made available for preprinting November 27, 1939.

* Personnel of 1938–39 AIEE Committee on Power Generation: E. C. M. Stahl, *chairman;* H. C. Albrecht, F. A. Annett, G. M. Armbrust, W. L. Cisler, C. A. Corney, H. M. Cushing, J. H. Foote, R. L. Silver, Philip Sporn, Robert Treat, Sidney Withington, and E. D. Wood.

For all numbered references see list at end of report.

being the maximum required. Combustion rates in furnaces remain about the same. Slag-bottom furnaces have been on the increase, and on recent units continuous slag tap has displaced the intermittent type. There has been a tendency toward bare water-cooled walls, eliminating blocks and studs.

Zoned air control for stokers has not advanced as expected. Principal development on underfeed stokers has been an improved tuyère which restricts air flow through the fuel bed at points of low resistance. Present experiments, which look promising, are high-velocity overfire air and auxiliary oil burners over the fuel bed.

TURBINE GENERATORS

There have been no further installations of very large turbine-generator units, the largest now under construction being a 100,000-kw cross-compound 3,600-rpm unit for the Burlington (N. J.) generating station of the Public Service Electric and Gas Company. Where high pressure and high temperature have been employed, there has been a preference for 3,600-rpm turbines because of smaller parts and less tendency for distortion. First-stage blading for the larger machines at this speed has presented a problem in design which has not been entirely solved. Apparently it is a matter of providing sufficient mechanical strength in the restricted space available, along with disposition of parts in a manner that will avoid resonant vibration.

Large-capacity generators for 3,600 rpm made necessary considerable advance in design. The largest generator in operation at this speed in 1933 had a capacity of 18,000 kw, whereas there are now in service a 60,000-kw and several 50,000-kw machines. Increase in capacity has been made possible by the use of high-tensile-strength steels for the fields, hydrogen cooling, and improvements in detail design. Operation of these larger machines has been in the main satisfactory, although there has been some trouble with double-frequency vibration.

There has been very little development of condensers, probably because of the relatively few condensing units installed.

Welding of piping has been carried out to a greater degree than before, and it is now common practice to weld valves into the line. Welded bonnets for high-temperature valves seem to be in the offing.

LJUNGSTROM TURBOGENERATORS

Considerable interest has been aroused in engineering circles by the installation in the Southwick Power Station, Brighton, England, of two 37,500-kw Ljungstrom turbogenerators (see figure 2). These are the largest of their kind in England, although sets developing 50,000 kw are in service in the Vastreas station, Sweden. It is claimed that these latter turbines have shown conclusively that the difficulties once associated with their construction have been completely overcome. It is also confidently predicted that these double-rotation turbines in a single cylinder can be built up to a capacity of 100,000 kw. One of the major advantages claimed for this design is that the turbine may be started without preliminary warming up. Test data on the Brighton machine operating at a pressure of 650 pounds per square inch and a temperature of 850 degrees Fahrenheit with 29-inch vacuum indicate a heat rate of 9,759 Btu per kilowatt-hour.[91] With the present development of this type of turbine they are now adaptable to feed-heating cycles.

GAS TURBINES

Cognizance must be taken of the more recent developments in gas turbines. One of the accelerating factors in this development is the fact that they are being used to provide bombproof stand-by plants, particularly in the fortified areas of Europe. A notable installation is in the city of Neuchatel, Switzerland. These turbines require no cooling water and no auxiliaries when in operation. Over-all thermal efficiencies have attained 23 per cent with well over 20 per cent for the normal operating range.

MERCURY CYCLE

There have been no additional mercury boiler installations for power generation, although the Sun Oil Company has installed another boiler used in oil distillation process. Considerable trouble developed with the Kearny, N. J., and Schenectady, N. Y., boilers described in the 1933 report of this committee. The Kearny boiler is now being completely replaced. The design of the new boiler is similar to water-boiler design in that there is only one drum. "Porcupine" tubes with internal cores and close clearances have been eliminated. The convection surface is new in principle in that instead of being completely filled with a liquid it carries a mixture of liquid and vapor, resulting in a marked reduction in the amount of mercury required per unit of heating surface. As a result of the elimination of tube cores, however, the total amount of mercury in the boiler is somewhat increased. In the redesign the water-wall furnace has been eliminated, resulting in a marked improvement in over-all efficiency. New materials now available and more suitable for the operating conditions involved are being utilized in the various parts of the heating surface. Operating practice, and particularly chemical treatment of mercury in the boiler, has advanced considerably. The mercury turbine generators have been very satisfactory, and the only recent change in design involves improvement of the turbine glands to reduce air leakage to a minimum.

Electrical-Plant Practice

GENERATING-STATION SWITCHING

Since 1933 few new steam generating stations have been built requiring low-voltage power distribution, with the accompanying bus-layout problems. Large new stations have been mainly of the hydroelectric type, far removed

from local load, with generators connected directly to transformer banks or through a minimum of low-voltage switching equipment with outdoor high-voltage switch yards for the connection to the transmission lines, such as the Boulder Dam development.[109]

The generator-voltage switching facilities of several stations have been reconstructed and modernized due in some instances to the addition of generating capacity or extensive interconnecting of systems, and in others to interruptions caused by fires in the older types of switch houses.

One of the first large stations to be modernized was the Connors Creek station of the Detroit (Mich.) Edison Company.[98] In this instance a new switch house, separated from the existing station building was erected to house the modern bus and apparatus.

In the last few years this topic has become of such interest that at the AIEE winter convention in January 1939 the committee on power generation held a session on the rehabilitation of the various stations of the Consolidated Edison Company of New York,[117] the Essex generating station of Public Service Electric and Gas Company of New Jersey[119] and the L Street station of the Boston Edison Company,[116] together with a paper on the general topic.[118] The papers presented at this meeting describe in detail the problems that were present at the various locations, the aim of reconstruction programs, and the methods used by the various designers to obtain the results desired. The authors in agreeing on certain principles show clearly the present trend of switch house construction:

1. Complete relay protection.
2. Improved arrangement of equipment.
3. Limitation of capacity connected to one bus section, so that a fault will not remove too great a proportion of the station capacity.
4. Better physical segregation of bus sections and oil circuit breakers, by means of smoke and fire barriers, coupled with forced ventilation.
5. Reduction of oil content of breakers.
6. Use of improved fire-fighting equipment.
7. Improvement as to control, segregation, and grounding.

As the length and extent of several recent interruptions were in part due to smoke and soot deposits on insulators and busses of portions of the station not directly involved in the fault, great pains have been taken in these rebuilding programs to segregate indoor sections physically. Barriers, without direct doors or other openings between sections, are desirable if the conditions permit. Access to sections is obtained from corridors or rooms free of electrical apparatus, which also may provide expansion space for the dissipation of pressures generated by explosions. With large-capacity ventilating systems to clear the faulted section of fumes, and with adequate fire-fighting equipment present, these modernized switch houses have a strong second line of defense if, in spite of improved protective schemes, an explosion or fire occurs. Recent tests demonstrating the capabilities of fire-fighting equipment and aiding in the training of operating forces have permitted more assurance in their effectiveness. Equipment of both the carbon-dioxide type and of the fine-water-spray or mist type, in both portable and permanently piped systems, has been used.

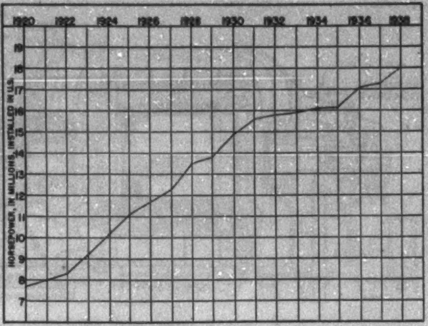

Figure 4. Growth of water-wheel installations in all classes of hydraulic plants in the United States

One of the most interesting recent developments is the nonmagnetic-steel-tube-enclosed gastight bus of the Consolidated Edison Company of New York,[117] which allows phase segregation and high carrying capacity in limited space. A number of installations of the more conventional metal-enclosed bus structures with metal breaker cubicles have been made, and in many such instances fault bus protection has been adopted, although differential protection is in use in the majority of cases.

ELECTRICAL EQUIPMENT

There has been a marked improvement in apparatus and equipment since the 1933 report. Extensive tests on oil circuit breakers with the modern arc-extinguishing devices have produced a breaker both electrically and mechanically more reliable than was heretofore available.

Opening times of eight cycles are now standard, and breaker speeds of five and three cycles may be obtained when necessary.

Many old oil circuit breakers have been equipped with the new arc-extinguishing devices and higher-speed mechanisms to gain in interrupting capacity and reduce the time to the present AIEE standard.

The tendency to reduce the oil content of breakers has caused a general interest and demand for oilless breakers, which has resulted in an increased use of available designs and new developments by the manufacturers. Breakers of the air De-ion type are in service with up to 750,000-kva interrupting capacity; breakers of the hydro-blast type are in service rated at 500,000-kva interrupting capacity with orders placed for capacities up to 1,500,000 kva; and breakers using compressed air as an arc-extinguishing medium are on order with interrupting capacity of 500,000 kva and are designed with ratings up to 1,500,000 kva.

Disconnecting switches have been developed for large capacities, mainly of the high-pressure type, using button or line contacts, or positive clamping action, all with silvered contacts; tests have shown them superior to those previously available for continued service at full loadings. High-capacity busses show a trend away from the flat-bar configuration toward the tubular, rectangular, or double-channel iron forms. Busses both with and without insulation in addition to the porcelain supports are used.

Manufacturers' research in test methods, increased laboratory facilities, and the accompanying design improvements as regards impulse strength, together with the work of the transformer subcommittee of the AIEE committee on electrical machinery, have made data available in the past few years so that the station designer may grade the insulation for surges in addition to normal frequencies, although the time is as yet too short to cause any agreement among operators as to the best co-ordination of insulation between line, transformers, breakers, and bus.

TRANSMISSION OF BULK POWER

Interconnection of large systems for bulk power interchange has continued which, with the hydroelectric-station development, has resulted in numerous 220-kv lines, the highest commercial voltage in the country being the 287 kv of the lines from Boulder Dam.[106] This interconnection of systems has caused further stability problems, which, together with the desire to reduce the damage caused by faults and lighten the effect on customers' services, has resulted in the development of high-speed relaying, both of the distance and balanced type, and the carrier-current and pilot-wire type; these types of relaying are being applied to transmission of all voltages. Relay times of one cycle or less are available, which, combined with five- or three-cycle breakers, give rapid clearing of faults where such extreme speed is necessary. To aid in permitting systems to ride through overhead line disturbances, the use of the Petersen coil, rapid reclosing of breakers, and discharge tubes is increasing.

The use of high-voltage cable for transmitting large blocks of power has increased, approximately 79 miles having been installed for 66 kv and above since 1933.

STATION AUXILIARIES

The majority of the steam additions to existing plants use electrical auxiliaries. Higher-pressure boilers have increased the demand for higher-speed boiler-feed pumps, and the trend is toward constant-speed or multi-speed motors for both this service and the forced- and induced-draft fans. Constant-speed squirrel-cage induction motors have been built as large as 2,000 horsepower for feed-water pumps and up to 700 horsepower in the wound-rotor type. Three-phase supply, 2,400 volts, is quite standard for this type of auxiliary, and the factory-built metal-enclosed bus structure is in general use, the lift type of breaker being popular. Air circuit breakers of the 5,000-volt 100,000-kva class are now available from several manufacturers for auxiliary station service, and as many consider it just as desirable to reduce oil contents of boiler rooms as of switch houses, the air breakers show increasing use. Noninflammable liquid, first applied to distribution transformers, is now used in power transformers and is particularly adaptable for auxiliary service in station locations where oil would be a hazard. More study is being made to ensure the continuity of auxiliary service, of obtaining separate sources of supply, and complete protection of auxiliary buses. The increasing use of pulverized fuel, with its intricate and delicate starting procedure, has introduced additional problems in

continuity of service during system disturbances, and undoubtedly more thought will be given to either ensuring the maintenance of auxiliary-bus voltage or automatic starting of the pulverized-fuel equipment.

Hydroelectric-Plant Practice

Annual water-power figures are beginning to look like those for 1928 and 1929, predepression years. During 1938 about 750,000 horsepower of new capacity went into service, bringing the total capacity of water wheels to around 18,000,000 horsepower for the United States, as shown by figure 4. At the present time in the United States over 2,000,000 horsepower of water-wheel capacity is under construction and work has been started on other projects representing an ultimate installed capacity of 750,000 horsepower for which the power units have not yet been ordered.

A large part of this capacity is in plants being built by governmental agencies. There are, however, many projects being developed by public-utility and industrial companies, particularly in the northeastern and midwestern sections of the country. In 1937 and 1938 work was started or completed on over 60 of these projects, representing an initial capacity of 500,000 horsepower.

Notable among public-utility projects are the four 26,000-horsepower units for 110-foot head in the Claytor development of the Appalachian Electric Power Company on the New River, Virginia; the 77,000-horsepower unit for 188-foot head installed in the Kerr power house of the Rocky Mountain Power Company on the Flathead River in Montana; the 14,700-horsepower and the 8,400-horsepower units for 91-foot head in the Grandfathers Falls power house of the Wisconsin Public Service Corporation; and the 10,950-horsepower unit for 45-foot head being installed in the Solon development of the Central Maine Power Company. Several other projects have been put into operation or under construction by public-utility companies in Maine, Vermont, New York, Virginia, Wisconsin, and other states.

In point of installed capacity, water-power projects being built by governmental agencies exceed all others. These, including those that have been built and on which work has been started, represent an ultimate capacity of over 9,000,000 horsepower, or one-half of the total installed in the United States. Nearly 3,500,000 horsepower of this is for Bonneville and Grand Coulee plants on the Columbia River, 526,000 horsepower in California, and 1,835,000 horsepower at Boulder Dam (see table I).

These projects represent about two-thirds of the total ultimate capacity. Of the remaining third over 2,000,000 horsepower is represented by projects of the Tennessee Valley Authority on the Tennessee River, leaving only about 1,000,000 horsepower in other parts of the country. TVA projects include Wilson Dam plant with space for 610,000 horsepower, built before that organization was created by Congress.

By June 1939, only 1,631,500 horsepower had been installed in Government financed projects since 1932, and this includes 260,000 horsepower in Wilson Dam plant. For these plants there are on order machines having an aggregate capacity of 2,000,000 horsepower of which 1,250,000 horsepower is for Grand Coulee, Bonneville, Shasta, and Boulder plants, in sections normally supplied by water power.

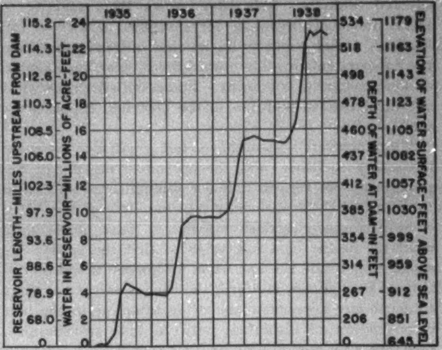

Figure 5. Rate at which Boulder Dam reservoir has filled since closing of the by-pass tunnels in 1935

Outside of Bonneville development, all the large governmental water-power developments in the Pacific Coast area are essentially water-supply and river-regulation projects from which large amounts of power can be generated, much of which will be required to pump water for municipal supply and irrigation. Grand Coulee is the largest of these and in fact is the largest in the world on which reliable data are available. It includes a straight concrete gravity-type dam 4,500 feet long, 553 feet high, and 500 feet thick at the base.

This dam will back the water up the river 150 miles to the Canadian border to form a reservoir with 9,645,000 acre-feet maximum storage and a maximum head of 360

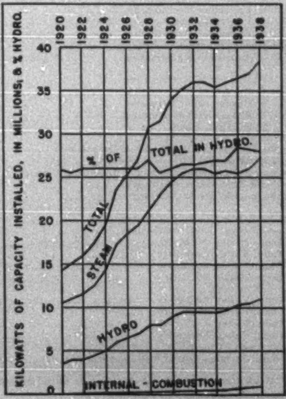

Figure 6. Growth of installed generating capacity in both privately and Government-owned public-utility plants of all classes in the United States

feet. A useful storage of 5,200,000 acre-feet will be available with 80 feet drawdown. At the midstream section of the dam will be a 1,650-foot spillway designed to pass 1,000,000 cubic feet per second. Between the ends of the spillway and the shores, two power houses will be built, each with nine 150,000-horsepower main turbines connected to 108,000-kw unity-power-factor generators. In addition, the west power plant will house three 14,000-horsepower service units.

Including the three service units, the total ultimate capacity of Grand Coulee plant is 2,742,000 horsepower, which is 900,000 horsepower more than planned for Boulder plant and 500,000 horsepower more than planned for the Beauharnois development on the Saint Lawrence River in Canada, which now has 483,000 horsepower installed.

Just above one end of the Grand Coulee dam and at right angles with it will be a pumping plant containing 12 vertical 65,000-horsepower synchronous-motor-driven pumps. Each pump will have a capacity of 1,000,000,000 gallons per day when pumping against a 295-foot head. These pumps will lift water from the main reservoir into a secondary reservoir formed by a dam across the lower end of the Grand Coulee, from where the water will flow to irrigate 1,200,000 acres of land. Six generators in the power house adjacent to the pumping plant will supply power to the pump motors. Three main generating units and two service units are now on order and are scheduled for initial operation in 1941.

Part of the power from the Shasta development now under construction on the Sacramento River in California will be used for pumping irrigation water. This project will have an ultimate capacity of 500,000 horsepower, of which four 103,000-horsepower units to operate under a 450-foot head are on order.

So much has been written about Boulder Canyon project that one hesitates to say more. But this project has so many interesting features that a report on water-power development would not be complete without calling attention to some of them. Construction work was started in 1931 and operation began in 1936. The project has four major purposes; namely, flood control, supply water for irrigation and municipal use, and power generation.

In the power house, which is designed for an ultimate capacity 1,835,000 horsepower, 752,000 horsepower has been installed and two 115,000-horsepower units are on order. These will give this plant the largest installed capacity of any hydroelectric project in the world, and the only steam plant to exceed its present capacity is the Hudson Avenue station, Brooklyn, N. Y., which has 770,000 kw installed. Eventually, 400,000 horsepower of pumping load on the Metropolitan Water District aqueduct, running from the Colorado River to Los Angeles, Calif., will be supplied by Boulder Dam. Initial installation of this aqueduct goes into operation this year.

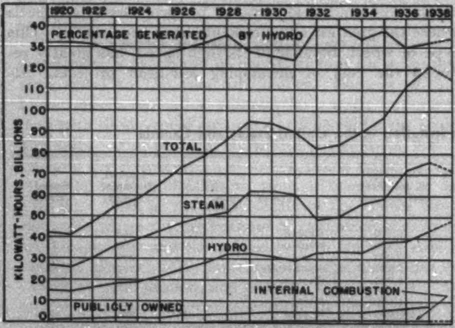

Figure 7. Growth of power generated in the United States in privately and Government-owned public-utility plants, and the relation between total generation and that produced by water power

Figure 8. This 42,500-horsepower Kaplan-type propeller runner has its blade surfaces machined and polished all over

As figure 5 shows, Boulder Dam, which is 730 feet high and forms a reservoir of 30,500,000 acre-feet capacity, has prevented several floods that would have been disastrous on the lower river, and has also prevented irrigation-water shortages. The sharp rise in the curve each year during May and June shows how severe the floods are. Last year during this period 6,000,000 acre-feet of water was stored. This is equivalent to a continuous flow of 55,000 cubic feet per second for two months, in addition to the water permitted to flow down the river. If average water supply is obtained in the river this year the reservoir should be filled to capacity.

These water-power developments by governmental agencies naturally raise the much discussed question of hydraulic versus steam plants and what effect these new hydraulic plants are having on the relation of hydroelectric and steam-electric installed capacity and generation. In spite of all the activity in water-power development by governmental agencies, the growth in hydroelectric generating capacity was more rapid before 1932 than since then, when the Government seriously entered the field, as is evident from figure 4.

For example, for the seven years from 1925 to 1931, inclusive, installed water-power capacity increased nearly

Figure 9. Modern type hydraulic-turbine-governing unit combines all parts of the governing system into a single cabinet with the exception of the servo-motors and generator for driving the actuator

5,500,000 horsepower, where from 1932 to 1938, inclusive, only 2,250,000 horsepower has been installed. Of course it must be admitted that the depressed condition of business has been a factor in the latter. But, if we compare only the three years from 1936 to 1938, inclusive, with the nine years from 1923 to 1931, inclusive, the latter shows a considerably steeper rise than the former. An even more important factor than the depression in slowing up water-power growth is that efficiency of steam plants has increased and their cost of construction decreased to where in many localities they now seriously challenge water-power developments on an economic basis.

An outstanding example of steam-plant construction in a water-power region is the new 160,000-kw plant of the Buffalo, Niagara and Eastern Power Corporation, being installed at Oswego, N. Y., in a region largely served by water power. Installation of this steam plant was not dictated by any shortage of water-power sites, for the company controls several within easy reach of where it is being built. When all factors were considered, economic and otherwise, the steam plant proved to be the most desirable. The city of Eugene, Ore., which operates its own power system and is only 160 miles away from the Federal Government's Bonneville hydroelectric plant, announced plans for a new peak-load steam or Diesel plant during the latter part of 1938. In 1937 the Tennessee Electric Power Company won the right from the State Public Service Commission to install a steam plant at Nashville, Tenn., by proving that this type of plant could supply power to its system more economically than it could be obtained from the Government-subsidized TVA hydroelectric system. Since then this plant has been sold to TVA.

Figure 6 shows the total generating capacity installed in all types of power plants operated by both privately and Government-owned utilities. Also the division of this capacity between steam, hydraulic, and internal-combustion-engine stations. A curve has also been added to show the relation that installed hydroelectric capacity bears to the total. This relation has remained remarkably constant since 1920. In this period installed hydroelectric capacity has increased only 2.1 per cent, or from 25.9 to 28 per cent of the total installed in all classes of plants.

Figure 7 shows power generated by the private and public agencies represented by figure 6. An interesting feature about these curves is that the per cent of total power generated by water power was practically the same (36 per cent) for 1937 as for 1920. Because of the total power load falling off sharply in 1938, and an abundant rainfall in practically all parts of the country, the per cent of water power showed an increase to about 37.5 per cent. These two factors, load growth or loss and rainfall, have a marked influence, and account for most of the peaks and valleys in the water-power curve. From the foregoing it is evident that as yet the relation between fuel-burning and hydraulic plants continues on a practically even keel. The curves in figures 4, 6, and 7 are plotted from data published by the Federal Power Commission, with the exception of 1938 for which figures published by *Electrical World* are used.

Even though Francis-type wheels have been built in unprecedented size and power during recent years, it is in the low-head field covered by propeller-type wheels where the greatest advancements have been made. This type of wheel, because of its high speed, has greatly reduced the cost of developing low-head projects. Al-

Figure 10. Outdoor-type plant at the Wheeler Dam project of the Tennessee Valley Authority has two 45,000-horsepower units, with space for six more

though developed less than 25 years ago, these units have come into wide use in both North America and Europe, in both large and small size. Table II gives data on some of the largest units installed in the United States and Canada. This type of wheel has been developed in three forms: fixed blade; Kaplan, the blade angle of which is adjusted by the governor; and the type on which the blade angle is automatically adjusted by change of water flow through the runner as the load changes. With the fixed blade design, its efficiency curve falls off quite sharply either side of maximum, but by adjusting the blade angle, high efficiency can be obtained over a wide range of load and head.

This type wheel has permitted an increase in specific speed from a maximum of about 90 rpm for a Francis-type wheel to 150 rpm and higher. Because of their higher speed, cavitation assumes far greater importance than with slower-speed runners, particularly for the larger-size units. This problem is handled in two ways, first by locating the runner at an elevation below tailwater level that will limit cavitation to what is considered a safe amount. Then in the construction of the runner vanes, the areas where pitting because of cavitation is expected are chipped out and these filled in with stainless steel by welding, after which in some instances the blades are machined all over, ground, and polished, as in figure 8. Any pitted areas that occur in operation are also chipped out and welded in with stainless steel. Experience has shown that stainless steel will stand the action of cavitation better than any other.

Welding is assuming an ever-increasing importance, not only in the maintenance of water wheels but also in their construction. For example, in the Bonneville propeller-type units, practically all parts, with the exception of the runners and shafts, were constructed by welding.

Governors for hydroelectric units have been improved in their ability to control speed and have been radically changed in appearance. Where a few years ago the actuator and valves were in one place, the oil-pressure pumps in another, and the pressure tanks in still another, the modern governor has these parts along with all instruments and indicators combined in a single unit, as in figure 9. On the front of this cabinet actuator are a speed and frequency indicator, draft-tube vacuum gauge, penstock-pressure gauge, duplex gauge showing generator-brake-system air pressure and brake-cylinder pressure, duplex gauge showing auxiliary and main relay valve port positions, speed-droop indicator with knob directly below, gate-limit and gate-position indicator with gate-limit knob directly below, speed-adjustment indicator with control knob directly below, manual generator-brake-valve control knob, control knob for transferring from main to auxiliary valve control and vice versa, cabinet-light switch and pilot lamp, emergency shutdown switch and pilot lamp.

Outdoor-type hydroelectric plants, which 10 or 15 years ago were attracting considerable attention, have been adopted in only a few installations. Wheeler Dam plant of TVA, figure 10, is an outstanding example.

Figure 1. An air view showing most of the 1,216-acre area of the New York World's Fair, and essentially all of the main exhibit area. The focal points marked are: (A) Court of Peace, government area; (B) Lagoon of Nations fountain; (C) Constitution Mall, with the Four Freedoms plaza (toward the Lagoon) and the heroic George Washington statue facing the Manship fountain and the Perisphere; (D) Theme Center with surrounding plaza; (E) New York City Building, one of the permanent structures; (F) transportation zone, marine and air at the right, automotive at the center, railroads at the left; (G) Bowling Green plaza; (H) Court of Communications; (I) Court of Power; (J) Plaza of Light, electrical-manufacturing and utilities zone; (K) amusement zone starts here and extends to the right. To help readers to orient themselves, the points from which the eight color views were photographed are indicated by numerals, which correspond to the plate numbers

Lighting the New York World's Fair

RICHARD C. ENGELKEN*
MEMBER AIEE

THE CONVERSION of more than 1,200 acres of salt marsh and waste land into the New York World's Fair, with its stimulating review of the world of today and its effective preview of the "World of Tomorrow," was a remarkable achievement, accomplished within the short span of three years. In this $150,000,000 transformation, electric light played a major role. Also, the Fair provided the stimulus that brought from the laboratories into commercial production some of the most significant developments ever made in the field of artificial illumination.

The magnitude and magnificence of the New York World's Fair resulted from the combined efforts of many minds and countless hands, all deserving of commendation. Accomplishments, however, mirror capable direction, for which special mention is made of Chairman Stephen F. Voorhees of the Fair's Board of Design, and Colonel John P. Hogan, chief engineer and director of construction. Illumination was headed by Bassett Jones, consulting engineer to the Board of Design, working with J. S. Hamel and the author as lighting consultants to the construction department. The problem of developing the spectacular displays for the Fair was delegated to a Committee on Displays which reported to the Board of Design. This committee was headed by Bassett Jones, and included Professor Jean Labatut, design; Howard Cooper, hydraulics; and the author, lighting. Operation of spectacles was headed by A. K. Morgan, director of displays.

GENERAL FEATURES

The exhibit area (figure 1) comprising about 1,000 acres, contains more than 200 structures, most of which are windowless exhibit buildings. A zoning and color scheme adopted prior to construction insured architectural unity, and harmony of plan, design, and treatment throughout the whole area. Seven classified zones (foods, governmental, distribution, communication, transportation, community interests, and business administration) are distributed around the Theme Center, with streets radiating from the center and crossed by circumferential avenues. The color scheme, also zoned, but on a basis of aesthetic values rather than occupancy zoning, is co-ordinated with the physical layout. Starting with white at the Theme Center, color treatments of red, blue, or gold radiate outward with progressively more saturated hues. Adjoining hues blend circumferentially along the avenues. By virtue of the proper selection of accents and relief tones, each structure presents a color scheme of interest in itself as well as appropriate to the general picture. The illumination was so fitted into this scheme as to maintain the basic pattern by night as well as by day, but with a new and added interest and charm after sunset (see color plates).

Thus illumination and lighting effects became definite elements in the architecture of Fair buildings. As part of the general plan, the exterior surfaces of the buildings themselves serve as major sources of illumination for adjacent street and plaza areas (figures 41–56; color plates). Brightly lighted entrances, niches, and murals, and backlighted plaques aid in effectively achieving this result. With few exceptions, street lights are used to complete the decorative effects rather than as primary sources of illumination (figures 68, 69).

In building interiors, unobtrusive built-in fixtures in general provide simple decorative effects and good aisle lighting with increased intensities at entrances and exits (figures 57–67). This allows exhibit lighting to be arranged to suit individual requirements.

To give the Fair a pleasingly varied skyline at night and to produce a desirable air of festivity, several tall and brilliantly lighted architectural features such as the pylons were provided for in the illumination scheme (color plates and figures 32–40). Also, the various courts and plazas contain suitable small architectural forms combined with the elements of water, light, and flame to produce scintillating animated effects by virtue of the combination of new elements and materials rather than by mere cyclic color variations. Finally, there were the outstanding "spectacles"; the Perisphere-Trylon, Constitution Mall, the Lagoon of Nations, the Court of Peace with its canopy of searchlight beams, and the combined light and fireworks display in Fountain Lake in the amusement area.

Obviously the successful completion of such a gigantic plan required not only the most exacting co-ordination and the closest co-operation among the many architects, engineers, constructors, landscapers, and others involved, but also the creating of new structural forms and new types of lighting equipment. To provide the necessary focal point for technical co-ordination, a test laboratory was established on the Fair grounds in the earliest stages of its development. This served as a medium of contact for the many different interested agencies, and also afforded facilities for research and the study of illumination sources and their possible uses.

Experiments performed in this laboratory served as a stimulus for the commercial development of many new light sources which at that time were found only in the lighting research laboratories. Also many entirely new lighting devices were designed there for the effective application of these new sources. Typical instances are the now well-known low-voltage fluorescent lamp and the high-intensity mercury capillary lamps, which were first used extensively at the New York World's Fair. Architectural elements to utilize new and existing light sources also were developed, or inspired by scale models giving a visible concept of their possibilities.

---

* Member of the firm of Morgan, Hamel, and Engelken, lighting consultants to the New York World's Fair 1939.

To insure architectural harmony and unity of effect, all general structural plans, including exterior lighting for private exhibit buildings as well as Fair projects, were first submitted for approval to the World's Fair Board of Design. Thereby the master plan was consistently sustained.

Space limitations preclude adequate description of any appreciable proportion of the many points of engineering and illumination interest throughout the Fair grounds. Therefore, the scope of this article is limited primarily to the "spectacles" which constitute the backbone of the "picture" presented by the Fair at night, and secondarily to typical details embracing the effective application of new light sources, including the material and equipment involved in those applications.

Theme Center

Because of the importance of the Perisphere-Trylon Theme Center in the general scheme of the Fair, special efforts were exercised to make it as unusual in its nighttime illumination, as it is unique in daytime by virtue of its novel architectural design (plates II and IV). Aside from aviation warning lights at its apex and at points on its sides, the 700-foot Trylon is illuminated only by spill light from adjacent structures.

The Perisphere, a 180-foot spherical structural part of the Theme Center, presented a lighting problem of unprecedented nature and proportions. The illuminating-engineering job of making an appropriate and attractive nighttime spectacle out of this huge ball paralleled the mechanical-engineering job of delicately poising a 4,600-ton steel-framed concrete "bubble" over a shallow mirror-pool of water. The exterior lighting problem involved facilities for flooding this sphere with suitable intensities of either amber, red, or blue light, and the further problem of projecting moving cloud patterns over its three-acre surface (plate IV). Even the floodlighting had to be accomplished by lens-controlled light-beam projection, because the roofs of the nearest buildings on which lighting units could be placed were some 250 feet away (figure 13).

Based upon extensive experimenting with scale models using a six-foot-diameter wooden ball painted white as a model, the lighting sequence adopted is an amber light thrown on as dusk approaches, subsequently fading into a sunset red, and then into a deep evening blue after dark. Water jets underneath the Perisphere, supplemented by blue floodlights beneath the surface of the reflecting pool, and white cloud-shapes projected onto the Perisphere combine to impart the desired effect—that of a translucent bubble poised over the surface of its reflecting pool.

Three types of projectors are used for the exterior floodlighting of the Perisphere. For the amber and red light, projector units of the Fresnel type fitted with 5,000-watt incandescent lamps are used (figure 5). Banks of 8 of these units, 4 red-beam projectors and 4 amber, are mounted on the roof of each of the 5 buildings selected as projection points, making a total of 40 units (figure 2).

The production of an adequate intensity of blue light on the extensive surface of the Perisphere presented a major problem in illumination and required the development of a new light source and related equipment for its use. Because of the blue deficiency of an incandescent light source, a 400-watt high-intensity short-arc mercury capillary lamp was developed and special projectors were designed for the

Figures 2–5. The three-acre exterior surface of the Perisphere is illuminated in any of three colors by 30 nine-lamp projectors using mercury capillary lamps with Fresnel lenses ribbed at the back to give a 10-degree horizontal spread (3) and 40 5-kw incandescent projectors, 20 red and 20 amber (5), drifting clouds are produced by 30 2.5-kw incandescent cloud projectors (4). This equipment is installed on the roofs (2) of five buildings around the Theme Center job. Each of these projector units accommodates nine of the new 400-watt mercury lamps, with suitable light-control optics (figure 3). Blue light for the underside of the Perisphere is provided by 96 blue-filter submerged projectors (similar to those of figure 17) using the new 100-watt mercury capillary reflector lamps.

Cloud projection, relatively simple with the 6-foot model, became another major problem when applied to the three-acre surface of the 180-foot Perisphere. To produce the misty cloud effect desired, an illumination intensity of nearly 10,000 lumens through the projector gate and objective lens is necessary. The resulting intense heat in the projector gate precludes the use of any photographic emulsion or ordinary painted slide; in fact, even the regular mica cloud-machine disks buckled and cracked from the heat. By experiment it was found that aluminum disks containing irregularly shaped apertures backed by small pieces of mica could be used, and that a heat-resisting paint could be applied to the mica to provide gradation in shadows. In the final installation, two such

Figures 6–12. Inside the Perisphere (11, 12) "Democracity" is illuminated by a continuous strip of floodlight projectors underneath the lowe platform (6); another continuous strip illuminates the horizon (6). Sky lighting is provided by a seperate row of projectors (10); moving clouds are thrown across the sky by special cloud projectors (9) and their companion shadows across the landscape by special shadow projectors (8). The night scene is complete with stars (7) representing the principal constellations as they appeared in nature. The motion-picture murals (12) are produced by ten special projectors (11, unlabeled unit)

mica-backed aluminum disks rotating at different speeds are used in each projector (figures 2, 4). Thirty of these cloud-projectors, each using a 2,500-watt high-color-temperature tungsten lamp, are used with overlapping patterns to cover the whole visible area of the Perisphere.

All projectors—amber, red, and blue floodlighting units and cloud machines—are connected to reactance-dimmers and preselective control equipment which permit any cycle of lighting to be used, and provide for automatic control of the 383 kw of exterior Perisphere lighting.

Additional projectors, located on the roofs of the two buildings facing the Perisphere from either side of Constitution Mall, enable special effects to be projected upon the Perisphere area facing the length of the Mall. In 1939 on Edison's birthday, a 75-foot portrait of Edison was projected onto the sphere by additively superposing projected images of identical pictures from these two machines. By similar means, the whole eastern face of the Perisphere became a 180-foot jack-o'-lantern in true color and configuration on Halloween; the jack-o'-lantern even winked occasionally. Undoubtedly this is the largest colored "movie" ever attempted.

INTERIOR ILLUMINATION OF PERISPHERE

Inside the Perisphere is the central theme exhibit of the whole Fair—"Democracity, The City of Tomorrow"—Henry Dreyfuss' carefully scaled and intricately detailed idealistic city, complete with all necessary supporting environs and facilities for agriculture, industry, commerce, air and surface transportation, and suburban residential area. The viewpoint of the spectator is that which would be secured from an airplane circling this scale model at an equivalent elevation of perhaps 10,000 feet (figure 12). The lighting problem was twofold: first, to provide a realistic 24-hour day-and-night cycle; second, to give the observer the physical impression of being suspended in space with the earth beneath him and the sky overhead extending to distant horizons.

The illumination problems encountered in the accomplishment of the desired results in the Perisphere interior, which is actually a large integrating sphere, were found to be even more exacting than those encountered on the outside. Frequent, rapid, and smooth changes in lighting effects are required, as well as exact synchronization of these visual effects with recorded sound effects ranging from voice to music; all automatically controlled in predetermined accurately timed repetitive cycles.

Spectators enter the exhibit through the base of the Trylon, and by means of the two longest (96 feet and 120 feet) electrically operated moving stairways built to date are carried up either 48 feet or 60 feet, respectively, to the lower or upper of two continuous electrically operated moving platforms that carry the spectators at a predetermined speed around the inside periphery, just below the equator of the Perisphere globe.

If the spectator happens to arrive during the day scene, he sees below him in bright "sunlight" the miniature scale City of Tomorrow and its supporting countryside stretching to far horizons and blending realistically with the "sky." Above him is the tremendous arched dome of the Perisphere, impressive in its resemblance to the sky, floodlighted unobtrusively in blue, giving the impression of the heavens complete with moving clouds and their companion shadows drifting across the buildings and landscape. The scene gradually changes, shadows actually lengthen to afternoon proportions, daylight fades smoothly and realistically into dusk, and the sky gradually becomes a midnight blue. Above in the seemingly limitless depths of the vaulted dome appear stars, including those accurately representing the major constellations as they appeared in nature on the night of April 30, 1939, when the Fair first opened. Night clouds drift across the sky. In the meantime, lights have appeared gradually and unobtrusively in the city, in the neighboring industrial area, and in the nearby community of small homes. As the night cycle progresses, the countryside becomes dark except for a few lighted windows and the illuminated highways.

Against a background of appropriate music, the voice of a commentator explains the symbolism of the changing scenes, and helps the spectator to note and follow the many and realistic changing effects. At one stage of the sequence, voices become audible in the distance and simultaneously from far off among the clouds approaching hosts of singing people become visible. As they come nearer, it is evident that they represent all the inhabitants of the city—the business men, the farmers, the workers, the professional people, and the housewives. As the groups draw closer and assume their greatest proportions, they descend out of sight behind a bank of horizon clouds as the concluding sequence of one cycle in the continuously repetitive "show." Immediately dawn and then daylight follow, and another cycle has started. The time cycle of spectator transit around the globe on the revolving platforms is so related to the automatically controlled day-night cycle of the exhibit that all spectators may view a complete cycle between the time they step onto the platform and the time they find themselves back to the starting point and on the way out.

The lighting of the sky dome in either daylight blue or deep night blue is accomplished by the use of continuous rows of concealed strip lights (figures 10, 11) arranged in two circuit groups—a blue group and a white group. The blue lights are on continuously, and the white lights vary from black-out to full brilliance as required.

The lighting for "Democracity" is produced by a continuous row of strip lights mounted under the structure that carries the lower platform (figures 6, 11). Every third unit in that continuous row is a 100-watt short-arc mercury capillary lamp equipped with appropriate "black-light" filter. These "black lights" remain on during the entire show, but are effective only during the "night" period of the cycle, when the windows, highways, and other apparently "illuminated" parts of the model are made to fluoresce under the influence of the ultraviolet radiation from these lamps by virtue of the fluorescent paint with which these parts are coated. Thus, the "lighting" in Democracity at night actually is entirely fluorescent.

Principal features of the special equipment required for the Perisphere interior "show" are the ten specially designed projectors that operate in synchronism to produce the 18- by 30-foot motion-picture "murals" in the "sky" (figure 12). These machines use Bantam-size glass slides in place of the successive film frames of ordinary motion-picture projectors. In each machine, a series of these slides is projected through four optical systems in succession. The slides are mounted on two 50-inch ring gears which revolve within the optical systems. Through a shutter arrangement in front of the objective lenses the slide images are cross-dissolved from one optical system to the next, producing a smooth motion with 8 images per second (as compared with 16 or 24 for standard motion-picture projectors). As intensity of light on the screen remains constant but for absorption by the slides, there can be no flicker regardless of the number of frames per second. It is a noteworthy achievement that the projections from the four individual optical systems of each machine can be registered so accurately in superposition on a screen 165 feet away as to produce a composite result of smooth and realistic motion. Each projector uses four 2,500-watt 65-volt lamps having differentially wound filaments similar to those used in the cloud machines, and is fitted with $f/2$ objective lenses of 8-inch focal length, the largest ever built for such a purpose. To keep all ten projectors in perfect synchronism, each is driven by a Selsyn motor equipped with a mercury damper; all in turn are driven by a common Selsyn generator.

The cloud projectors for the Perisphere interior are similar to those already described for the exterior, with the exception that a lower illumination intensity at the gate permits the use of tempered glass cloud slides (figure 9). Two six-inch cloud slides in each machine are mounted in frames eccentrically driven to produce a rolling effect of the projected clouds.

The entire Perisphere theme show—including the time, music, earth, sky, and voice elements—is entirely automatic, and timed to split-second accuracy. The various operations, including the many lighting circuits and ten special motion-picture projectors, involved in a typical operating cycle of 336 seconds are under the control of motor-driven cams which operate through one revolution and then stop for a few seconds awaiting the initiating impulse which starts each new show cycle. The single signal impulse which initiates each new cycle automatically originates from a notch cut in the sound film. Thermionic tubes constitute the nerve center of this equipment, controlled by the cams and in turn regulating saturable-core control reactors in each of the lighting circuits.

THEME-PLAZA ILLUMINATION

The desired composition of the vista looking toward the Theme Center from any of the five thoroughfares radiating therefrom involved the problem of preserving the full effect of the blue light and cloud effects on the Perisphere. In general, this result was accomplished by keeping all objects of relatively high brightness out of the field of view, and by effecting as much control as possible over the quantity of stray or spill light that would tend to fog the atmosphere and thus dilute the color effect of the Perisphere. The levels of illumination on the exteriors of exhibit buildings were kept low in the vicinity of the Theme Center, grading to higher intensities farther away. Brightly lighted pylons, fountains, and other accents were kept at the opposite ends of connecting courts and thoroughfares.

Around the Theme Plaza itself, the illumination of building façades is accomplished chiefly through the use of back-lighted sculptures (figure 49). These provide spots of visual interest and also provide adequate illumination for adjacent walks. Remaining illumination, aside from reflected light from the blue sphere itself, is provided by luminescent trees activated by mercury light.

Constitution Mall

Connecting the Theme Center and the Lagoon of Nations and constituting a portion of the main backbone of the Fair is Constitution Mall, a 2,000-foot tree-shaded esplanade built around a series of rectangular lagoons and reflecting pools (figure 1). Principal architectural feature of the Mall is the 55-foot statue of George Washington, which is lighted only by spill light from structures on either side of the esplanade. Nevertheless it is as prominent and effective a part of the nighttime picture of Constitution Mall as it is of the daytime vista. The statue is the work of the noted sculptor James Earl Fraser, designer of the AIEE Edison Medal. Other architectural features of the Mall are the Manship sundial, fountain, and associated sculpture group just off the Theme Plaza, and the "Four Freedoms" statues (representing freedoms of press, religion, assembly, and speech). Like the Washington statue, the Freedoms statues are illuminated only by spill light.

The lighting of the Mall creates a strikingly beautiful night effect (plates I, II). Along either side of the Mall for its entire length is a double row of 50-foot luminescent trees which constitute an effective part of the view after sundown and at the same time provide all illumination necessary for the main walkways. Supplementary lighting for walks adjacent to exhibit buildings is provided by light from building entrances, and from illuminated murals, plaques, and niches on the sides of the buildings.

Underneath each of the trees along the Mall, one of the new 250-watt short-arc mercury capillary lamps is set into the ground, in a suitable fixture fitted with a cylindrical metal collar which projects above the ground line for the dual purpose of controlling the side light and of protecting the fixture from physical damage (figures 13, 19). Under the influence of the peculiar radiation from these flood lamps, the leaves, twigs, and branches of the trees become luminous with a soft greenish glow, producing a beautiful effect. The same type of lighting also is applied to the trees in the Theme Center Plaza, the Court of Communication, and the Court of Power (figure 1). In all, some 360-odd trees are so lighted.

WATER LIGHTING

Another attractive feature of the lighting composition of the Mall is a variety of water-lighting effects, chief of which is the animated play of colored light and water in the Manship fountain at the head of the Mall (figure 13). The Manship fountain and associated sculptures are intended to connote the passage of time (indicated by the sundial itself) and the moods of time affecting the human race. This latter effect is simulated by the alternate floods of gold light and blue light which seem to pour in repetitive cycles from three apertures in the abutment of the sundial terrace and flow in successive waves down the entire length of the pool in the layer of mist which overlies the pool. These effects are created by a cyclic play of light upon three columns of water which pour from the sundial abutment and upon curtains of mist overlying the pool. During the operation of the fountain, the columns of water flow continuously, the volume magnified by an ingenious arrangement (figure 16) that produces in actuality a relatively thin-walled cylinder of water 20 inches in diameter. Waterproof lighting units built into the central portion of the discharge "megaphones" of this fountain introduce into each water column alternate cycles of blue and gold light which grade smoothly from dark to maximum brilliance and back to dark for each color. In the pool of the fountain (figure 13) a set of continuous striplights (figure 17), on the center line of each of the three water columns, extends for a distance of approximately 115 feet. Flanking each of these striplights is a

Figures 13–19. The main esplanade of Constitution Mall (13, plate I) consists of reflecting pools lined with small illuminated water jets (17, plate II) and enlivened by several small back-lighted cascades (18). Broad tree-shaded promenades along either side are illuminated by the trees themselves, which luminesce under the influence of radiation from mercury capillary units, one underneath each tree (19). At the west end of the main esplanade is the Manship fountain with special mobile effects produced with water and light (13, 16, 17). Various illuminated murals (15) add decorative touches along the Mall, and in other parts of the grounds. The principal plazas are lighted by special projector standards (14) which concentrate the light on the ground, keeping it out of the range of vision

row of atomizer nozzles which produce three parallel spray curtains and a supplementary layer of mist over the pool generally. As in the three main water columns, two colors—blue and gold—are provided in each line of striplights by fitting each alternate projector with a gold or blue filter. The alternate cycles of blue and gold light that progress down these strips in accordance with a prearranged sequence are synchronized with the corresponding colors in the main water columns. The two color circuits for the column lights as well as for the associated atomizer strips are connected to a special cycle-dimmer arranged to produce the effect of, first, a flow of one color, followed by a flow of the second color, then a flow of both colors combined. The effect begins with the main column lights and continues down the length of the pool with a rate of color flow of approximately ten feet per second and with alternate colors based on five-second intervals. The control device used is a brush-type flasher operating in combination with a motor-driven bank of variable autotransformers. These control the intensity as well as the switching of the separate color circuits, which are brought out at ten-foot intervals to groups of the striplights.

Along both sides of the center pool of the esplanade group and across the head of the pool at the base of the George Washington statue are vertical water jets projected to a height of about eight feet above the surface of the reflecting pools (plate II; figure 13). Each of these jets is individually lighted from beneath the water surface by a single 150-watt reflector lamp (figure 17). Across the head of the pool at the base of the Washington statue is a cascade electrically illuminated from behind (figures 13, 18). A similar back-lighted cascade heads the next pool of the group. The third pool, nearest the Lagoon of Nations, has no lighting features of itself, but serves rather as a reflecting pool in which the fountain display and the Court of Peace searchlight-canopy are mirrored (plate III).

The two plazas of the Mall—George Washington and the Four Freedoms—are lighted by means of special stanchions (figures 13, 14) topped by lighting units fitted with optical systems which project light down to the surfaces of the roadway and walkway, eliminating dispersion.

Lagoon of Nations Display

Dominant and popular lighting spectacle of the Fair, the Lagoon of Nations combines the elements of water, light, sound, flame, and fireworks in one mammoth display. Regardless of weather the evening performances of this "show" (plates I, VIII) regularly have packed thousands of Fair visitors into every available vantage point from which the spectacle could be viewed. Centrally located in the main exhibit area, the Lagoon forms a pivotal focus of interest, by day as well as by night, flanked to the west by Constitution Mall leading to the Theme Center, and to the east by the Court of Peace with its phalanx of government buildings (figure 1).

The Lagoon is an elliptical pool some 800 feet long and 400 feet wide. This area, approximately five acres, originally was a slough over which a supporting mat covered by a coating of gravel had to be laid. At the center of the pool is a wooden platform 400 feet long and 200 feet wide, mounted on piling and normally about two feet under water. This submerged platform supports the array of piping, wiring, and equipment required by the fountain itself and also supports four cylindrical kiosks 24 feet in diameter and 7 feet high which house groups of sound projectors as well as miscellaneous electric and hydraulic-valve control equipment. The plan view (figure 27) shows the "three ring" arrangement of the fountain and indicates the general arrangement of more than 1,400 water-jet nozzles, 133 gas-flame nozzles, 285 fireworks mortars, and 552 special light boxes.

At the center of each of the three circular sections of the fountain is a group of nozzles capable of projecting a column of water 150 feet into the air. Equally spaced around the concentric rings of each section are nozzles capable of projecting water jets to a height of 75 feet. Each of these 552 heavy-duty nozzles has its own twin-unit projector box for light and color effects (figures 27, 28). Miscellaneous other nozzles provide for a wide variety of water configurations. A border of graceful shape is provided around the triple operating center of the fountain by approximately 1,100 feet of strip lighting which illuminates a spray screen produced by atomizer nozzles (figures 27, 28).

PLANNING AND ARRANGEMENT

The physical arrangement and relationship of these various elements were determined through the medium of extensive studies of small-scale working models, and of experimental equipment both in miniature and full size. In the experiments with full-scale working models, several important observations were made which had a direct influence on the design of the lighting and control equipment. For example, it was found that the effect of mercury-vapor lighting of the tall water jets was especially desirable, not alone because of the rich and intense blues, greens, and other cool shades thus obtainable, but also because of the scintillating and animated "sparkle" imparted to the myriad particles of water by the stroboscopic effects of the mercury light. Also, many interesting and hitherto unobtainable shades of colors were found to be attainable by combining certain of the colors derived from the mercury lamp with other colors derived from the incandescent light sources.

Probably one of the most significant experimental observations was the extent to which color values obtained from incandescent sources were enriched by direct color-filtering of the lamp with its filaments burning at maximum temperature, as compared with color effects produced by blending the primary filtered colors from incandescent sources with conventional dimmer-control and consequent subnormal filament temperatures.

TWIN-PROJECTOR LIGHTING UNITS

The necessity for color control of the mercury light sources led to the development of an effective mechanical color-shifting and dimming device, which, as just intimated, also lends itself effectively to color control and dimming of incandescent light sources. Thus, to provide the range and combination of colors that make the fountain display famous, a special semisubmersible twin-projector lighting unit was developed. Each of these units (figures 21, 22) utilizes a 1,500-watt concentrated-filament incandescent lamp and a 400-watt mercury capillary lamp. Each light source in each unit is fitted with a suitable reflector. Around each reflector is a specially devised six-sided revolving color drum, the sides of which support natural-colored glass filters, open frames, or blank metal sheets, in selected sequence. (The trade term "natural-colored" refers to color throughout the thickness of the filter glass, as compared with surface treatment.) These color drums enable effective mechanical dimming of the incandescent light as well as of the mercury light, and permit not only combinations of various colors of the two sources, but also the use of any of the several colors or tints from either of the two sources independently of the other. The complete twin unit, including incandescent lamp, mercury lamp, and all associated driving and control equipment, is mounted in a waterproof sheet-metal tank approximately 28 inches long, 28 wide, and 27 deep.

Each color drum is separately driven by a three-phase 208-volt $^1/_{75}$-horsepower 1,800-rpm synchronous motor at a speed of one revolution per minute. This speed requires a ten-second interval to pass from one color into another, or into black-out, and was determined by test and experiment to be the most desirable for smooth blending.

The problem of keeping several drums operating in multiple and with color filters always in the same relative positions was solved by a magnetic braking system that brings all drums on any circuit to a quick stop—actually within $1^1/_2$ revolutions of the motor shaft. The power for braking is supplied by a separate 60-volt d-c source, and the motor circuit is so arranged that whenever motors are disconnected from their a-c power source, two phases of the motor instantly and automatically are short-circuited and connected to one side of the d-c circuit, the other side of the d-c braking circuit being at all times common with the third a-c phase wire. In addition to the d-c braking feature, all color drums on any circuit are arranged to be resynchronized automatically at the black-out position of the color drum. This feature requires the use of a small relay, together with a cam and limit switch for each motor.

The colors and their relative positions as actually selected for the mercury projector of each twin unit are: clear, light blue, dark blue, black-out plate, "surprise" pink, and black-out plate. For the incandescent source they are: clear, yellow, blue-green, black-out plate, red, orange. The 1,500-watt screen-grid incandescent lamp has a rated efficiency of about 25 lumens per watt, or a total output of 37,500 lumens. The 400-watt mercury capillary lamp has a rated efficiency of about 45 lumens per watt, or a total output of about 18,000 lumens. Because actual tests indicated as much as 65 per cent light absorption for a one-inch depth of the brackish water available for use in the Lagoon, underwater placement of the twin lighting units was abandoned, and each unit so placed as to project approximately six inches above normal water line. Thus the glass covers of these twin units are subjected not only to the battering of the heavy deluge of falling water, but also to severe heat stresses, particularly over the incandescent unit. The narrow-beam reflectors so concentrate and localize the light beam that temperatures as high as 425 degrees Fahrenheit have been measured on the surface of the glass covers of the boxes directly above the incandescent lamps. A solution to this problem finally was achieved through the use of specially tempered plate-glass panels having exceptionally high transmission efficiency for the infrared rays. Standard heat-treated glass was found to be satisfactory above the mercury lamps.

To produce a mist or "curtain" effect around the base of the entire fountain display, there is a continuous row of atomizing nozzles. Illumination of this mist curtain is accomplished by continuous strip lighting. These strips are made up with receptacles spaced six inches on center to accommodate some 1,800 of the new 100-watt *R*-40 reflector-type lamps divided into four color groups—clear, amber, green, and red. Each reflector lamp is set in a separate adjustable cylindrical sheet-metal housing (figure 23) and provided with a natural-colored glass roundel.

FOUNTAIN CONTROLS

All elements of the Lagoon display—water, light, sound, flame, and fireworks—are remotely controlled from bench-type switchboards in a control room atop one of the government buildings overlooking the Lagoon (figures 24, 25). Water valves are selectively operated from small pilot switches which energize solenoid valves in the kiosks; these valves in turn admit city water to large hydraulically operated valves at the nozzles (figure 25). Water nozzles and associated twin-unit light projectors are placed to enable the formation of a variety of fountain patterns.

Control of the twin-light projectors is accomplished through contactor panels in the kiosks that in turn are operated from the control room. Lighting controls correspond to the water controls, so that groups of lights may be operated selectively with their associated water nozzles in a wide variety of patterns. In all, there are 19 main lighting-group controls (figure 24). Color control of these projectors is accomplished through close and accurate control of the synchronous motors driving the color drums.

The different switches on the panels in the control room permit independent operation of either mercury or incandescent color drums, facilitating ready combination of a wide variety of color tones. The grouping of a number of drums on one color switch (as many as 63 per switch) reduces to 19 the number of pairs of color-selection controls actually required for the 552 twin units on the Lagoon platform. An ingenious circuit arrangement permits the drum-control switches to be preset to any color, and then operated either individually or from master switches at the desired moment. An outstanding result of this method of color control is the subtle, almost imperceptible, transition from one color to another—an effect aided materially by the previously mentioned experimental selection of the optimum (ten-second) interval for a color translation.

Plate I (facing page). Constitution Mall, scenic backbone of the exhibit area, presents a picture of rare beauty at night. This view, looking east from high in the Trylon during the evening fountain show in the Lagoon of Nations, shows how the various effects are combined into one spectacular display; note also subdued illumination near the Theme Plaza (foreground)

Plate VI. Decorative pylons representing man's first-known elements (earth, fire, water, air) form the southern terminus of the Court of Power (figures 37, 39). Floodlighted building façades constitute the principal source of illumination for streets and walkways

Vol. 59
1940

Plate VII. Clustered around the Plaza of Light south of the Court of Power are several electrical-industries exhibit buildings. The small fountain in the foreground illustrates how centers of interest are provided in small plazas and courts throughout the grounds

Courtesy Westinghouse

Corresponding to the 19 main lighting-group controls already mentioned, there are 19 panels in the central control board (figure 24). One of the dials on each panel controls the mercury units, and the other controls the incandescent units, throughout the corresponding group of twin-projector units associated with that panel. Each control dial is so arranged that it may be rotated in either a forward or a reverse direction to any preselected color position. The arrangement of circuits and associated relay and other equipment is such that the associated group of color drums will rotate correspondingly to the selected color position. At the same time, the motor-driven pointer on the control panel immediately behind each dial accurately follows and at all times shows the position of the associated color drums. This motor-driven indicator is a duplicate of the motor, limit switch, and cam arrangement that is associated with each color drum inside the twin units on the fountain platform, and the circuits provide identical d-c braking and synchronizing control.

Control of the striplights for the border curtain of illuminated mist is accomplished through the medium of motor-driven variable autotransformers located in the kiosks, but operated from the central electrical control board. All gas burners are electrically operated from the control room and are ignited by a small pilot flame which is kept burning, in spite of the deluge of falling water, by a 10,000-volt spark ignition system. Some 280 fireworks mortars are controlled electrically through connections to central patching-panel boards in the kiosks. A total of 50 firing positions is available at jack outlets above the mortar jacks, and jumpers permit any mortar or combination of mortars to be plugged into any firing position. A step-by-step relay energizes one after another of the firing jacks in response to the closing of the "fire" button on one of the main control panels in the control room.

In a separate pump room (figure 26) convenient to both the Lagoon and the control room are motor-driven centrifugal pumps totaling some 2,700 horsepower and capable of furnishing approximately 100,000 gallons per minute. Arranged to comprise an operating exhibit in themselves, these pumps supply the Lagoon fountains. Pumps and associated equipment lend themselves to a flexibility of control (figure 25) and a promptness of response that adds to the effectiveness of the fountain "shows."

Power for the lights and equipment located on the submerged Lagoon platform is transmitted from the main distribution board near the pump room to the kiosks by 11 700,000-circular-mil three-phase feeders. All wiring in the Lagoon consists of ordinary rubber-covered conductors, with so-called watertight insulation. All conductors, including those of control circuits, are merely laid in the water and strapped to the deck of the submerged platform without any additional protection.

FOUNTAIN OPERATION

Once each evening, just at dark, a 15-minute prearranged "show" is presented in the Lagoon, combining the various elements appropriately to render an unusual form of composition that has proved to be an ever-popular attraction (plates I, VIII). The music, played by a 42-piece band in a studio in an exhibit building, is picked up stereophonically by two microphones, relayed by wire to the control room where it is amplified and monitored, and then transmitted over two separate channels to the loud-speakers in the four kiosks on the submerged fountain deck. Each diagonally opposite pair of kiosks is served by one of these channels, thus giving a two-point stereophonic effect along both axes of the Lagoon. Each kiosk contains four high-frequency and two low-frequency speaker units, totaling 500 watts in audio output capacity. This is one of the first large stereophonic installations. The sound system has a total audio output of 2,000 watts.

Split-second synchronization of the various elements during the 15-minute nightly "shows" is accomplished with the aid of specially developed "cueing" machines, one located at the top of each of the triple-unit central control boards (figure 25) and one located in the music studio. These ingenious machines are in effect special adaptations of the machinery of curve-drawing electrical measuring instruments, with the curve-drawing elements removed. Basically, each machine consists of a synchronous-motor-driven mechanism that draws the cue sheet at 60 inches per minute under a wire marker which indicates the cue instant. Each cue sheet consists of a roll of graph paper, marked off in two-second intervals, on which are plotted against the time axis all the cues and special instructions necessary for the particular group of operators served by the particular cue machine. The several operators translate the cues into the actual operation of the various control switches, including the firing of the fireworks mortars. All "cueing" machines are started and stopped simultaneously by a master switch in the central control room. By means of this system, all operations are accomplished within a fraction of a second of the predetermined time schedule and the productions have been kept so uniform that their accuracy has become a byword.

Some of the same general type of equipment is used in Fountain Lake where a spectacular element appropriate to the amusement area is furnished by the mammoth fireworks display that follows the nightly Lagoon show. The feature of this display is its mobility. Pumps, light projectors, fireworks mortars, and all such equipment are distributed among several barges which may be shifted to provide different effects, subject to control from shore through equipment similar to that used for the Lagoon.

Court of Peace

The searchlight canopy over the Court of Peace constitutes the third and easternmost portion of the feature lighting spectacle of the Fair that begins at the Theme Center (plates I, III, V). This canopy of searchlight beams gives a third dimension to this part of the nighttime picture, producing the visual impression of a raftered or coffered ceiling over this whole 450- by 900-foot area, which is flanked on either side by the pavilions of foreign governments and dominated at its easterly terminus by the $3,000,000 United States Government Building.

Plate VIII (facing page). The nightly fountain "shows" in the Lagoon of Nations ingeniously combine the elements of water jets, light, color, flame, fireworks, and sound into one harmonious whole. Part of the spectacle are the thousands of visitors who nightly jam every vantage point for this wholly unusual and enormous display

Oriented and designed to climax the vista down Constitution Mall from the Theme Center, the searchlight canopy is keyed to a pyramidal structure comprising five main searchlight beams which are directed to intersect at a point some 400 feet directly above the center of the Lagoon of Nations and which form an outer framework for the fountain display. Four of these searchlights are mounted on the tops of convenient buildings at the four points of the compass at distances averaging some 700 feet from the center of the Lagoon (plate I). Each of these four units is a 36-inch 125-ampere high-intensity automatic-feed carbon-arc projector. The fifth and most powerful searchlight beam comes from a similar 60-inch army-type searchlight mounted on the roof of the Federal Building exactly on a continuation of the center axis of the Mall. Intersecting this latter "ridge pole" beam of the canopy of light structure are two groups of eight parallel pencils of light from projectors mounted on the roofs of the foreign-government pavilions flanking the Court of Peace (plate III). Each of these 16 beams has as its source one of the newly developed 1,000-watt water-cooled mercury capillary lamps mounted in a suitable searchlight housing (figure 31). The small size of the actual source of this light (approximately 1.5 by 25 millimeters) is ideal for the purpose, producing a narrow "pencil" of light.

WITHIN the limits of this article it has been possible only to outline the plan and purposes underlying the lighting scheme of the New York World's Fair of 1939; to describe in some detail the most prominent lighting displays, and show how they have been accomplished; and to mention the significant new forms of lighting developed. Throughout the enormous exhibit area are numerous other interesting and novel lighting creations, unmentioned only because of space limitations. Most of the significant basic forms of lighting, however, are represented among the various illustrations and application sketches, although, of course, many different variations, combinations, and adaptations were used by different exhibitors, all of whom made effective use of new and attractive lighting arrangements.

A World's Fair, by its very nature, offers exceptional opportunities for the presentation of new ideas. The keynote of the New York World's Fair is "better living in the world of tomorrow." Especially in the field of illumination has this keynote successfully and significantly been carried out. The Fair served as a stimulant to creative minds seeking departures from the conventional; also as a proving ground for new and better light sources, for improved methods, systems, and techniques. Its success is evidenced by such developments as the rapid commercial acceptance of the low-voltage fluorescent lamp, and the increased consciousness of lighting as an element of architectural design, a foretaste of the practices of tomorrow.

THE AUTHOR is indebted to many individuals and companies for helpful co-operation in the course of his work at the New York World's Fair. The Westinghouse, General Electric, and Eastman Kodak companies all went out of their way to place their facilities at the disposal of the Fair for carrying through many of the new developments. The Westinghouse company's Lighting Division gave every assistance in the final design and manufacture of most of the special lighting equipment used in the Lagoon of Nations, the Court of Peace, and at the Theme Center; the General Electric Company expedited the development of the low-voltage fluorescent tubes and related equipment; the Eastman Kodak Company designed and manufactured the significant new motion-picture projector for the Theme Building.

Special acknowledgment for valued and comprehensive co-operation is made to Edward H. Sniffin and H. M. Hays of the Westinghouse company; also to W. F. White and Irving Yost of that company for their untiring assistance. C. M. Cutler of General Electric acted very effectively throughout the construction period as liaison engineer between the Fair and the laboratories and plants of his own company. Fordyce Tuttle, of the Eastman company, in addition to his work in the development of the special Perisphere motion-picture projector, contributed much to the solution of other important optical and projection problems. The author's indebtedness is acknowledged to John H. Kliegl for the development of special-effect projection equipment; to Daniel Rollins of the Ward-Leonard Electric Company for the design and manufacture of control equipment; to D. D. Gillespie for the manufacture of the intricate control boards for the Lagoon of Nations display and the Perisphere Theme Show; also to A. B. McKenna of the Westinghouse Lamp Company and to Albert Fuller of the Eastman Kodak Company. The author expresses special appreciation to Editor G. Ross Henninger of the AIEE and his staff for their helpfulness in the preparation of this article.

Editor's Note: Incidental to the preparation and publication of this article, persons and organizations too numerous to mention have made valuable contributions which are acknowledged hereby. Special credits are due as follows: To P. L. Giering, J. G. Lawrence, and other members of the World's Fair staff, especially Wm. W. Morris who carried his camera 300 feet up into the Trylon to secure the view shown on plate I; to Harry Flowers, of the Flowers Photo Engraving Corporation, New York, for valuable assistance in the preparation of the color plates; to the Westinghouse company for making these plates available for use in ELECTRICAL ENGINEERING; *to the General Electric Company, the General Motors Corporation, the Westinghouse company, and the World's Fair Corporation for various illustrations.*

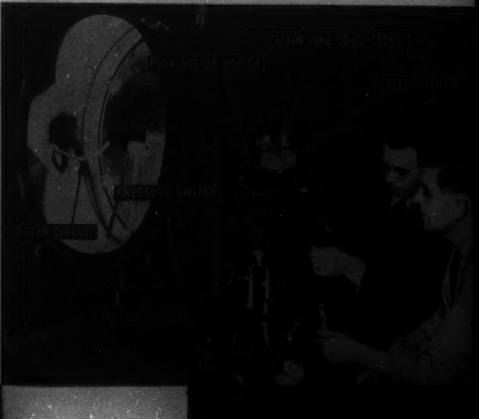

Figure 31. The 16 pencil-like searchlight beams forming a canopy over the Court of Peace (plate III) have as their source the newly developed 1,000-watt water-cooled mercury capillary lamp. One of the searchlights with associated control equipment is shown here

This lamp operates at 840 volts and produces some 65,000 lumens, an equivalent brightness of about 300 candle power per square millimeter, which is about one-fifth the brightness of the sun. About three quarts of cooling water per minute is required for each lamp

Some Pylons

Decorative pylons, strikingly illuminated at night, provide sharp accents that contribute sparkle to the nighttime scene, at the same time serving as points of orientation for New York World's Fair visitors

Typical Exteriors

IN general the design of each Fair exhibit building provides a single dominating architectural element such as the spiral pylon on the Operations Building (figure 48). These elements serve to individualize the buildings and in most instances are the primary source of "sparkle" lighting for the structure itself. Thus the lighting treatment for individual buildings is developed to meet the special needs of those buildings, as in all decorative pylons (figures 32–40), and utilizes a wide variety of light sources including high- and low-voltage fluorescent tubing, much of which is used exposed (figures 45, 53). In some instances where a particular translucent effect is desired, tubing of different colors is concealed as in the fin of the Chemicals and Plastics Building (figures 41, 44). The façades of the structures in general are treated

Figure 48. The spiral pylon of the Operations Building is composed of 12-inch 40-watt T-8 lamps on four-inch centers mounted in a spiral trough supported by a central pipe. The facade at the left is lighted by blue fluorescent tubes in fluted coves. A decorative strip (47) underneath the portico illuminates mural and walkway

with built-in lighting units; these serve to illuminate the painted wall murals which in turn reflect soft diffused light to adjacent walkways. The colors of light sources are selected to accentuate the colors of the murals or façades, and in some instances additional color filters are applied. The use of plaques, as on the Hall of Communications (figures 50, 51), provides many possibilities for accent color lighting applicable to both decorative and utilitarian purposes. On this and the facing page are presented selected night views showing typical exterior lighting. Space limitations obviously permit illustrating only a few typical applications of the significant types of exterior illumination at the Fair.

Figure 52. At the entrance to the Shelter Building are two rows of 150-watt units with prismatic lenses; the inner row is directed toward the mural, difficult to light because of its specular surface, and the outer row downward

Modern Rail Transport

A. M. WRIGHT
ASSOCIATE AIEE

Because of diversion of traffic to the highways, the railways have experienced severe reductions in operating revenue over the past several years. Since revenue must cover operating expenses and fixed charges, to remedy this condition the traffic density must increase and the operating expenses per traffic unit must be reduced. This article discusses the achievement of this by suitable co-ordination of rail and road transport, with certain consolidations of rail lines and restriction of heavy long-haul traffic to the railways. Such a program introduces important engineering problems, and the problem of motive-power adequacy is discussed with particular reference to steam and electric locomotives. A short outline of other important developments in rail transport also is included.

THE most important problem facing the railways today is that of maintaining revenues and financial structures in the face of falling traffic. Since the advent of the automobile a great deal of the most profitable land transport business has been diverted to highways, and this has resulted in a general decrease in net railway revenue, despite the fact that this same period of decreasing traffic witnessed a general rise in productive activity and the use of manufactured consumers' goods.

Nor is this diverted traffic confined to short hauls and to packaged or small-bulk commodities. For example, it is estimated that about 3,000,000 tons of anthracite coal are hauled annually by motor truck from the Pennsylvania mines to the centers of population in Philadelphia, Pa., and New York, N. Y.; and the haulage of perishable foodstuffs by highway from Florida and other southern states to the markets of the north Atlantic seaboard is now a business of large proportions.

This change in the transportation structure has appeared in varying degree in all countries—in many cases so far that the railway system is threatened with bankruptcy, and in all cases to such an extent that a solution has been, or must be, found.

The cost of producing a unit of transportation by rail is made up of the actual operating cost, including train-crew wages, fuel and supplies, maintenance of way and rolling stock, etc., plus a portion of the fixed charges on the investment in the railway property. If the actual cost per unit of transportation produced is to be low, obviously the fixed charges must be distributed among a large number of traffic units. When the traffic density decreases to a value close to or below the economic operating point, there are several courses of action that may be taken all of them radical but nonetheless essential.

A possible but specious remedy for the financial difficulty is to establish state ownership and operation, whereby operating deficits are made up out of taxation. In 1937 existing well-established and privately owned railways were taken over by the Government in Mexico in accord with the Government policy of socialization, and in France in the interest of efficiency and consolidation. The British railways were subjected to radical interference by the Government under the Transportation Act of 1921, being consolidated into four large systems with the elimination of about £100,000,000 of capital.

The trend of railway-traffic diversion to the highways is most pronounced in the U.S.A., but there has been no serious agitation for Government ownership as a solution of the problem of properly co-ordinating rail and road transport to give the most economical operation of the whole transportation system. The Federal Government, through the agency of the Interstate Commerce Commission, is authorized to regulate only interstate transport, and it seems that if any policy of co-ordination and consolidation of the United States railways is to be carried out, as was done in England, it must be commenced, if not carried to its conclusion, by private enterprise with constitutionally limited assistance from the Federal Government.

In fact, under the pressure of economic necessity, there has been for some years a steady progress toward a more logical organization of transportation methods. At the outset we recognize the fact that the railways can handle heavy long-haul traffic more economically than any other land transport agency. We also recognize that for collection and delivery of freight in metropolitan areas, and indeed for most consignments to points within 50 to 100 miles of the consignor's premises, transport by motor truck is more expeditious than by ordinary rail-freight service. Another defect in the railway organization of freight transport is the loss of time incurred in classification yards and at transfer stations.

There has been a pronounced tendency in recent years for business to be conducted with reduced inventories, which makes quick deliveries essential. The motor truck provides one good means of giving this rapid service in shipment of moderate consignments over moderate distances. Twenty-four-hour delivery at distances up to 400 miles or so has come to be a regular and reliable service. Under the traditional operating methods of the railways a shipment consigned to a point 400 miles away could be counted on to take several days in transit; with present business methods, such delays are intolerable. Under pressure from customers on the one hand, and from truck competition on the other, then, the railroads have

Paper 40-122, recommended by the AIEE committee on transportation, and presented at the AIEE summer convention, Swampscott, Mass., June 24–28, 1940. Manuscript submitted December 20, 1939; made available for preprinting May 16, 1940; specially prepared in response to an invitation addressed by the New Zealand Institution of Engineers to the AIEE (and kindred societies) in connection with the New Zealand Centennial Celebrations held in 1940, and published in volume 26 (1939–40) of the *Proceedings* of that society.

A. M. WRIGHT is assistant engineer, Reading Terminal, Philadelphia, Pa. The author received from the New Zealand society a "1940 Commemoration Medal" for the preparation of this paper, only ten such medals being awarded to overseas authors.

1. For all numbered references see list at end of article.

been forced to modify their operating methods to expedite the movement of freight over their lines. This by no means has been forced to the point where it can be said that no further improvement is possible, but all indications point to an ultimate organization of the transport system on some such basis as this:

1. Rail transport, in heavy fast trains, is a means by which huge quantities of transportation can be produced very rapidly, particularly where long distances are concerned; for example, certain railway systems today are producing transportation at an average rate of about 60,000 gross ton miles per train hour, this being an average for all trains operated on these systems. With such performance, trains are easily capable of removing freight from a terminal at the rate of 10,000 net tons per hour. It is inconceivable that any reasonable assignment of highway vehicles could handle traffic at such a rate. Therefore heavy long-haul traffic will be concentrated on the railway lines, such traffic being excluded from the highways.

2. Collection and delivery service in standard railway practice, where there exists in any metropolitan area a multiplicity of freight stations and industrial sidings, is slow, inefficient, and costly. The tendency is toward elimination of these facilities, freight being picked up or delivered at the customer's door from a central depot.

3. Delays en route for classification of freight cars are incompatible with quick delivery over long distances. In many cases, short-haul and long-haul freight is now segregated, the long-haul freight being made up in solid trains for "through" or "main track" movement to its destination without stops except for changing engines or car inspection.

4. Short-haul freight often is handled by motor truck. and the ultimate outcome will probably be the diversion of most short-haul traffic from rail to road vehicles.

5. Where the traffic density on any railway line falls below a certain magnitude, operation of that line is no longer an economic proposition; and if the traffic offered by the district served by that line can be properly and economically handled by motor truck, its abandonment is indicated. If the traffic has decreased because of diversion to a competing line, consolidation is indicated, with probable abandonment of the lightly loaded line.

6. In most countries where the railways have been constructed under private enterprise, the present systems have been developed by consolidation of smaller systems, either by legislative fiat, as in England, or by gradual absorption of the weaker systems by the stronger, as in the U.S.A. The American railways are still being slowly consolidated into fewer competing systems, and it is at least possible that Government interference will act to hasten this process, resulting in the abandonment of unnecessary mileage, in decreased duplication of rolling stock and personnel, and in reduction of operating expenses, accompanied by sharp increases in traffic density.

When these tendencies are followed to a conclusion, the railways appear in the transportation picture as the principal means by which dense long haul-traffic is handled. With such an organization the general scale of railroad operation, both as regards terminals and the main connecting lines, will be enlarged beyond anything now existing outside of a few instances, and the engineering problems connected therewith will become more pressing as the developments outlined proceed. Leaving out of account the terminal problem, namely, that of providing loading facilities, driveways, approaches, etc., for handling in a few main terminals the freight entering and leaving a large city each day, the main problem will be that of providing rolling stock and motive power to haul a greater concentration of freight over the tracks available.

The traffic capacity of a piece of railway track, expressed as the ton miles per mile of track per annum, is a function of the size of trains, the permissible headway between trains, and the speed of travel. These in turn are dependent on track alignment, gradients, capacity of rolling stock, and the locomotive power available. To give a concrete picture of the influence of these factors, figure 1 depicts the profile and track arrangement of a double-track railway line connecting points *A* and *F*, 200 miles apart. With certain stretches of four-track route, at *B*, *C*, and *E*, where freight trains can take the side track to permit overtaking by passenger trains, the most dense disposition of traffic is shown on the accompanying graphic train sheet. The track arrangement permits dispatch of freight and passenger trains at hourly intervals, which means that the maximum traffic this railway can handle is 24 freight and 24 passenger trains per day in each direction.

It is important to note that this is a theoretical figure. In scheduling a heavy freight train there is an element of chance; delays will be encountered en route from a variety of causes. In this connection a study made by the committee on economics of railway operation of the American Railway Engineering Association[1] showed that train movements are seriously interfered with by accidental delays and track limitations when the actual traffic is about 50 per cent of the theoretical capacity.

The following assumptions were used in making up the train sheet of figure 1:

Freight-train trailing load	3,000 tons
Freight-train locomotive	3,000 horsepower
Freight-train maximum speed	40 miles per hour
Passenger-train maximum speed	70 miles per hour
Passenger-train weight	450 tons
Passenger-train locomotive	2,400 horsepower

Using these figures with the traffic density shown on the train sheet, the theoretical traffic-handling capacity of the line is 26,000,000 ton miles per mile of track per annum; 50 per cent of this gives 13,000,000 ton miles per track mile per annum as being the actual limit of the freight-handling capacity of the road. The foregoing figures for train weights and locomotive power rating represent what is attainable with present-day practice, using steam locomotives of conventional design.

While a freight-traffic density of 13,000,000 ton miles per track mile per annum is a high average, it is by no means unheard of and is even exceeded on several American railways. But when coupled with a dense passenger traffic, the problem of keeping the rails clear is likely to become very difficult, which is particularly marked where the termini of the railroad are situated in centers of large population.

Without resorting to a program of rebuilding the railway, there are several ways of relieving congestion and so increasing the traffic-handling capacity of the railroad depicted in figure 1. The most obvious of these are as follows:

1. The weights of freight trains might be increased. If the trailing loads of all the freight trains indicated on figure 1 were doubled, obviously the freight traffic capacity of the railroad also would be doubled, provided train speeds were not reduced.

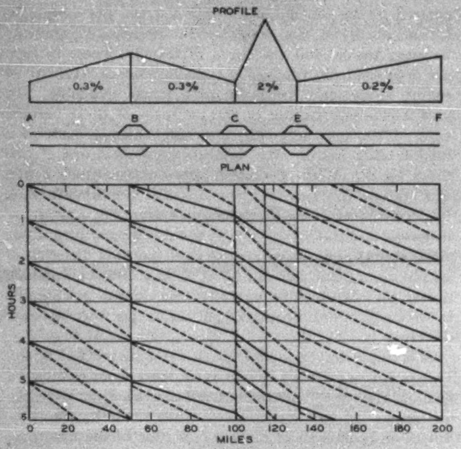

Figure 1. Train sheet showing maximum traffic on two-track railway

Each sloping line is a time/distance chart for a train. Dotted lines indicate freight trains; solid lines passenger trains

2. The freight-train speeds may be increased. If the speed of the freight trains indicated in figure 1 were the same as that of passenger trains, then the headway between trains could be reduced to something determined principally by the length of the signal blocks.

3. The capacity of the rolling stock may be increased. This enters in a very important way into the problem of determining locomotive power, principally because (*a*) the tractive resistance, or drag, of a train made up of heavy large-capacity cars is much less than that of a train of the same weight made up of light small cars, and (*b*) the tare weight of a large-capacity freight car is much less than the tare weight of a small-capacity car in proportion to the load. For example, a goods wagon of eight tons load, as commonly used in England, might have a tare weight of four tons. A 120-ton coal car, as used in the U.S.A. has a tare weight of about 30 tons. The American railways thus are hauling only about half as much dead load per revenue ton as the English railways; and the number of serviceable cars required to handle a given traffic directly affects operating costs. The greater capacity of the rolling stock is a very important reason that freight transport per ton mile in the U.S.A. costs only one-third as much as in England. The trend of past developments, as well as such general considerations as the foregoing, point to a continued increase in the capacity of rolling stock, which permits the net ton miles produced to increase in relation to the gross ton miles.

The increase in speed and weight of trains, as mentioned under the foregoing items 1 and 2, involves an increase in the power output of the locomotives. Every increase in the ton miles produced per train hour, which is an index of the rate at which transportation can be produced with any given equipment, brings up the question of the adequacy of the motive power. If development proceeds along the lines outlined, that is by restricting long-haul traffic to the railways, and by a program of consolidation and abandonment of certain existing lines, thus increasing the traffic density on lines remaining in service, the question of locomotive capacity will be one of pre-eminent importance.

The power output of a locomotive is the product of the tractive effort exerted at the rims of the driving wheels and the velocity of the locomotive. If the tractive effort is in pounds and the velocity in miles per hour, then this product must be divided by 375 to give the locomotive horsepower at the rails.

In the example depicted in figure 1, the freight locomotives were assumed to have a rail horsepower of 3,000 and the trailing loads were assumed to be 3,000 tons. Such trains can move at 38 miles per hour over a gradient of 0.2 per cent using the maximum power of the locomotive.

A Pacific-type passenger engine of 2,400-horsepower capacity with a 500-ton trailing load can traverse this same gradient at 80 miles per hour; and if the headway between trains is 30 minutes, the passenger train will overtake the freight train 46 miles from the terminal. This means that the freight train would have to take to a siding to permit the passenger train to pass after at most 46 miles.

But if the freight-train speed can be increased to 60 miles per hour, then with the same headway between trains the passenger train would not overtake the freight train until a point is reached 120 miles from the terminal. The effect of speeding up the slower trains is thus very beneficial in clearing up the right of way and in permitting a reduction in the time interval between successive trains.

However, to move a 3,000-ton train at 60 miles per hour over a 0.2-per cent grade requires a steam locomotive of about 6,300 horsepower at the rails, and the questions to be answered are: First, can a locomotive of such capacity be built within reasonable limitations of weight and size; and second, can any other type of locomotive, such as Diesel or electric, do the job better?

The power developed by a steam locomotive is a function of the rate at which the fuel is burned in the firebox; therefore, locomotives of larger horsepower rating must be provided with larger fireboxes and heating surfaces, which in turn leads to larger boilers and greater weights for the complete locomotives. It seems to be pretty definitely established that the weight efficiency of conventional steam locomotives of large output, in pounds per horsepower, is not much better than that of locomotives of moderate output.

The traffic-handling capacity of a railway track, and its attendant problems of locomotive power, have been the subject of study for some years by the committee on economics of railway operation of the American Railway Engineering Association.[1] In volume 40 of the *Proceedings* of the AREA[2] are summarized the results of a study of a great number of steam engines and engine types as regards the relation between weight and power rating for modern locomotives. Without here discussing the methods for obtaining the figures given, other than to point out the obvious fact that the locomotive power depends on the size and weight of the boiler and on the firebox grate area, which in turn determine the wheel arrangement and weight on the driving axles, the normal rail horsepower of modern locomotives equipped with all economizing devices gives specific weights about as follows:

2-8-2 "Mikado" type	188 pounds per horsepower
2-10-4 type	187 pounds per horsepower
4-6-2 "Pacific" passenger type	202 pounds per horsepower

These weights are based on the total weight of engine and tender, and the rail horsepower was estimated by taking the cylinder or indicated horsepower and deducting losses based on the usual 25 pounds per ton on drivers for machine friction. The weight efficiencies given apply to the "normal horsepower", which is defined as being 75 per cent of the maximum or test-stand horsepower. In actual service we cannot count on being able to develop the full test-stand power of a steam locomotive. The maximum power is developed at a firing rate of about 150 pounds of coal per square foot of grate area per hour, but at this rate the over-all thermal efficiency of the locomotive is very low, leading to excessive fuel consumption. In service the usual firing rate is between 50 and 100 pounds per hour per square foot of grate area, depending on gradients and the necessity for "forcing" the locomotive, so that the power output actually developed is between 50 and 80 per cent of the maximum possible. The result of these various factors is that the weight efficiency on which we can count is rarely better than 200 pounds of total locomotive weight per rail horsepower developed.

On this basis a locomotive of 6,300 horsepower would weigh 630 tons, of which with normal modern designs 40 per cent, or 252 tons, would be on the driving wheels. A 2-10-4-type locomotive of 6,300-horsepower capacity would then have a driving-axle load of 100,800 pounds per axle. Such an axle weight as this would be intolerable from the standpoint of bridge-structure and track stresses. If we decide to go to an articulated type of locomotive, say having eight driving axles in two groups of four, the axle loading is reduced to 63,000 pounds per driving axle. This is within the permissible axle loading for most American railways, and if bridge structures have sufficient strength to take the total locomotive weight, the vertical track stresses perhaps would not be excessive. If at 60 miles per hour the driving wheels are limited by considerations of dynamic augment to 300 rpm, the required driving-wheel diameter is 67 inches and the rigid wheel base 18 feet—6 inches. When the lateral restraint in the articulation hinge is taken into account, it cannot be said offhand that such a long rigid wheel base will not introduce lateral track stresses of undesirable magnitude. But other difficulties following an adoption of locomotives of greatly increased rating would be that of providing engine-house facilities, turntables, etc., for engines of much greater length than any now used.

Any program of railway reorganization resulting in such traffic density that it would become necessary to move 3,000-ton or heavier freight trains at 60 miles an hour thus would bring the motive-power problem very prominently forward, and its economic as well as physical aspect would prompt consideration of a radical change in the type of tractive power to be used.

It does not seem likely that there will be in the near future any noteworthy improvement in the performance or weight efficiency of steam locomotives. The thermal efficiency of a steam engine theoretically can be improved by increasing the steam pressure and temperature and by superheating; but despite what is done in these respects, the fundamental fact remains that the principal cause of the inefficiency of a steam locomotive lies in imperfect combustion. Admittedly it is possible to reduce the firing rate in a locomotive firebox, and at the same time to raise the boiler pressure and steam superheat to the point where the over-all thermal efficiency might reach, say, 20 per cent; but the large firebox necessary to give the required evaporation at a low firing rate would entail such a great increase in the weight of the engine that the over-all weight efficiency would be no better than it is with conventional designs.

The problem of providing locomotives of 6,000 horsepower and over therefore must be solved by some means other than that of increasing the size of the conventional steam engine. The most promising rail tractor in this respect is the electric locomotive. The electric locomotive is not a prime mover; it is a transformer of energy furnished to it from a generating station situated at some distant point, and hence its inherent limitations as a rail tractor are not fixed by any considerations of combustion or thermal efficiency. The power it can develop is fixed by the characteristics of the electric motors by which the driving wheels are propelled, and the characteristics of the whole locomotive therefore are determined by the type of motor used.[3]

As a result of significant improvements in the single-phase series traction motor during the past ten years, going hand in hand with progress in methods of solving the difficult circuit-analysis problems met in a-c traction,[4,5,6] there has been in the United States during this period a great extension in the use of single-phase alternating current for heavy-traction electrification; for this reason the following discussion, looking to the possibilities of moving heavy freight trains at high speeds by

Westinghouse

electric locomotives, is confined to the single-phase a-c system using series traction motors. For the time being it may be taken as axiomatic that the overhead contact line from which the electric locomotive draws energy has infinite capacity and that it is possible to install a step-down transformer on the locomotive of enough capacity to handle whatever power is required by the traction motors. With these assumptions the limitations of the electric locomotive coincide with the limitations of the motors. The output of a series motor is limited by two factors, (1) commutation and (2) heating, with the additional mechanical limitation of (3) the peripheral speed of armature and commutator.

Taking account of these limitations, it has been shown in a previous paper[2] that the starting tractive effort at the rails exerted by a single-phase traction motor is given by the formula

$$TE = 5{,}000\,\frac{pl}{\text{mph max}}\ \text{pounds at 25 cycles per second}$$

In this expression

p is the number of poles on the motor
l is the active length of the commutator in inches

Thus for a 12-pole motor having an active commutator length of 9 inches and geared for a maximum speed of 70 miles per hour, the starting tractive effort would be 7,700 pounds. Using two motors per driving axle and assuming 25-per cent adhesion, the required weight per driving axle is then 62,000 pounds. Using six driving axles and a guiding truck at each end of the locomotive, with a 2C+C2 wheel arrangement, the total locomotive weight would be about 280 tons; and we know from previous designs that a locomotive of this type can be built to give one horsepower of continuous rating for each 100 pounds of weight (about 40 pounds per horsepower for the electrical equipment, and about 60 pounds for the mechanical parts). Thus the example indicates that we can build a high-speed freight locomotive of conventional wheel arrangement and conservative axle loads to give a continuous rating of at least 5,600 horsepower, or 933 horsepower per axle. This rating is not excessive, since three-axle locomotives have been built and are in service with 1,250 horsepower per axle.

It is necessary to point out that the electric locomotive is not a constant-output machine. The speed–tractive effort curve for an electric locomotive has a much steeper slope than that for a steam locomotive of the same nominal rating. If we denote the tractive effort by p and the train velocity by v, then the speed–tractive effort curve of the steam locomotive is given by $pv=\text{constant}$. The electric locomotive has a characteristic curve for which the equation is pretty closely $pv^{2.8}=\text{constant}$. The continuous rating of an electric locomotive is that continuously maintained power output at the rails at which the temperature rise of the motors does not exceed that specified in the Standards of the American Institute of Electrical Engineers. The effect of the steeper slope of the characteristic curve of the electric locomotive is to make the locomotive assume an overload when its speed is reduced by adverse gradients. Thus on a gradient the rail horsepower output of an electric locomotive rated at 5,600 horsepower will be greater than 5,600 horsepower, and the electric locomotive is able to maintain a much better schedule speed than a steam locomotive of the same rating.

It has been mentioned that the specific weight of an electric locomotive of modern design is of the order of 100 pounds per horsepower, as compared with the 200 pounds per horsepower of the steam locomotive. The effect of this is to reduce the dead weight of the equipment to be hauled and to permit a reduction in the rating of the electric locomotive as compared with the steam locomotive.

To see how this comes about, we may take the same example as before, namely, that of a 3,000-ton train moving at 60 miles per hour up a 0.2-per cent grade. To generalize, let W tons be the weight of the train and w tons the weight of the locomotive. Then using average figures for train resistance:

Train resistance $= 6W+10w$
Grade resistance $= 4(W+w)$
Total resistance $R = 10W+14w$

Also

$$HP=\frac{Rv}{375}$$

and

$$w=\frac{HP}{10}\ \text{(steam locomotive)}$$

or

$$w=\frac{HP}{20}\ \text{(electric locomotive)}$$

Substituting $W=3{,}000$, and solving for w and HP, we find the required steam-locomotive rail horsepower is 6,200, the weight being 620 tons. For the electric locomotive the required horsepower is 5,400, the weight being 270 tons.

This striking contrast, of a 270-ton electric locomotive being able to do the same work as a 620-ton steam locomotive, seems to indicate clearly the method by which the motive-power problem will be solved as railway-traffic density becomes so concentrated as to require more rapid movement of freight over the lines. But the use of electric locomotives brings with it the attendant problems of transmission and distribution of electric energy to the trains.

The dimensions and configuration of the transmission and distribution system of an electrified railway are, of course, dependent on the loads the system has to supply; they are also dependent on the voltage and frequency of the contact line and supply system. This question was the subject of a paper by McGee and Harder[3] whose investigations showed that it is easily possible, with a contact line voltage of 11,000, to provide enough capacity in the distribution network to handle traffic up to the limit of the tracks available. But since a large capital investment is required to provide a distribution system for an electric railway, there remains the engineering problem of so designing the transmission and contact lines and substations that the cost will be as low as possible.

A large part of the cost of the distribution system is chargeable to the step-down-transformer substations, and economical construction requires therefore that the substation spacing be as great as possible. If a given load is to be supplied with a given voltage drop between the substation bus bar and the load, an increase in distance between substations makes it imperative that the contact-line voltage be increased. In the United States the standard line voltage has hitherto been 11,000 volts for single-phase systems, but some electrified railways have provision for a change-over to 22,000 volts. In a general scheme of railway electrification, it now appears that even this voltage might be insufficient, and it is at least possible that a contact line potential of 50,000 volts will be considered.

In this discussion of electric traction, attention has focused on its engineering aspects. It is not possible in a reasonable space to analyze the economic features of electric traction as compared with steam, but it might be well to state in a broad fashion the general economic factors that lead to a decision for or against electric operation of a railway. In electric traction as in any other form of transportation the cost of producing a ton mile is made up of the operating cost and a proportion of the fixed charges on the investment. Since it may cost some $35,000 per track mile to equip a railway for electric operation exclusive of rolling stock, it is evident that electric traction will greatly increase the fixed charges on the property. Hence, unless a great increase in traffic density accompanies the electrification, there must be a considerable reduction in operating cost per ton mile produced. This reduction in operating cost always is obtained, arising principally from the following:

1. The number of electric locomotives required to handle a given traffic is always less than the number of steam locomotives needed for the same traffic. Since an electric locomotive (per horsepower at the rail) costs about the same as a steam locomotive, the investment in electric rolling stock is moderate. The reduced number of locomotives results in a great reduction in engine-house and maintenance costs.

2. The maintenance cost per horsepower mile of an electric locomotive is very much less than that of a steam locomotive. In nearly every case where electric traction has been applied, the cost of maintaining electric locomotives has proved to be about half that of the pre-existing steam locomotives.

3. The "availability", or the percentage of the total time during which electric locomotives are available for service, usually exceeds 90 per cent, as compared with at best 50 per cent for steam locomotives. This is why a given traffic density can be handled with far fewer locomotives than when steam locomotives are used, and the result is a great reduction in locomotive expense for such services as hostling.

4. Because an electric locomotive will assume an overload when its speed is reduced by adverse gradients and will develop up to twice its normal power output during acceleration, a given tonnage can be moved over the rails at much better schedule speed than can be achieved with steam or other constant-horsepower locomotives. This results in a reduction in the number of train-hours, with a consequent saving in crew expense.

5. With electric traction, there is a considerable item of expense in the maintenance of overhead transmission and distribution lines and substations. It usually happens, however, that this expense is of the same order of magnitude as that of maintaining fuel and water facilities required with steam traction.

6. It is a popular belief that because of the high thermal efficiency of modern electric generating stations, the cost of power for electric traction is much less than the cost of fuel required for steam traction. This, however, is not the case where coal is cheap. In the eastern part of the United States, for example, the cost of electricity per ton mile moved by electric traction is of the same order of magnitude as the cost of coal per ton mile moved with steam locomotives. This is due to the effect of the demand clause in all power contracts, by which the cost per kilowatt-hour is devoted in part to carrying the fixed charges on the electric-power equipment.

The result of these considerations, particularly items 2 and 4 is that electric traction always shows an operating saving when compared with steam traction. A decision for or against electrification is therefore dependent on the economic consideration of capital cost. To express this algebraically, let

C_s = the operating cost per ton mile with steam traction
C_e = the operating cost per ton mile with electric traction
F = the total annual fixed charges on the investment required for electrification
D = the total ton miles hauled per annum

Then electrification is economically justified when

$$C_s > F/D + C_e \tag{1}$$

In any well-planned electrification scheme C_e always will be less than C_s, so that the deciding factor for or against electric operation will be the quotient F/D. This should be as small as possible, which can be attained by keeping the cost of the electrification to a minimum or by increasing the traffic density. The cost of equipping a railway for electric operation is dependent principally on the engineering skill brought to bear on the physical problems involved; and as engineering science progresses, improved methods perhaps will tend to lower the first costs of electrifying, although these improved methods often are adapted to increase the operating reliability of the system at some sacrifice in cost.

The picture of the rail-transport system as developed herein has pointed to the desirability of developing the railways into a tool for the concentrated mass production of transportation by consolidation and reorganization. As this development progresses the traffic density on the favored lines will increase, perhaps until the quantity F/D in equation 1 is vanishingly small. In such a case the physical advantages of using electric motive power undoubtedly will dictate a policy of railway electrification on a scale sufficiently broad to exploit its real advantages. At any rate the considerations outlined will warrant a careful study of the motive-power problem.

In this discussion of motive power for rail traction no mention has been made of the Diesel-electric locomotive. It is frequently thought that the use of electric traction motors confers on these locomotives all the merits of the electric locomotive. Such, however, is not the case. Obviously the rail output of a Diesel-electric locomotive is fixed by the rating of the Diesel engine, which has a definitely limited output. On the other hand, the power available for propelling an electric locomotive is for practical purposes infinite, and the rail power output is limited principally by the commutation and heating of the traction motors, which with modern locomotives allows them to develop 25-per cent adhesion up to speeds of 50 miles an hour. The weight efficiency of the Diesel locomotive is about half that of the electric, and the first cost is about twice as great. Therefore, it does not seem that the Diesel locomotive offers any special advantages over steam locomotives for the handling of dense main-line traffic. The cleanliness of the Diesel-electric engine favors its use for the hauling of de luxe passenger trains, and it has been widely applied in this field. The Diesel locomotive also is being used increasingly in switching service, where its high degree of availability and low stand-by losses show up very favorably against the steam switching engine. But for very heavy main-line traffic the choice of locomotives probably always will be between the steam and the electric, with electric traction showing pronounced advantages when the traffic density exceeds the economic limit given by equation 1.

This article has outlined some of the problems that are arising in the railway field, and has discussed in more detail the question of motive power. In a reasonable space it is impossible to consider all the engineering problems that are most pressing today as a result of the increase in train weights and speeds now used in an attempt to retain or regain business in the face of competition. But some of these developments are so important that they cannot be overlooked in any review of modern rail transport, and the following list outlines a few of the most outstanding:

1. *Reduction of Tare Weight of Rolling Stock.* Modern freight rolling stock is of all-steel construction, using high-strength special alloys to give a greater proportion of load to tare. A more spectacular development is that of the stainless-steel and aluminum-alloy passenger rolling stock, resulting in equipment weighing about half that of the former designs of all-steel passenger cars.[7]

2. *Strength of Track.*[8] For many years past an intense study has been made of rail stresses, in an attempt to eliminate the cause of transverse rail fissures and broken rails. The battering of rail ends under heavy wheel loads also has come under this study, and has led to the development of the continuous welded track and to experiments with concrete subgrade. As another part of this development there have been radical changes in the design of steam-locomotive driving wheels and reciprocating parts, to reduce the pounding of drivers caused by dynamic augment at high speeds. Incidentally, it may be pointed out here that dynamic augment is absent with electric or Diesel-electric drive.

3. *Train Control.* There is a pronounced and rapid development toward the governing of all train movements by signal indication. While all passenger and many freight trains move under official printed time table authority, no train can be permitted to occupy a block against a restrictive signal indication. It is therefore imperative to furnish reliable track circuit and relay equipment for displaying proper signals, and for informing the dispatcher as to the condition of any piece of track. A recent and expanding development in this connection is the "centralized traffic control", whereby a dispatcher is given control and indication over the territory under his jurisdiction, all switching operations being performed remotely by an electric control system similar to the "supervisory control" used in power systems.

4. *Speed.* In recognition of the fact that schedule speeds are affected by deceleration to the same extent as by acceleration, and because the use of higher speeds with modern equipment has involved questions of the adequacy of train-stopping distances in relation to signal spacing, there have been important developments in braking equipment. One of the most radical has been a means of automatically varying the braking force as a function of train speed, to take account of the variation in the coefficient of friction between brake shoes and wheels with variations in speed.

5. *Passenger equipment.* To the public, the most striking railway development of recent years has been the improvement of passenger equipment as regards speed and comfort. The most rapidly spreading improvement in this regard has been the use of air-conditioning apparatus, whereby the interior air of passenger cars is maintained at a predetermined state of temperature and cleanliness regardless of outdoor conditions. The general appearance and design of modern passenger trains also has undergone radical change at the hands of professional industrial designers engaged by the railroads and manufacturers to aid in the improvement of rolling stock. The reduction in weight of passenger trains already has been discussed.

Parallel with these engineering developments, noteworthy economic experiments in rail transport are under way. The greatest of these is undoubtedly the electrification of the Pennsylvania Railroad.[9,10] The Pennsylvania on its New York-to-Washington line handles perhaps the heaviest mixed traffic density in the world, and is the first instance of electric traction having been adopted on a scale broad enough to exploit its real advantages and to look on electric traction primarily as a tool for efficient transport rather than as a means of solving a specific problem in motive-power application.

All these developments seem to point to the future organization of the railways as a machine for the rapid and efficient production of traffic units—ton miles or passenger miles. The railway system shows up most favorably when it has to handle very dense traffic over long distances, or, in other words, when it can manufacture transportation on a mass-production basis. The interpretation of recent developments in the physical equipment of the railways as steps toward such an organization may be incorrect, but the fact remains that the railways cannot survive as an economic unit unless the traffic density has a sufficiently high average to pay the operating expenses and fixed charges. It seems to the author that increases in traffic density and reductions in operating expenses can best be attained by some program of co-ordination and consolidation such as outlined earlier in this article. If such a program is carried out, the engineering problems discussed here will be of very real importance.

Discussion

For discussion see page 1247.

Report of the Board of Directors

THE board of directors of the American Institute of Electrical Engineers presents herewith to the membership its 56th annual report, for the fiscal year ending April 30, 1940. A general balance sheet showing the condition of the Institute's finances on April 30, 1940, together with other detailed financial statements, is included herein. This report contains a brief summary of the principal activities of the Institute during the year, more detailed information having been published from month to month in ELECTRICAL ENGINEERING.

BOARD OF DIRECTORS' MEETINGS

During the year, the board of directors held five meetings, four in New York City, and one in San Francisco, Calif. The executive committee meetings in December and March were held in place of meetings of the board. Information regarding many of the more important activities of the Institute which have been under consideration by the board of directors and the committees is published each month in the section of ELECTRICAL ENGINEERING devoted to "Institute Activities".

PRESIDENT'S AND NATIONAL SECRETARY'S VISITS

President Farmer and National Secretary Henline attended the combined summer and Pacific Coast convention, the winter convention, the Great Lakes District meeting in Minneapolis, Minn., and the Middle Eastern District meeting in Scranton, Pa. They also visited many Sections and Student Branches. During May, President Farmer will visit the following Sections: Cincinnati, Cleveland, Erie, Worcester, Niagara Frontier, and Rochester; also he will attend a conference on student activities of the North Eastern District at Troy, N. Y. Both President Farmer and National Secretary Henline will attend the summer convention in Swampscott, Mass.

The places visited by President Farmer follow:

Alabama
Alabama Section, Birmingham
University of Alabama Branch, University

California
Summer and Pacific Coast convention, San Francisco

Connecticut
Connecticut Section, New Haven

District of Columbia
Washington Section
American Engineering Council, Washington

Georgia
Georgia Section, Atlanta
Georgia School of Technology Branch, Atlanta

Illinois
Chicago Section, executive committee
Midwest Power Conference, Chicago

Louisiana
New Orleans Section
Tulane University Branch, New Orleans
Louisiana State University Branch, Baton Rouge

Michigan
Michigan Section, Ann Arbor

Minnesota
Great Lakes District meeting, Minneapolis
Conference on student activities, Great Lakes District, No. 5, Minneapolis

Mississippi
Conference on student activities, Southern District, No. 4, State College, Miss.

New York
New York Section
Winter convention
Ithaca Section
Cornell University Branch, Ithaca
Schenectady Section
Syracuse Section
Syracuse University Branch

North Carolina
North Carolina Section, Durham

Pennsylvania
Middle Eastern District meeting, Scranton
Conference on student activities, Middle Eastern District, No. 2, Scranton
Pittsburgh Section
Philadelphia Section

Canada
Toronto Section

The places visited by the national secretary are the following:

California
Summer and Pacific Coast convention, San Francisco
Conference on student activities, Pacific District, No. 8, and North West District, No. 9, San Francisco

District of Columbia
Washington Section
American Engineering Council, Washington

Idaho
University of Idaho Branch, Moscow

Illinois
Armour Institute of Technology Branch, Chicago
Urbana Section

Indiana
Central Indiana Section, Indianapolis
Fort Wayne Section

Massachusetts
Lynn Section
Worcester Section
North Eastern District meeting, Springfield
Conference on student activities, North Eastern District, No. 1, Springfield

Minnesota
Great Lakes District meeting, Minneapolis
Conference on student activities, Great Lakes District, No. 5, Minneapolis

Montana
Montana Section, Butte

New York
New York Section
Schenectady Section
Winter convention

Ohio
Akron Section
Columbus Section

Pennsylvania
Sharon Section
Philadelphia Section
Middle Eastern District meeting, Scranton
Conference on student activities, Middle Eastern District, No. 2, Scranton

Rhode Island
Providence Section

Washington
State College of Washington Branch, Pullman
Seattle Section
Spokane Section

Wisconsin
Madison Section
Milwaukee Section

Canada
Vancouver Section

NATIONAL CONVENTIONS

Two national conventions were held during the year, and a brief report on each follows:

Summer and Pacific Coast Convention. The 55th summer convention combined with the 27th Pacific Coast convention was held in San Francisco, California, June 26–30, 1939. In addition to the annual business meeting, and conference of officers, delegates, and members, there were nine technical sessions at which 41 papers were presented, one general session, and two informal technical conferences. Doctor Adam S. Bennion, assistant to the president of the Utah Power and Light Company, gave an address on "Human Relationships" at the general session. In addition, there were two student technical sessions with presentation of 11 papers, and a Student Branch dinner with informal addresses by President John C. Parker, Vice-President H. W. Hitchcock, and Doctor R. W. Sorensen, chairman of the committee on student branches.

Entertainment and sports features of the convention were a tea, "AIEE Day" at the Golden Gate International Exposition on Treasure Island, banquet, and golf and tennis tournaments held in competition for the Mershon, Lee, and John B. Fisken trophies. The attendance was 940.

Annual Meeting. The annual business meeting of the Institute was held on Monday morning, June 26. The annual report of the board of directors for the fiscal year which ended April 30, 1939, was presented in abstract by the national secretary. A report on the finances of the Institute was presented by National Treasurer W. I. Slichter. The report of the committee of tellers upon the election of officers for the year beginning August 1, 1939, was presented, and President-Elect Farmer responded to his introduction with a brief address. During this session, the Lamme Medal for 1938, which was awarded to Marion A. Savage, was presented, being received by P. L. Alger who represented the medalist.

Winter Convention. The 28th winter convention was held in New York City, January 22–26, 1940, with a program including 85 papers presented in 18 technical sessions and 8 technical conferences. A brief general session was held at which the Alfred Noble prize was presented to C. E. Shannon (A'39).

At an evening session, the Edison Medal was presented to Philip Torchio, and the Hoover Medal was presented to Doctor Gano Dunn.

A smoker, numerous inspection trips, and ladies' events completed the program of the convention. The registration was 1,626, which was slightly above the 1939 figure, and the highest since 1924.

DISTRICT MEETINGS

Brief reports on the three District meetings held during the year are given below:

North Eastern District Meeting. This meeting and student Branch convention was held in Springfield, Mass., May 3–5, 1939.

There were four technical sessions, two student sessions, and a general session with addresses by President John C. Parker and President C. W. Kellogg of the Edison Electric Institute, the latter on the subject "The Engineer as a Citizen". The Faraday Medal of The Institution of Electrical Engineers, Great Britain, was presented to Doctor W. D. Coolidge, director of the General Electric Company Research Laboratory, Schenectady, N. Y., by Dr. Gano Dunn, local honorary secretary of the IEE for the United States. Inspection trips, stag smoker, ladies' entertainment, and banquet completed the meeting. The attendance was 439.

Table I. Section and Branch Statistics

	For Fiscal Year Ending				
	April 30, 1936	April 30, 1937	April 30, 1938	April 30, 1939	April 30, 1940
Sections					
Number of Sections	61	62	65	67	70
Number of meetings held	540	621	624	635	701
Total attendance	85,501	74,950	110,148	85,692	91,949
Branches					
Number of Branches	118	119	120	120	121
Number of meetings held	1,045	1,363	1,334	1,190	1,346
Total attendance	45,304	46,121	60,446	53,380	64,972

Great Lakes District Meeting. This meeting was held in Minneapolis, Minn., September 27–29, with four technical sessions, at which 18 papers were presented, and one student session. The entertainment program consisted of a dinner and dance with a demonstration by Doctor Phillips Thomas, research engineer of the Westinghouse Electric and Manufacturing Company. Also Doctor W. A. O'Brien, pathologist of the University of Minnesota, addressed an audience at a noon luncheon. Inspection trips, ladies' events, a District conference on student activities, and a District executive committee meeting were included in the program. The registration was 230.

Middle Eastern District Meeting. The tenth meeting of this District was held in Scranton, Pa., October 11–13, 1939, with 5 sessions at which 21 technical papers were presented. A District conference on student activities, a District executive committee meeting, ladies' events, inspection trips, stag smoker, and informal dinner, at which President R. E. Desvernine of the Crucible Steel Company of America gave an address on "Business and World Politics", completed the program. The attendance was 313.

SECTIONS

The three new Sections organized, Charleston, El Paso, and South Carolina, brought the total number to 70. The name of the Dallas Section was changed to "North Texas", and its territory was extended to the north and northwest. On account of the fact that its territory includes the major part of the state of Maryland, the name of the Baltimore Section was changed to "Maryland". Nine unassigned counties in Maine were assigned to the Lynn Section, which now has the entire state. Organization of new Sections and extensions of the territories of others have reduced to about 100 the number of members in the United States outside Section territories.

Activity was reported by all Sections. The total number of meetings reported was 701 as compared with 635 for the preceding year, and this was the sixth consecutive year in which the number exceeded that for the preceding year.

Fifteen Sections reported that their 30 technical groups or other subdivisions had held 124 meetings of these types in addition to the 131 regular Section meetings.

In October, the Sections committee issued a printed pamphlet "Section Activities", which is expected to be of material assistance to Section officers by indicating the types of activities which have been found to be most effective. A second edition of the pamphlet "The Electrical Engineer", for the guidance of high school students interested in electrical engineering, was prepared under the joint direction of the Sections committee and the committee on Student Branches.

The Sections committee sent a communication to all Sections, in October, recommending the appointment by each of committees on (*a*) legislation, (*b*) economic and social affairs, and (*c*) vocational guidance.

Many Sections have shown increased interest in the stimulation of younger members to participate in the activities more freely. The continuing interest in and success of the technical group discussion plan, the inclusion of younger members among Section officers and committees, and the appointment of committees to develop activities for the younger engineers are a few of the tangible evidences of progress in this direction.

The Sections committee has been developing a comprehensive plan for the preparation of news items on outstanding Section activities for publication in Electrical Engineering, and many such items have appeared in recent months. Through the use of extensive questionnaires the committee is making a thorough study of all phases of Section activities.

More detailed information on these activities may be found in the annual report on Section and Branch activities in the June issue of Electrical Engineering, pages 250–3.

STUDENT ACTIVITIES

A new Branch organized at the University of Alberta brought the total number to 121.

The total number of meetings reported was 1,346, as compared with 1,190 for the preceding year, 1,334 for 1937–38, and 1,363 for 1936–37. Only two Branches failed to report any activity, 21 held more than 15 meetings each, 24 held from 12 to 15, 40 held from 8 to 11, 26 held from 4 to 7, and 8 held from 1 to 3 meetings.

Although the total number of student talks at Branch meetings was higher than for the preceding year, 767 as compared with 725, it was far below the numbers for some previous years. The largest number reported for any year was 1,130 for 1936–37.

The numbers of student sessions and papers at the summer-Pacific Coast convention and three District meetings are given in the reports on those meetings. The students have continued to show keen interest in such participation, and the quality of student papers and their presentation has been high.

With the co-operation of the committee on Student Branches, the committee on safety again suggested that each Branch have presented a paper on prevention of accidents or remedial measures after electric shock. A large number followed the suggestion.

A meeting of the committee on Student Branches was held during the 1940 winter convention, with 50 members and invited guests present. A report on the meeting appeared on pages 124–5 of the March issue of Electrical Engineering.

The committee on Student Branches and the Sections committee co-operated in the preparation of a second edition of the pamphlet "The Electrical Engineer" for the guidance of high school students interested in electrical engineering. Distribution of copies was begun in March.

The committee on Student Branches urged the Branches to celebrate the 75th birthday of Doctor Charles F. Scott, originator of the plan for organizing Branches. The Scott motion-picture films were shown by about 75 Branches, in many cases at joint meetings with neighboring Sections or Branches.

Of the 1,624 enrolled students whose terms were expected to expire on April 30, 911 (56 per cent) applied for admission as Associates. Some are eligible to continue as enrolled students on account of remaining in school.

A more detailed summary of student activities may be found in the annual report on Section and Branch activities in the June issue of Electrical Engineering, pages 250–3.

TECHNICAL PROGRAM COMMITTEE

The technical papers on convention programs have been of a high quality, with many favorable comments received. Pursuing the policy of the previous year, the technical program for the 1940 winter convention was enlarged to 18 technical sessions and 8 technical conferences, one more technical session and three more conferences than were held in the previous year. The enlarged program met with an excellent response from the membership, as evidenced by the registered attendance, 1,626, which was slightly more than the attendance of the previous year, and the largest attendance since 1924. The committee also arranged the technical program for the 1939 summer and Pacific Coast convention, and papers were supplied for the District meetings in Springfield, Mass.; Minneapolis, Minn.; and Scranton, Pa. A total of 177 papers were presented at these two national conventions and three District meetings, of which 151 were recommended for Transactions publication.

Table II presents statistics for the pro-

Table II. Technical Programs, Last Two Years

	Year Ending April 30, 1940	Year Ending April 30, 1939
Number of national conventions	2	3
Number of District meetings	3	3
Registration at national conventions and District meetings	3,548	4,100
Number of papers presented	177	184
Number of papers recommended for TRANSACTIONS	151	169
Estimated number of pages required for printing papers in TRANSACTIONS	886*	986*
Average length of papers recommended for TRANSACTIONS	5.86	5.83
Number of technical sessions	43	50
Number of technical conferences	10	12

* Partly estimated.

grams of the past two years. These statistics are not directly comparable, as there was one less national convention during the past year due to the fact that the summer and Pacific Coast conventions were combined.

Oral Presentations. With a view toward improving the effectiveness of the oral presentations, each speaker and presiding officer at the last winter convention has been canvassed. Many helpful suggestions from a broad section of actual experience have been received. These suggestions will be carefully analyzed, mimeographed, and sent to speakers on future programs. In this way it is hoped to bring about improvement in some of the oral presentations to the mutual advantage of both the speakers and the audience.

Technical-Committee Reports. The preparation of technical-committee reports on the progress of the art has been stimulated. A report on progress of the art in electrical machinery was presented at the summer convention. Reports on progress in the production and application of light and progress in power generation, 1933–39, were presented at the winter convention. Reports by the committees on communication, protective devices, electronics, and instruments and measurements are in preparation. As most of the technical committees have not had reports since 1934, and it is planned to include developments during the intervening years, the reports will be more comprehensive than heretofore. As an experiment and for the purpose of making the reports more readable and presentable, some of the reports will be prepared by an experienced writer. Through this service, technical committee reports will receive more extensive publicity in circles outside of Institute activities.

New Trends in Policy. While the average length of papers for the fiscal year has remained practically the same as for the preceding year, 5.86 pages per paper as compared with 5.83, nevertheless the papers for the past winter convention as compared with the winter convention of the previous year were reduced from 6.50 pages per paper to 5.60. Technical committees have been requested to continue their efforts for shorter papers, which will permit the scheduling of more papers within the annual budget. Notwithstanding this reduction, when the winter convention program was determined, there still remained 51 papers on the docket which had to be held over for future meetings.

As a result of the foregoing situation, a subcommittee was appointed. It was believed that some of the more highly specialized papers of limited interest could be presented in technical conferences without TRANSACTIONS publication, and that more material could be presented in this way. The duties of the subcommittee were to study the whole problem, and a report entitled "Suggested Modifications in Methods of Handling AIEE Technical Papers and Conferences" has been made. This report was discussed at the March 15 meeting of the technical program committee, and referred back to the subcommittee for revision in the light of the discussion at that meeting.

The revised report of the subcommittee, if accepted, will divert some of the more highly specialized papers of interest to only a few and other papers which are only of transitory interest from the TRANSACTIONS to a less expensive form of publication. These papers would be permanently recorded by the publication of synopses. Preprints would be made available and the original copy filed in the Engineering Societies Library. Other unapproved conference papers would also be preserved by filing in the Library at the option of the author. The report also recommends the publication of a synopsis of every formal paper in ELECTRICAL ENGINEERING as soon as the paper has been approved for preprinting. It also recommends that some papers with longer mathematical calculations should have the appendices made available in preprint form only.

Acknowledgments. The committee is grateful for the active participation and cooperation in the work by its members, the chairmen of the technical committees, the reviewers of papers, and the members of the Institute's staff.

PUBLICATION COMMITTEE

With the transition period involved in the adoption of the present publication policy largely behind, constant attention has been given to observing residual defects and devising minor modifications to overcome them. While the general reaction of the membership continues to be very favorable, some adverse criticisms have been received and these have had and are having careful consideration.

The booklet "Preparation of Manuscripts" has been completely revised and enlarged, and is now available under the title "Information for Authors". A lack of familiarity of some authors and members with the provisions of the present publication policy has caused confusion in some cases. The new booklet "Information for Authors" contains for the first time a full statement of publication policy, and it is hoped that members and authors will take advantage of this opportunity to become thoroughly familiar with the publication policy.

During the year, a critical study has been made of AIEE publication costs, and this study included a comparison with the publication costs and procedures of three other national technical organizations. The analysis shows that in relation to the total cost to them, our members receive publication service which compares very favorably with that provided by the other organizations. The economy and efficiency of our publication procedures is indicated by the fact that last year the net publication expense per member in our Institute was only one-half of the corresponding figure in another organization having nearly the same membership.

The operating statement for the first half of the appropriation year (October 1st, 1939, to March 31st, 1940) shows that the publication committee has operated within its budget for that period.

Recently Donald M. Simmons, who has rendered valuable service on the publication committee for several years, was appointed vice-chairman of the committee.

The publication committee continues to welcome comment and criticism from all Institute members.

MEMBERSHIP COMMITTEE

The membership committee has endeavored to improve its effectiveness this year by laying increased stress on better organization of its various groups, thereby obtaining better co-ordination of effort and less duplication of work among the many members assigned to this activity. The national committee duties were outlined in

Table III. Membership Statistics for the Fiscal Year Ending April 30, 1940

	Honorary	Fellow	Member	Six-Year Associate	Associate	Total
Membership on April 30, 1939	9	722	4,392	5,726	5,756	16,605
Additions						
Transferred		58	171	515		
New members qualified			127	25	1,472	
Former members reinstated		1	3	16	12	
	9	781	4,693	6,282	7,240	
Deductions						
Died	1	10	47	37	8	
Resigned			39	140	126	
Transferred			58	151	535	
Dropped		4	54	230	352	
	1	14	198	558	1,021	
Membership on April 30, 1940	8	767	4,495	5,724	6,219	17,213

Table IV. Number of Applications Received From Enrolled Students and From All Others

Year Ending	From Students	From All Others	Total
April 30, 1940	911	918	1,829
April 30, 1939	849	872	1,721
April 30, 1938	739	932	1,671
April 30, 1937	716	1,040	1,756
April 30, 1936	631	946	1,577

Table V. Number of Enrolled Students

April 30, 1940	5,517	(2,991)
April 30, 1939	5,242	(2,271)
April 30, 1938	5,037	(2,428)
April 30, 1937	4,503	(2,249)
April 30, 1936	4,049	(1,991)

Following the number of students reported for April 30 of each year is indicated within parentheses the number of new applications received during that year; the difference between this number and the reported total, of course, reflects the number of renewals of Student enrollment for the corresponding period.

Table VI. Number of Members in Section Territory Reinstated

August 1, 1939 to April 30, 1940	249
Year Beginning August 1, 1938	354
Year Beginning August 1, 1937	325
Year Beginning August 1, 1936	503
Year Beginning August 1, 1935	663

a communication from the chairman at the start of the committee year.

The Section membership committees were supplied copies of specially prepared instructions and guides to assist their early organization into efficient working groups. A census of Section membership committee personnels was requested early in the year to stimulate early organization in the Sections and to permit the Institute to give these men recognition for the effort they put forth each year. Accordingly, the complete Section membership committee lists were published in the January 1940 issue of ELECTRICAL ENGINEERING. The membership committee is grateful to the publication committee for its full co-operation in this effort.

As of January 1940, there were 494 men assigned to Section membership committees with an unknown additional number working on Section subcommittees.

In the national committee ten vice-chairmen continued as the membership "chiefs" of their respective Districts, and a small group of five members-at-large was set up for advice and assistance to the chairman. The committee held two meetings during the year at headquarters.

The committee has gone further in the direction of personalizing membership work both to bring the Institute closer to its Section committees and to bring the entire membership closer to the Institute. The Sections have been asked to give personal recognition to each new member at his first meeting and to give recognition to the proper membership committeeman responsible for obtaining the new addition to the Section at the same meeting.

The chairman has written personally, so far as was possible, to each member who desired information concerning membership matters, and has received many letters indicating favorable reaction to this policy.

Table VIII. Memberships Fully Paid

Year	Membership as of April 30	Number of Members Fully Paid as of April 30	Per Cent Fully Paid
1940	17,213	14,997	87.1
1939	16,605	14,371	86.5
1938	16,078	14,127	87.9
1937	15,308	13,439	87.8
1936	14,600	12,446	85.2
1927*	18,344	16,247	88.6

* Year of maximum membership.

Table IX. Record of AIEE Membership

	Total Membership May 1		Total Membership May 1		Total Membership May 1
1884	71	1904	3,027	1923	15,298
1885	209			1924	16,455
1886	250	1905	3,460		
1887	314	1906	3,870	1925	17,319

1893	673	1911	7,117	1930	18,003
1894	800	1912	7,459	1931	18,334
		1913	7,654	1932	17,550
		1914	7,876	1933	17,019
1895	944			1934	15,230
1896	1,035	1915	8,054		
1897	1,073	1916	8,202	1935	14,269
1898	1,098	1917	8,710	1936	14,600
1899	1,133	1918	9,282	1937	15,308
		1919	10,352	1938	16,078
1900	1,183			1939	16,605
1901	1,260	1920	11,345		
1902	1,549	1921	13,215	1940	17,213
1903	2,229	1922	14,263		

The assistance of the student counselors was solicited in January and February in an effort to encourage a maximum number of eligible Enrolled Students to apply for Associate grade. The counselors' help was very valuable, and the committee extends its appreciation to them.

It is the feeling of the committee that the improvements attained in organization were effective and well worth the effort. Evidence of this may be seen in tables III and IV, where it is shown that the total membership has increased from 16,605 to 17,213, and that 1,829 applications were received during the year ending April 30, 1940. The number of applications shows an increase of over 6 per cent above the same figure last year.

Table V shows another increase in the number of Enrolled Students. This is important since about half of the applications for membership come from the Students, as will be seen in table IV.

Table VI shows a continuing decrease in the number of delinquents reinstated, as may be expected unless business conditions become more adverse over a considerable period of time. This is due to the number of probable prospects being continually reduced.

Table VII shows about the same conditions as last year, though table VIII indicates a small improvement in the percentage of the members with dues fully paid.

DEATHS

The deaths of 103 members reported during the year are listed in table X.

BOARD OF EXAMINERS

The board of examiners held 11 meetings during the past year, averaging about two and one-half hours each, and considered 4,250 cases, divided as shown in table XI

The Procedure of the Board. It has become increasingly apparent to the board of examiners that the membership of the Institute needs to know more of the requirements in the constitution and bylaws with regard to membership grades as well as the technique of the board in handling applications for admission and transfer. Evidence of this is found in requests for procedure whereby the board could give advance indications of likely action in cases in which certain Sections are particularly anxious to avoid embarrassment to the applicants and to the membership and transfer committees. Realizing that every effort should be made to make the problems and procedures of the board of examiners better understood by the membership, it was voted that the following statement should be incorporated in this year's annual report to the board of directors.

A study of the "advance or informal opinion" suggestion makes it evident that the motivating factor is doubt as to eligibility, usually with regard to transfer to the grade of "Fellow", of men of local prominence. An attempt to provide for this situation is evidenced by the adoption in 1923 of the revision of the bylaws legalizing a "transfer proposal" form, which now, however, applies only to Member grade. The practical application of that proposal form immediately resulted in serious trouble. Due to local pressure, the signatures of endorsers were obtained on the proposal form, yet on the confidential reference blanks sent out by headquarters, as required by the constitution, the former endorsers in certain instances failed to recommend transfer. Again, the abbreviated records supplied on the proposal forms were not sufficient in many cases to permit the examiners to form even informal opinions on eligibility. Finally, men were proposed for advancement who had no desire to transfer, and

Table VII. Membership of the Institute, April 30, 1940

Of the 17,213 members reported for April 30, 1940, 14,997 are fully paid to April 30, 1940. The balance of 2,216 are divided into the following groups:

1. Members owing dues to April 30, 1939 Total number of members who have not acted upon resolution of board of directors adopted in January 1940 providing an extension of time for payment of dues	634
2. Members owing dues to April 30, 1940	1,582

(During the period May 1 to 15, 1940, 326 members have paid dues to April 30, 1940, reducing the total to 1,256.)

when word reached them of the action taken they expressed their objections to the procedure in no uncertain terms. In one notable case, where the examiners on consideration of the complete formal application felt compelled to reverse their informal decision based on a "proposal" record, a Section secession threat resulted. The board of examiners has therefore not encouraged the "advance opinion or proposal form" as an ineffective mechanism for obtaining the advance of applicants to appropriate and constitutionally authorized grades of membership.

The suggestion that unfavorable action be postponed until some local group has been contacted has also been studied on many occasions by many boards. As a matter of fact, the suggested procedure has been practiced as far as practical by the examiners for many years, within the limits of the constitution and bylaws. A considerable part of the correspondence of the secretary of the board of examiners is concerned with building up of complete professional records of applicants and obtaining the required number and grade of references. This correspondence is with local Section officers where the situation warrants such action, otherwise it is with the applicants or their references. The examiners believe, however, that to restrict the board in its present freedom to accommodate the method of inquiry to the circumstances in each case would lead to added difficulties, particularly in transfer cases. On all direct admission applications, the character question is involved; they are therefore posted and are the subject of general knowledge in advance of examiners action. On the contrary, transfer applications are frequently transactions solely between the applicants and the Institute; they are not published in any way and are otherwise known only to the supporting references. To divulge likelihood of unfavorable action to local officers or committees would be seriously objected to by many as a violation of a confidential privilege accorded to members. It might easily defeat the desired objective of encouraging meritorious transfers.

The suggestion has been made that the board of examiners be instructed to report tentative decisions to the local Sections in advance of final action on cases of direct admission or transfer to higher grades. The board feels, however, that stipulation of such procedure would tend to limit freedom of final action in accordance with the requirements of the constitution and bylaws and thus seriously curtail the independence and hamper the effectiveness of the board in its function of maintaining a high standard of Institute membership in the upper grades. It should be pointed out here that most of the members of the board of examiners have been active in Sections, local and national membership committees, over a long period of years and have had full experience in the problems now before us. To this they have added the experience on the board of examiners in dealing with many difficult cases. The board, after giving careful consideration to these important problems, therefore, does not look with favor upon the prescription of a procedure which would require a divulgement of probable action based on incomplete information about the applicant. Sponsors of such applicants often have receded from an advocacy which was founded on an incom-

plete record of professional attainment. On the contrary, the board believes the responsibilities and necessarily confidential procedures of the board would be better appreciated by the members if more emphasis were placed on the importance of filing complete professional records on the initial applications for direct admission or transfer to higher grades.

To correct any false impression as to the number of applications for admission and transfer on which the examiners have felt compelled to rule unfavorably, a summary for the last ten-year period, 1931–40, is presented in table XII.

It should be noted that the figures in table XII show a total rejection of Fellow grade applications over the ten-year period of only 29. The Member rejections (about 11 per cent) are apparently due in part to a failure to appreciate the technical experience required for that grade and the tendency of applicants to select Member grade merely because they have passed the 27-year lower-age limit. Comparison of conditions before and after the increase of Associate dues at the end of the six-year period seems to indicate that it has also been a potent factor in developing ineligible Member applications.

Table XI. Applications for Admission and Transfer

Applications for Admission		
Recommended for grade of Associate	1,724	
Re-elected to the grade of Associate	86	
Not recommended	4	1,814
Recommended for grade of Member	122	
Re-elected to the grade of Member	12	
Not recommended	44	178
Recommended for grade of Fellow	1

Fellows	23	10
Transfers		
Members	1,781	184
Fellows	284	19

STANDARDS COMMITTEE

The four standards co-ordinating committees organized during the past year have devoted themselves to the tasks assigned to them.

Committee No. 1, Reference Values for Standards, has collected extensive data relating to existing practices on reference values. A paper covering this subject will be presented at the summer convention.

Committee No. 2, Standard Voltages and Currents, is keeping in close touch with the activities of the corresponding NEMA and EEI committees dealing with voltages above 100. Furthermore, a subcommittee has been organized to study the possibilities of standardization for voltages below 100. This subcommittee has collected considerable information on existing practices, and is ready to co-operate with the newly organized ASA sectional committee on the same subject.

Committee No. 3, Insulation Testing and Co-ordination, has appointed a group of AIEE representatives to work with the NEMA and EEI committees handling insulation co-ordination. In addition, a subcommittee on insulation testing and evaluation has been organized, which for the present is collecting data on existing practices in insulation testing and on methods for evaluating insulation. Another subcommittee on the standardization of wet tests has just been organized, and will attempt to unify greatly divergent standards provisions now existing.

Committee No. 4, Basic Principles for Rating of Electrical Machinery and Apparatus, sponsored several papers relating to its activity during the 1939 AIEE summer convention and at the District meeting in Scranton, Pa. The committee has had several meetings, and worked out a complete revision of standard No. 1, General Principles Upon Which Temperature Limits Are Based in the Rating of Electrical Machinery and Apparatus, which has been approved by the standards committee. The co-ordinating committee is now undertaking a study of short-time and intermittent ratings and loads, and a number of papers covering the subject will be presented at the summer convention.

In addition to these four committees, two new co-ordinating committees have been organized, namely: No. 5, Basic Theories and Units, and No. 6, Interference, Sound, and Noise Problems. Both committees are preparing to start actual work.

The first topic requiring the consideration of committee No. 5 will be the relative merits of the rationalized versus the unrationalized system of mks units, and the advisability of the endorsement of the preferred system by the Institute. The article "Revision of Electrical Units" by E. C. Crittenden in the April 1940 issue of ELECTRICAL ENGINEERING bears on this topic.

The co-ordinating committees, in addition to carrying on their major activities, have been active in reviewing various standards submitted to the standards committee for approval, to assure the maximum uniformity and co-ordination of these standards with others in existence. Additional co-ordinating committees may be organized as the desirability or need for other activities becomes apparent.

A decided increase in the activities of various sectional committees of ASA concerned with problems in the electrical field was noted during the year, and this called for the appointment of individual Institute representatives as well as AIEE delegations. Among such activities may be mentioned the following: Vacuum Tubes for Industrial Purposes—*C*60; Wire and Sheet Metal Gages—*B*32; Storage Batteries—*C*40; Industrial Lighting—*A*11; Radio—*C*16; Dry Cells—*C*18; and Carbon and Graphite Brushes—*C*64.

The chief development in published standards and one of great interest to the Institute was the issuance by ASA of the Proposed Standard for Transformers. This publication, it is hoped, will shortly be approved as an American standard. It replaces AIEE standards Nos. 12, 13, 14, 100, and the Test Code for Transformers. In addition, three revisions of existing Institute standards were submitted and will be published, as follows: General Principles Upon Which Temperature Limits Are Based in Rating of Electrical Machinery; Measurement of Test Voltages in Dielectric Tests; Air Switches and Bus Supports.

In line with the attitude of the standards committee during recent years in urging greater activity by the technical committees in the standards field, a plan has been suggested which should not only lead to a co-ordination of the standards work of those committees, but also provide for the continued development of that work from year to year.

UNITED STATES NATIONAL COMMITTEE OF THE IEC

The United States National Committee has been saddened during the past year by the death of its honorary president, Doctor Arthur E. Kennelly, and also of James Burke, one of its most prominent members and a past president of the International Electrotechnical Commission. Doctor Kennelly, who was also an honorary president of the commission, served as technical advisor to the USNC on several subjects. The loss of these two valued members will be keenly felt by the USNC.

The 1939 annual meeting of the USNC elected Doctor Clayton H. Sharp honorary president of the committee and E. C. Crittenden, representing the National Bureau of Standards, president. L. F. Adams, representing the National Electrical Manufacturers Association, was elected vice president and Doctor H. S. Osborne, representing the AIEE, was re-elected vice president and treasurer.

Because of the European situation, the work of the International Electrotechnical Commission, and consequently of the USNC, has been considerably curtailed. However, the general secretary of the IEC has advised the national committees that the central office intends to carry on as much work by correspondence as possible under existing conditions, and hopes to issue, as provisional IEC recommendations, those documents which had been circulated under the six months rule prior to the beginning of the war. These are: Specifications for Transformers (excluding instrument and testing transformers); Specifications for the Resistivity of Aluminum; Specifications for Porcelain Insulators for Overhead Lines of 1,000 V and Upwards; Specifications for Safety Requirements for Electric Mains-operated Radio Receiving and Amplifying Apparatus; Revision of Publication 42, Part 3, Graphical Symbols for Weak-current Installations; Rules for the Measurement of Test-Voltages by Sphere-Gaps in Dielectric Tests, Appendix to IEC Publication No. 46 on Steam Turbines—Supplementary Notes to Section 4 Instruments and Methods of Measurement.

The meetings of the IEC advisory committees which had been scheduled for September 1939 in New York have been indefinitely postponed. However, these meetings will be held in New York eventually, after world conditions have returned to normal.

Hydraulic Turbines, IEC 4. The USNC, as secretariat of the IEC committee on hydraulic turbines, has prepared proposed specifications for hydraulic turbines including rules for acceptance tests. These documents have been sent to the central office of the IEC for transmission to the national committees for their comments.

Rating of Rivers, IEC 14. At the last meeting of the committee of action of the IEC, held in Paris in June 1939, it was agreed by implication that the IEC project on rating of rivers should be abolished because the committee had ceased to function. The USNC has registered with the central office of the IEC an objection to the abolishing of this committee, with the information that there appears to be a good likelihood that an American standard will be adopted and that a further effort should be made to reach international agreement.

Rules for the Measurement of Test-Voltage by Sphere Gaps in Dielectric Tests. Early in 1939, there was circulated to the national committees of the IEC a document giving draft rules for the measurement of test voltage by sphere gaps in dielectric tests, which had been prepared following the Torquay meeting in 1939. Comparison showed considerable differences in these proposed IEC standards from the standards in common use in this country. It was deemed desirable, therefore, that the matter be reopened within the IEC sphere gap subcommittee, and a meeting was arranged in Paris in July 1939. This meeting was attended on behalf of the USNC by P. L. Bellaschi. It was agreed that certain modifications should be made in the proposed standards. The modifications were to be carried out by the British, German, and American representatives. This decision has opened the question of sphere-gap standards again in such a way that it will be possible for a general compromise satisfactory to the USNC to be arrived at.

COMMITTEE ON PLANNING AND CO-ORDINATION

The comprehensive report of the committee dated April 3, 1939, was presented at the meeting of the board of directors held on May 26, 1939. Recommendations regarding discussion of social and economic questions, presentation and publication of papers, financial support of research, and nominations procedure were approved. The president was authorized to refer any or all of the remaining topics in the report to regular or special committees for further study and report.

The committee held meetings in October and January, and considered many topics which had been referred to it by the board of directors, or the president, or received from other sources. It made recommendations to the board of directors on a considerable number of matters involving a wide range of Institute activities, and has others still under consideration. Additional topics have come to it, and an all-day meeting will be held on May 23.

The committee, as usual, invited District and Section officers to submit requests for any national conventions and District meetings desired in the calendar year 1941, and prepared a schedule of such meetings which was approved by the board of directors in January.

COMMITTEE ON LEGISLATION AFFECTING THE ENGINEERING PROFESSION

At the start of the administrative year, the committee on legislation affecting the engineering profession absorbed the special committee on model law for registration of engineers. In June 1939, the AIEE model law was endorsed by the Board of Directors. Committee activity during the 1939–40 year has been limited to following up the discussion of this law and correspondence with engineers regarding proposed legislation in the various states.

Copies of the AIEE model law were circulated to various groups for comment. Much favorable comment has resulted and a small amount of adverse criticism. In some states principles underlying the AIEE model law are being drafted into proposed legislation.

Following the committee's recommendation, a number of AIEE Sections have appointed committees on legislation to keep posted regarding licensing activity in their states and to support or oppose according to local opinion. It is highly desirable that all Sections appoint such committees. Sections should afford all AIEE members opportunity to review personally proposed legislation, so that any position taken by a Section may be the considered majority opinion after full discussion. It should also be recognized that the scope of such committees should be confined to legislation affecting the profession.

The AIEE committee on legislation affecting the engineering profession desires to be kept informed by Sections on local activity in licensing.

COMMITTEE ON CONSTITUTION AND BYLAWS

The committee interpreted several sections of the bylaws referred to it, resulting in amendments to the bylaws. There were no meetings of the committee, the work being conducted by correspondence.

COMMITTEE ON ECONOMIC STATUS OF THE ENGINEER

The committee was very glad to cooperate with the similar committee of The American Society of Mechanical Engineers under the chairmanship of Dean C. J. Freund, in a consideration of unionization of engineers. This took the form of a paper on this topic by James H. Herron in *Mechanical Engineering* for November 1939, and discussions in the January 1940 issue of the same magazine. Professor Sorensen has contributed a discussion which is planned for the June issue of ELECTRICAL ENGINEERING.

The chairman of the Institute committee was appointed a member of Mr. Bickelhaupt's AEC committee on engineering and allied technical professions. Since similar appointments were made representing the American Society of Civil Engineers, the ASME, and the Washington Society of Engineers, an opportunity was presented to coordinate the efforts of the several committees dealing with the economic status of the engineer.

During the year great interest developed in a request for knowledge of the classification and salaries of electrical engineers particularly on the part of the younger members of the Institute and of faculty and industrial personnel officers. Analyses made by Dean F. M. Feiker of the distribution of engineers by industry indicate that more than 40 per cent of all civil engineers are employed by federal, state, and local governments; fewer than 3 per cent of electricals and mechanicals are so employed. Thus there is a distinct difference in the personnel problems of the three Founder Societies, and the subject is a very difficult one. Nevertheless, the Pittsfield Section of the Institute has studied the matter intensively during the year, and has requested more data and information. In order to explore the field and see if there is any basis for uniformity in the classifications and ranges in various industries which might be fairly representative of the profession as a whole, President Farmer has appointed a committee under the chairmanship of A. C. Stevens to obtain information and report its findings to the board.

COMMITTEE ON AWARD OF INSTITUTE PRIZES

Four national and eight District prizes were awarded for papers presented during the calendar year 1939 and for the student papers presented during the academic year ending June 30, 1939.

The committee considered a large number of eligible papers which were of a high quality, and, in determining the awards for the national best paper prizes and initial paper prize, it had the benefit of the gradings and recommendations of the technical committees which had reviewed the papers. In addition to the national paper prize awards, six other papers were given honorable mention.

On recommendation of the committee on award of institute prizes, the board of directors approved changes in the rules governing the award of all District prizes. These changes permit consideration of all papers for each prize subsequent to the periods covered by the last previous awards.

COMMITTEE ON SAFETY

The committee on safety continued the discussion of a number of subjects related to electrical safety during the year. One meeting of the committee was held during the year, and other matters have been handled through correspondence.

A paper on "Safe Practices in College Laboratories," prepared by M. S. Coover of Iowa State College, was presented at the annual meeting of the Society for the Promotion of Engineering Education in June 1939. The committee understands that the National Safety Council is now preparing a pamphlet on this subject for inclusion in its standard safe practice series.

The committee was represented by its chairman at an open meeting held during the National Safety Congress in October 1939, to review the NSC Safe Practice Pamphlet on Portable Electrical Hand Tools, prior to the development of a revised edition.

Inasmuch as it has not been practicable to print an AIEE pamphlet on artificial respiration due to the expense involved, an effort was made to secure sufficient copies of such material from the American Red Cross. A review of the Red Cross material indicated that it contained many phases of first aid, in addition to artificial respiration instruction, and was probably too voluminous for the purpose intended by the committee. Copies of a small pamphlet issued by the American Gas Association and the Edison Electric Institute will be asked for by the committee for use in making contacts with colleges and Student Branches concerning the development of resuscitation instruction.

A subcommittee has been appointed to develop further contacts with colleges and Student Branches in co-operation with the committee on Student Branches, and another subcommittee has been appointed to develop further contacts with the AIEE Sections on matters pertaining to electrical safety.

After a discussion of accidents in the medical field, the chairman and secretary of the committee agreed to inquire, through individual contact, regarding any steps which may have been taken by the medical fraternity to reduce accidents in handling electrical medical equipment.

COMMITTEE ON AUTOMATIC STATIONS

The committee on automatic stations held two meetings during the year, and sponsored the presentation of two papers at the summer and Pacific Coast convention and one paper at the winter convention.

COMMITTEE ON BASIC SCIENCES

The committee on basic sciences has reviewed eight papers, and has four in process of review. One-half of a session at the winter convention was sponsored by the committee, and it will provide papers for one-half of a session at the summer convention. A technical conference on definitions was held at the winter convention, and a conference on nonlinear analysis will be held at the summer convention.

COMMITTEE ON COMMUNICATION

Under the sponsorship of the committee on communication 16 technical papers on communication were presented at the summer-Pacific Coast convention, the winter convention, and the District meetings in Springfield and Minneapolis, and technical conferences were held at the two national conventions. Much attention has been given to radio subjects, and 8 of the 16 papers mentioned above deal specifically with radio. Several others are of interest to specialists in that field. A communication session at the summer-Pacific Coast convention was sponsored jointly with the Institute of Radio Engineers, and another joint session will be held at the 1940 Pacific Coast convention. A paper on frequency modulation, with demonstrations, will be presented at the summer convention.

COMMITTEE ON EDUCATION

The principal effort of this committee has been devoted to considering, planning, and putting into effect a program which might be continued into future years. As early steps in this direction, an outline of suggested activities was considered, and an inquiry regarding the desirability of organizing committees on education in the Sections was sent to the Section chairmen. On account of the generous response from the Sections and their keen interest in educational activities, a subcommittee was formed to secure detailed information on efforts of an educational nature intended to aid young engineers, and to make it available to all Sections. Two other subcommittees were organized: one to study vocational guidance activities of the Sections, and the other to secure, for publication in Electrical Engineering, papers of an educational character of special interest to younger members. The committee hopes to make a significant contribution at the 1941 summer convention.

COMMITTEE ON ELECTRICAL MACHINERY

Five of the seven subcommittees of this committee have been active in developing and revising standards and test codes. The committee supplied three papers on "Hydrogen-Cooled Turbine Generators" for the North Eastern District meeting held in Springfield, Mass., in May 1939, and sponsored one session at the summer-Pacific Coast convention, and two sessions at the winter convention. A session and a technical conference on test codes at the 1940 summer convention will be sponsored by the committee.

COMMITTEE ON ELECTRIC WELDING

A session on welding sponsored by this committee at the 1940 winter convention created a large amount of interest. The committee has been devoting itself to the advancement of an educational program for extending co-operation among the manufacturers of welding equipment, the users, and the power companies to the end that good welding results may be secured at minimum first cost and operating cost. Parts I and II of a subcommittee report entitled "Power Supply for Resistance-Welding Machines" was presented at the winter convention, and several thousand reprints are being distributed.

COMMITTEE ON ELECTROCHEMISTRY AND ELECTROMETALLURGY

The committee held two meetings, and sponsored a joint symposium on power in the electrochemical industry by the Niagara Frontier Section of the Institute and the Niagara Falls section of the Electrochemical Society. It is planning a technical session for the 1941 winter convention in co-operation with the American Society of Metals. A subcommittee is investigating the effects of overvoltage in connection with large electrochemical and electrometallurgical installations.

COMMITTEE ON PRODUCTION AND APPLICATION OF LIGHT

A report, "Progress in Production and Application of Light" was published, in the name of the committee, in the December issue of Electrical Engineering. A demonstration lecture based on the report, together with addresses on lighting of the New York World's Fair and the New York Municipal Airport, constituted a session at the winter convention. The planning of and the soliciting of papers for this program constituted one of the major activities of the committee. The attendance, and the reception of the papers were most gratifying. Several additional papers have been reviewed and approved for presentation at the summer convention. The committee has collaborated with the editor in obtaining special articles for Electrical Engineering, and has a subcommittee which furnishes items of news interest. It has collaborated with the illumination group of the New York Section in organizing meetings for the discussion of lighting practice and developments in illuminating engineering.

COMMITTEE ON APPLICATIONS TO MARINE WORK

This committee has thoroughly reviewed standard No. 45, "Recommended Practice for Electrical Installations on Shipboard", through the work of 10 subcommittees. The editing committee is now preparing the recommended changes for submission to the standards committee.

COMMITTEE ON INSTRUMENTS AND MEASUREMENTS

The activities consisted primarily of reviews of technical papers, sponsorship of technical sessions at the two national conventions, preparation of reports on various phases of the progress of the art, and revision and extensions of AIEE standards. Material is being prepared for a comprehensive report on "Progress in the Art of Metering" covering electric power metering from its inception to the present day. A report on progress in telemetering is nearing completion. A report on "Wave Form in Dielectric Testing and Power Factor Measurements" was submitted to the standards committee. A revision of Standard No. 4, "Measurement of Test Voltage in Dielectric Tests", was completed and was approved by the standards committee and the board of directors. The committee also has reviewed several test codes prepared by other Institute technical committees; is compiling a bibliography on dielectric measurements made in the field; and is surveying possible sources of papers on oscillograph technique.

COMMITTEE ON POWER GENERATION

The committee on power generation has sponsored nine technical papers and one committee report for the two national conventions and the District meeting in Springfield. The committee report was for the years 1932–39, and was presented at the winter convention. In the development of plans for next year, two papers, on load swings and stability, and turbine generator governing, are in preparation for informal presentation and discussion at a round-table conference at the summer convention, with the thought that this procedure will aid in the selection of subjects for the 1941 winter convention.

COMMITTEE ON POWER TRANSMISSION AND DISTRIBUTION

One session at the summer-Pacific Coast convention and two sessions at the winter convention were sponsored by the committee. At a meeting of the committee, in September, the discussion of general organization work was followed by a prearranged discussion of engineering developments in the field of the committee. Such discussions have been of great interest to the members. A subcommittee has nearly completed a revision of standard No. 41, Insulators. A joint subcommittee representing three technical committees is preparing standards for bushings. A joint subcommittee is being organized to revise the grounding report prepared in 1931. A subcommittee is studying the advisability of a reorganization of committee on power transmission and distribution to meet present-day needs more effectively.

COMMITTEE ON PROTECTIVE DEVICES

The committee on protective devices has four subcommittees handling important divisions of its activities: circuit breakers, switches, and fuses; lightning arresters; relays; and fault-current-limiting devices. Each has carried on work in the development of standards and in other studies. Several standards have been substantially completed. A fifth subcommittee is cooperating with the committees on electrical machinery and power transmission and distribution. The committee sponsored three sessions on protective devices at the 1940 winter convention, one session and two technical conference papers at the summer-Pacific Coast convention, and one paper at each of the District meetings in Springfield and Minneapolis, with a total of 23 papers presented. A progress report is expected to be ready for the summer convention.

COMMITTEE ON RESEARCH

The principal activity of the committee on research has been in connection with service for the Institute as sponsor of two research projects supported by the Engineering Foundation: No. 66, Stability of Impregnated Paper Insulation, at Johns Hopkins University, and No. 74, Insulating Oils and Cable Saturants, at the Massachusetts Institute of Technology. Consideration has been given to the problems of the research method to ascertain whether there is sufficient interest to justify arrangements for a symposium on this subject. No definite conclusion has been reached. Efforts have been made to continue an activity started several years ago for the preparation of occasional news items on research subjects for ELECTRICAL ENGINEERING.

COMMITTEE ON TRANSPORTATION

The greater part of the work of the committee on transportation has been concerned with arranging to have papers written, reviewed, and presented at conventions. An effort has been made to have them cover the entire field of electrical engineering applied to transportation, and those presented at the winter convention covered a wide range of subjects with excellent discussion. The committee voted to initiate action toward having American tentative standard for railway motors (AIEE No. 11) advanced to status of full standard. At the invitation of the New Zealand Institution of Engineers, the committee also sponsored the preparation of a paper "Modern Rail Transport", by A. M. Wright of the Reading Railroad, for presentation at the New Zealand Centennial Engineering Congress scheduled for February 1940, but later cancelled on account of the war. The paper will be presented at the summer convention.

CHARLES LE GEYT FORTESCUE FELLOWSHIP COMMITTEE

A fellowship for graduate study in electrical engineering was established as a memorial to the late Charles LeGeyt Fortescue "in recognition of his valuable contributions to the electric power industry". The Westinghouse Electric and Manufacturing Company, with which Dr. Fortescue was associated throughout his professional life, set up a trust fund of $25,000 for this purpose.

The income will be administered by the Charles LeGeyt Fortescue fellowship committee of the Institute, and will provide fellowships of $500 or more to candidates selected annually by the committee. A bachelor's degree from an accredited college is a prerequisite, and the holders of the fellowships are expected to carry on their graduate studies in accredited engineering schools and to engage in research problems meeting the approval of the committee.

The first fellowship (1940–41) was awarded in March to Norman Z. Alcock, a senior in Queens University, Kingston, Ontario, who expects to engage in graduate study at the California Institute of Technology, Pasadena.

COMMITTEE ON AWARD OF COLUMBIA UNIVERSITY SCHOLARSHIPS

Seven formal applications were made for this scholarship, and from these the committee selected Cecil Clay Clements, a graduate of Alabama Polytechnic Institute. Mr. Clements qualified and registered in September, and pursued his studies during the winter session. However, in January, his father was taken very sick, and he was obliged to give up his work at Columbia, resigning the scholarship, and returning to his home.

The scholarship was not filled during the spring session because of the difficulty of making transfers in the middle of the academic year.

EDISON MEDAL

The Edison Medal, which is awarded by a committee composed of 24 members of the Institute, was, for 1939, awarded to Philip Torchio "for distinguished contributions to the art of central station engineering and for achievement in the production, distribution, and utilization of electrical energy", and was presented on January 24, 1940, during the winter convention. The medal may be awarded annually for "meritorious achievement in electrical science, electrical engineering, or the electrical arts".

JOHN FRITZ MEDAL

The John Fritz Medal board of award, composed of representatives of the national societies of civil, mining, mechanical, and electrical engineers, awarded the 36th medal (for 1940) posthumously to the late Doctor Clarence F. Hirshfeld, formerly chief of the department of research, Detroit Edison Company, "for notable leadership through research and development in power generation and electric traction and for being a great teacher and friend of men both young and old".

LAMME MEDAL

The Lamme Medal committee awarded the medal for 1939 to Norman W. Storer, retired consulting railway engineer, Westinghouse Electric and Manufacturing Company, "for pioneering development and application of equipment for electrical traction". Arrangements are being made for the presentation of the medal at the summer convention in Swampscott, Mass., June 24–28, 1940. The medal may be awarded annually to a member of the AIEE "who has shown meritorious achievement in the development of electrical apparatus or machinery".

ALFRED NOBLE PRIZE

This prize, established in 1929, consists of a certificate and a cash award of $500 from the income from a fund contributed by engineers and others to perpetuate the name and achievements of Alfred Noble, past president of the American Society of Civil Engineers and of the Western Society of Engineers. It may be made to a member of any of the co-operating societies, ASCE AIME, ASME, AIEE, or WSE, for a technical paper of particular merit accepted by the publication committee of any of these societies, provided the author, at the time of such acceptance, is not over 30 years of age. The award for 1939 was presented to C. E. Shannon (A'39) for his paper on "A Symbolic Analysis of Relay Switching Circuits".

WASHINGTON AWARD

The Washington Award for 1939 was bestowed upon Daniel Cowan Jackling, "for pioneering in large-scale mining and treatment of low-grade copper ores, releasing vast resources from formerly worthless deposits", and was presented to him at a dinner on April 15, 1940. This award may be made annually to an engineer by the commission of award composed of nine representatives of the Western Society of Engineers and two each of the American Society of Civil Engineers, American Institute of Mining and Metallurgical Engineers, American Society of Mechanical Engineers, and AIEE.

HOOVER MEDAL

The Hoover Medal was established through a trust fund created by a gift from Conrad N. Lauer, and is to be awarded periodically "to a fellow engineer for distinguished public service" by a board representing the national societies of civil, mining and metallurgical, mechanical, and electrical engineers. The fourth recipient of this medal was Doctor Gano Dunn, who was cited as "Long honored by his fellow engineers for professional achievement, he has, beyond that, exemplified high civic purpose and a devotion to public service which have earned for him the Hoover Gold Medal for 1939".

IWADARE FOUNDATION COMMITTEE

No Iwadare lecturer was chosen to go to Japan for the current year, nor has any Iwadare Fellow come to the United States.

EMPLOYMENT SERVICE

The Institute co-operates with the national societies of civil, mining, and mechanical engineers in the operation of the Engineering Societies Employment Service with its main office in the Engineering Societies Building, New York. Offices are operated in Chicago and San Francisco also. In addition to the societies named, others co-operate in certain of the offices as follows: New York—Society of Naval Architects and Marine Engineers; Chicago—Western Society of Engineers; San Francisco—California Section of the American Chemical Society and the Engineers' Club of San Francisco.

The service is supported by the joint contributions of the societies and their individual members who are benefited. In addition to the publication of the employment service announcements monthly in ELECTRICAL ENGINEERING, weekly subscription bulletins are issued for those seeking positions.

An analysis of this employment service as reported to the national societies is given in table XIII.

AMERICAN ENGINEERING COUNCIL

The American Engineering Council has continued to carry on a wide range of activities within the scope of its objectives: "to further the public welfare wherever technical and engineering knowledge and experience are involved, and to consider and act upon matters of common concern to the engineering and allied technical professions".

The broad range of the Council's activities is indicated by the titles of its committees: *Standing*—constitution, by-laws and standing rules, engineering and allied technical professions, finance, membership and representation, publicity and publications, regional activities, and public affairs; *Special*—patents, public works, surveys and maps, engineering economics, and inter-American engineering relations.

At the 20th annual meeting of the assembly held in Washington, D. C., January 11 and 12, 1940, a wide range of subjects received consideration. The 10th conference of secretaries of engineering societies was held on January 11 in connection with the meeting of the assembly.

It was reported at the annual meeting that the joint patent inquiry conducted under the sponsorship of the Council, the National Association of Manufacturers, and the National Industrial Conference Board, with funds supplied by NAM, had been nearly completed, and the report would be submitted to the sponsoring organizations within a few weeks.

A joint committee has been considering the reorganization of the Council in an effort to provide for "a combined professional approach to both public problems and interprofessional problems".

UNITED ENGINEERING TRUSTEES, INC.

This organization is the corporate body which holds title in the name of the four Founder Societies to their joint physical properties, namely, the Engineering Societies Building, the Engineering Societies Library, and the endowment funds of the Engineering Foundation. It operates and manages the Engineering Societies Building and administers certain joint activities of the four Founder Societies.

An abstract of the annual report of the UET, Inc., for the year which ended September 30, 1939, was published in ELECTRICAL ENGINEERING for December 1939, pages 531–2.

During the year, the "History, Charter, and Bylaws" was revised and brought up to date, new heating controls were installed in the Engineering Societies Building, and improvements in the ventilation of the meeting halls were made.

The John Fritz Medal Fund Corporation and the Daniel Guggenheim Medal Fund, Inc., dissolved their corporations and became committees of UET, Inc., which had, for a long period, managed the funds of the former and the books of the latter.

Table XIII. Analysis of Employment Service

Month	Men Registered				Men Placed			
	New York	Chicago	San Francisco	Total	New York	Chicago	San Francisco	Total
1939

ENGINEERING FOUNDATION

The Engineering Foundation is a joint organization of the national societies of civil, mining and metallurgical, mechanical, and electrical engineers established for "the furtherance of research in science and engineering, and the advancement in any other manner of the profession of engineering and the good of mankind".

A comprehensive abstract of the annual report of the Engineering Foundation for the year which ended September 30, 1939, was published in ELECTRICAL ENGINEERING for December 1939, pages 533–4, including information on each of a wide range of technical researches receiving support or assistance from the Foundation.

The research on "Stability of Impregnated-Paper Insulation" at the Johns Hopkins University is sponsored by the Institute. The work of the "Welding Research Committee" is sponsored by the American Welding Society and the Institute. The Foundation recently has granted support for a research on "Insulating Oils and Cable Saturants", at the Massachusetts Institute of Technology, under the sponsorship of the AIEE.

Assistance in nontechnical matters related to engineering has been granted to the Engineers' Council for Professional Development.

ENGINEERING SOCIETIES LIBRARY

The Engineering Societies Library, which was formed by combining the separate libraries of the four national societies of civil, mining and metallurgical, mechanical, and electrical engineers, and the preparation of a composite card catalog, has been expanded as a single engineering library, which probably constitutes the best collection of its type in the United States.

On September 30, 1939, the library had 146,999 volumes, 7,564 maps, and 4,440 bibliographies. Books, pamphlets, and maps totaling 15,914 were received during the year ending at that time. Current issues of 1,340 periodicals were received. Work progressed rapidly on a classified index to periodicals, and the index now contains more than 242,000 references to articles published since 1927.

Special services rendered by the library include: photoprints, searches, abstracts, translations, bibliographies, book loans by mail, etc. An abstract of the annual report of the library appeared on page 532 of ELECTRICAL ENGINEERING, December 1939.

ENGINEERS' COUNCIL FOR PROFESSIONAL DEVELOPMENT

This council was organized in 1932 to engage in activities leading to the enhancement of the professional status of the engineer. It includes three representatives of each of the seven participating organizations: the national societies of chemical, civil, electrical, mechanical, and mining and metallurgical engineers, the Society for the Promotion of Engineering Education, and the National Council of State Boards of Engineering Examiners.

The principal activities of ECPD include programs for the guidance of young individuals thinking of entering the engineering field, the accrediting of curricula of engineering schools, encouragement and assistance to individuals in their engineering and cultural studies during several years after graduation, and the development of criteria for indicating the attainment of the status of an engineer.

At the annual meeting held on October 20, 1939, the committee on engineering schools presented recommendations on 7 curricula, in four institutions, not previously acted upon, 74 curricula which had been provisionally accredited, and 9 curricula which had been rejected. It reported that 144 out of the total of 150-odd degree-granting engineering institutions had applied for inspection. The actions taken at that meeting brought the total number of curricula acted upon to 687, divided as follows:

Accredited unconditionally	433
Accredited for limited periods	82
Not accredited	172
Total	687

The complete list of accredited curricula appeared on page 526 of the December 1939 issue of ELECTRICAL ENGINEERING. A report on the annual meeting was published in the November 1939 issue of ELECTRICAL ENGINEERING, page 485.

REPRESENTATIVES

The Institute has continued its representation upon many joint committees and national bodies, with which it co-operates in a wide range of activities of interest and importance to engineers and others.

A list of representatives was published in the September 1939 issue of ELECTRICAL ENGINEERING and in the 1940 Year Book.

FINANCE COMMITTEE

The preparation of the annual budget is one of the major duties of the finance committee. The budget for the current year (beginning October 1) has some interesting features.

While the European War results in appreciable loss in revenue to the Institute, the steady growth in membership is expected to offset this influence, and it is anticipated that the revenues for the year will be substantially the same as for last year. By careful attention to economy in some items and by estimating closely the necessary expenses it has been possible in the current budget to provide for carrying on the activities of last year and for the expansion of these activities in some respects. Provision was made for about a 10 per cent increase in the Institute publications and for the addition to the headquarter's staff of one engineer whose time is largely devoted to standards work. The allowance for traveling expenses for delegates to Institute meetings and to District conferences was made more nearly adequate. An item of especial interest is the establishment of a pension reserve fund by the initial payment into this fund of $5,000 as a part of the current year's expenses. This is done as a first step toward the eventual establishment of a pension system for superannuated employees.

Under advice of investment counsel, the investments representing the reserve funds of the Institute are for the present being kept in fluid condition, cash and short-term bonds representing about one-half of the total.

Haskins and Sells, certified public accountants, have audited the books, and their report follows.

APPRECIATION

The board of directors again expresses to the national committees and the District, Section, and Branch officers its sincere thanks for their effective conduct of the activities in these important divisions. Their leadership has continued to produce a high degree of enthusiasm and constructive accomplishment. The board of directors also deeply appreciates the generous interest and support which the members have accorded its efforts on their behalf.

Respectfully submitted for the board of directors.

H. H. HENLINE,
National Secretary

May 24, 1940

HASKINS & SELLS
CERTIFIED PUBLIC ACCOUNTANTS

22 EAST 40TH STREET
NEW YORK

May 16, 1940

American Institute of Electrical Engineers,
33 West 39th Street, New York.

Dear Sirs:

We have made an examination of your balance sheet as of April 30, 1940, and of your recorded cash receipts and disbursements for the year ended that date. Our examination consisted of a review of the system of internal control and the accounting procedures of the Institute and examination or tests of its accounting records and other supporting evidence by methods and to the extent we deemed appropriate. We present the following:

Balance Sheet, April 30, 1940 (Exhibit A).
  Property and Restricted Funds Securities, Less Reserve for Securities of Doubtful Value (Schedule 1).
Statement of Recorded Cash Receipts and Disbursements of General Fund for the Year Ended April 30, 1940 (Exhibit B).
Statement of Recorded Cash Receipts and Disbursements of Property and Restricted Funds for the Year Ended April 30, 1940 (Exhibit C).

In accordance with the terms of our engagement, members and other debtors, except certain advertisers, were not requested to confirm to us the amounts receivable from them at April 30, 1940. In accordance with the usual practice of the Institute, no provision has been made for dues which may prove to be uncollectible.

In our opinion, subject to the comments in the next preceding paragraph, the accompanying Exhibit A fairly presents your financial condition at April 30, 1940, and the accompanying Exhibits B and C fairly present your recorded cash receipts and your disbursements of funds, as indicated, for the year ended that date.

Yours truly,

HASKINS & SELLS

AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS

Balance Sheet, April 30, 1940

Exhibit A

ASSETS		
Property Fund Assets:		
One-fourth interest in the total net assets of United Engineering Trustees, Inc., exclusive of Trust Funds	$498,448.48	
Equipment:		
Library—volumes and fixtures	37,296.37	
Office furniture and fixtures (less reserve for depreciation, $30,091.16)	4,973.26	
Works of art, etc.	3,001.35	
Securities—at cost (market quotation value, $6,505.45)—Schedule I	6,355.45	
Cash (see Exhibit C)	3,330.32	
Total property fund assets		$553,405.23
Restricted Fund Assets:		
Securities—at cost, less reserve for securities of doubtful value (market quotation value, $177,352.94)—Schedule 1	$190,237.27	
Cash (see Exhibit C)	50,256.80	
Accrued interest receivable	69.99	
Total restricted fund assets		240,564.06
Current Assets:		
Cash (see Exhibit B)	$ 32,156.58	
Accounts receivable:		
Members—for dues	19,921.28	
Advertisers	518.40	
Miscellaneous	3,596.94	
Accrued interest on investments	1,588.72
